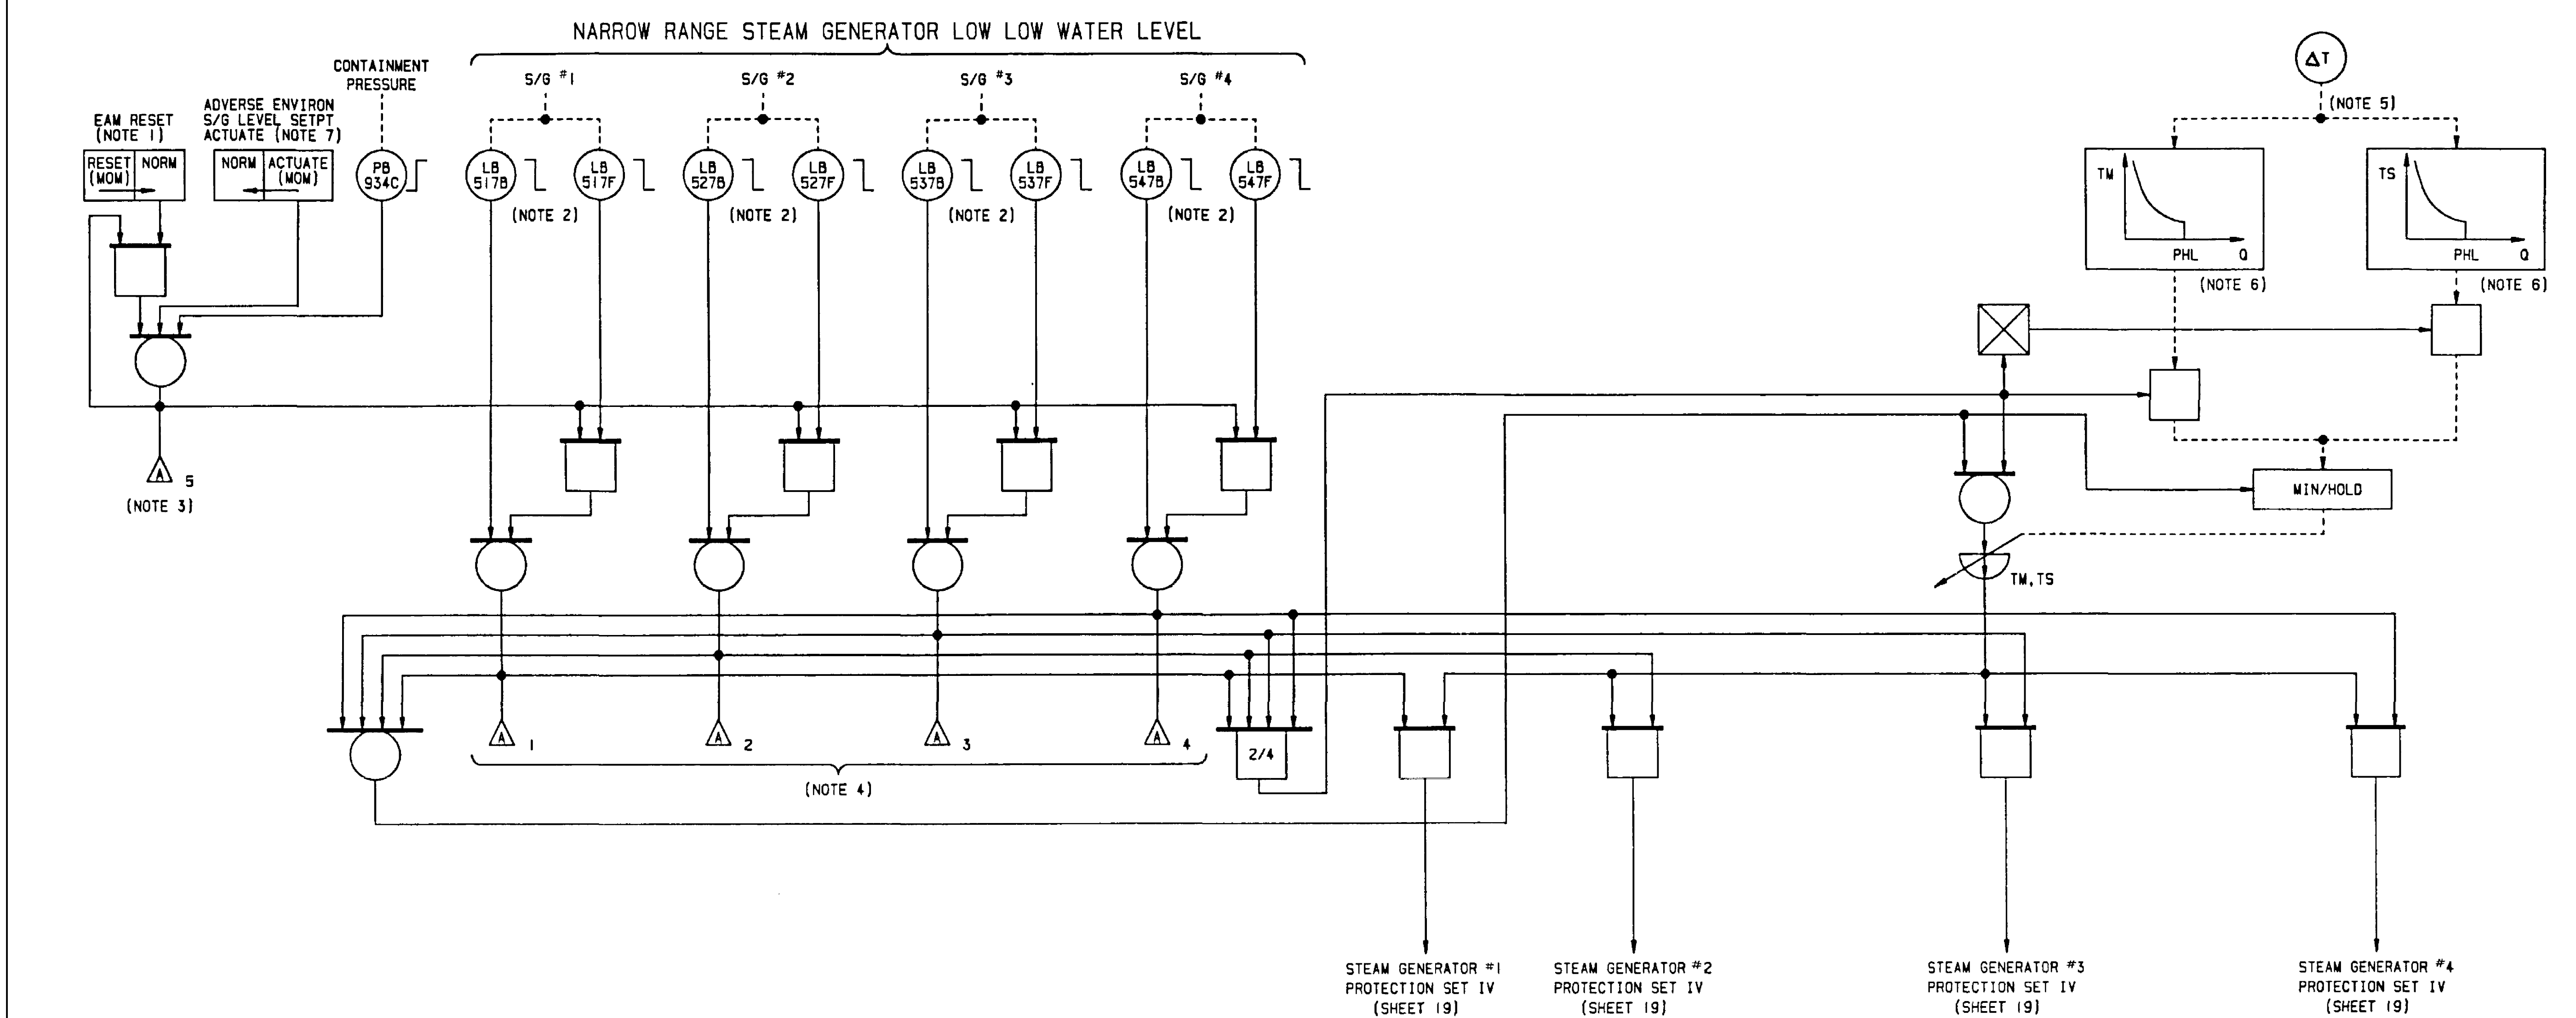
FUNCTIONAL DIAGRAMS ENVIRONMENT ALLOWANCE MOD & TRIP TIME DELAY LOGIC
(REVISED BY AMENDMENT 13)



NOTES:

1. THE EAM RESET CONSISTS OF FOUR MOMENTARY SWITCHES LOCATED IN THE PROCESS CABINETS, ONE PER PROTECTION SET.
2. BISTABLES LB-517F, 527F, 537F AND 547F PROVIDE THE ADVERSE STEAM GENERATOR LEVEL SETPOINT. THE NORMAL LEVEL SETPOINT IS PROVIDED BY LEVEL BISTABLES LB-517B, 527B, 537B AND 547B.
3. ONE COMMON ANNUNCIATOR WINDOW IS SHARED WITH ALARMS GENERATED IN THE OTHER PROTECTION SETS.
4. ONE COMMON ANNUNCIATOR WINDOW FOR EACH STEAM GENERATOR IS SHARED WITH ALARMS GENERATED IN THE OTHER PROTECTION SETS.
5. ΔT IS A SPECIAL TEMPERATURE SIGNAL USED FOR POWER INDICATION ONLY. CONVERSION TO POWER IS PERFORMED PRIOR TO THE TIMER FUNCTION GENERATER.
6. THE FOLLOWING DEFINITIONS APPLY TO THE FUNCTION GENERATOR:

   TM = ELAPSED TIME IF SETPOINT REACHED IN MULTIPLE STEAM GENERATORS.
   TS = ELAPSED TIME IF SETPOINT REACHED IN ONE STEAM GENERATOR.
   PHL = POWER HIGH LIMIT.
   Q = THERMAL POWER.
7. THE ADVERSE EAM STEAM GENERATOR LEVEL SETPOINT LATCH-IN CONTROL CONSISTS OF FOUR MOMENTARY SWITCHES LOCATED IN THE PROCESS CABINETS, ONE SWITCH PER PROTECTION SET.

7.3 ENGINEERED SAFETY FEATURES ACTUATION SYSTEM

In addition to the requirements for a reactor trip for anticipated abnormal transients, the facility will be provided with adequate instrumentation and controls to sense accident situations and initiate the operation of necessary Engineered Safety Features. The occurrence of a limiting fault, such as a loss of coolant accident or a steam break, requires a reactor trip plus actuation of one or more of the Engineered Safety Features in order to prevent or mitigate damage to the core and Reactor Coolant System components, and insure containment integrity.

In order to accomplish these design objectives the Engineered Safety Features System will have proper and timely initiating signals which are to be supplied by the sensors, transmitters and logic components making up the various instrumentation channels of the Engineered Safety Features Actuation System.

7.3.1 Description

The Engineered Safety Features Actuation System senses selected plant parameters, determines whether or not predetermined safety limits are being exceeded and, if they are, combines the signals into logic matrices sensitive to combinations indicative of primary or secondary system boundary ruptures (Class III or IV faults). Once the required logic combination is completed, the system sends actuation signals to those Engineered Safety Features Components whose aggregate function best serves the requirements of the accident. This conforms to 1971 GDC 13 and 20.

7.3.1.1 System Description

The Engineered Safety Features Actuation System is a functionally defined system described in this section. The equipment which provides the actuation functions identified in 7.3.1.1.1 is listed below and discussed in this section and the referenced WCAPs.

1. Process Instrumentation and Control System (Reference 9)
2. Solid State Logic Protection System (Reference 3)
3. Engineered Safety Features Test Cabinet (Reference 6)
4. Manual Actuation Circuits

The Engineered Safety Features Actuation System consists of two discrete portions of circuitry: 1) A process portion consisting of redundant channels which monitor various plant parameters such as the Reactor Coolant System and steam system pressures, temperatures, and flows and containment pressures; and 2) a digital portion consisting of two redundant logic trains which receive inputs from the process protection channels and perform the needed logic to actuate the Engineered Safety Features. Each digital train is capable of actuating the Engineered Safety Features equipment required. The intent is that any single failure within the Engineered Safety Features Actuation System shall not prevent system action when required.

The redundant concept is applied to both the process and logic portions of the system. Separation of redundant process channels begins at the process sensors and is maintained in the field wiring, containment vessel penetrations and process protection racks, terminating at the redundant groups of safeguards logic racks. This conforms to 1971 GDC 20, 21, 22, 23 and 24.

The variables are sensed by the process circuitry as discussed in Reference 1 and in Section 7.2. The outputs from the process channels are combined into actuation logic as shown on various sheets of Figure 7.2.1-1. Tables 7.3.1-1 and 7.3.1-2 give additional information pertaining to logic and function.

The interlocks associated with the Engineered Safety Features Actuation System are outlined in Table 7.3.1-3. These interlocks satisfy the functional requirements discussed in Section 7.1.2.

Controls are also provided to switch from the injection to the recirculation phase after a loss of coolant accident.

7.3.1.1.1 Function Initiation

In order to accomplish the design objectives the Engineered Safety Features System will have proper and timely initiating signals which are to be supplied by the sensors, transmitters and logic components making up the various instrumentation channels of the Engineered Safety Features Actuation System. The specific functions which rely on the Engineered Safety Features Actuation System for initiation are:

1. A reactor trip, provided one has not already been generated by the Reactor Trip System.

2. Engineered Safety Features Actuation System sequence which actuates the following items and insures the proper sequencing of Engineered Safety Features power demands on the Engineered Safety Features busses (supplied by either preferred or standby power supply).

    a. Cold leg injection isolation valves which are opened for injection of borated water by centrifugal charging pumps into the cold legs of the Reactor Coolant System.

    b. Charging pumps, safety injection pumps, residual heat removal pumps and associated valving which provide emergency makeup water to the cold leg of the Reactor Coolant System following a loss of coolant accident.

    c. Motor driven auxiliary feedwater pumps to protect the reactor and the steam generator during accident or emergency conditions by maintaining the steam generator heat sink without excessive cooldown of the primary coolant system.

3. Phase A containment isolation, whose function is to prevent fission product release.

4. Steam line isolation to prevent the continuous, uncontrolled blowdown of more than one steam generator and thereby uncontrolled Reactor Coolant System cooldown.

5. Main feedwater line isolation to limit the energy release in the case of a steamline break and to limit the magnitude of the reactor coolant system cooldown and prevent or mitigate the effect of excessive cooldown.

6. Start the emergency diesels to assure backup supply of power to emergency and supporting systems components.

7. Initiate a Control Room Isolation to meet control room occupancy requirements following a loss of coolant accident.

8. Containment Spray Actuation, which initiates containment spray to reduce containment pressure and temperature following a loss of coolant or steam break accident inside containment.

9. Phase B Containment Isolation to isolate the containment following a loss of coolant accident or steam or feedwater line break within the containment. Containment air return fans, actuated after a Phase B, to cool the containment and reduce the pressure in event of an accident.

10. Emergency Gas Treatment Actuation.

11. Essential Raw Cooling Water and Component Cooling Water Pump Start and Isolation.

12. Containment Ventilation Isolation.

13. Automatic switchover of the RHR pumps from the injection to the recirculation mode (post-LOCA).

14. Isolates the Auxiliary Building and actuates Auxiliary Building Gas Treatment.

7.3.1.1.2 Process Circuitry

The process sensors and racks for the Engineered Safety Features Actuation System are covered in References 1 and 9. Discussed in this report are the parameters to be measured including pressures, flows, tank and vessel water levels, and temperatures as well as the measurement and signal transmission considerations. These latter considerations include the basic current transmission system, transmitters, orifices and flow elements, resistance temperature detectors, and pneumatics. Other considerations covered are automatic calculations, signal conditioning and location and mounting of the devices.

The sensors monitoring the primary system are located as shown on the piping flow diagrams in Chapter 5, Reactor Coolant System. The secondary system sensor locations are shown on the steam system flow diagrams given in Chapter 10.

The following is a description of those process channels not included in the Reactor Trip or Engineered Safety Features Actuation Systems which enable additional monitoring of containment conditions in the post loss of coolant accident recovery period. These channels are located outside of the containment (with the exception of sump instrumentation) and will not be affected by the accidents.

1. High head safety injection pumps discharge pressure

   These channels clearly show that the safety injection pumps are operating. The transmitters are outside the containment.

2. Pump energization

   Pump motor power feed breakers indicate that they have closed by energizing indicating lights on the control board.

3. Valve position

   All Engineered Safety Features remote operated valves have position indication on the control board in two places to show proper positioning of the valves. Red and green indicator lights are located next to the manual control station showing open and closed positions. The Engineered Safety Features positions of these valves are displayed on the monitor light panels, which consist of an array of white lights which are dark when the valves are in their normal or required positions for power operations. The monitor lights for automatically actuated valves are energized when the valve is in the automatically actuated position. These monitor lights thus enable the operator to quickly assess the status of the safeguards systems. These indications are derived from contacts integral to the valve operators. In the cases of the accumulator isolation valves, redundancy of position indication is provided by valve stem mounted limit switches which actuate annunciators on

the control board when the valves are not correctly positioned for Engineered Safety Features Actuation. The stem mounted switches are independent of the limit switches in the motor operators. See Section 7.6 for additional information.

7.3.1.1.3 Digital Circuitry

The Engineered Safety Features logic racks are discussed in detail in Reference 3. The description includes the considerations and provisions for physical and electrical separation as well as details of the circuitry. Reference 3 also covers certain aspects of online test provisions, provisions for test points, considerations for the instrument power source, considerations for accomplishing physical separation, and provisions for assuring instrument qualification. The outputs from the process channels are combined into actuation logic as shown in Figure 7.2.1-1.

To facilitate engineered safety features actuation testing, two cabinets (one per train) are provided which enable operation, to the maximum practical extent, of safety features loads on a group by group basis until actuation of all devices has been checked. Final actuation testing is discussed in detail in Subsection 7.3.2.

7.3.1.1.4 Final Actuation Circuitry

The outputs of the solid state logic protection system (the slave relays) are typically energized to actuate. These devices are listed as follows:

1. Safety Injection System pump and valve actuators. See Chapter 6 for flow diagrams and additional information.

2. Containment Isolation (Phase A - signal isolates all non-essential process lines on receipt of safety injection signal; Phase B - signal isolates remaining process lines (which do not include safety injection lines) on receipt of 2/4 high-high containment pressure signal). For further information, see Subsection 6.2.4. (Both containment isolation Phase A and Phase B may be manually actuated by the Operator).

3. ERCW and CCW pump and valve actuators. (See Chapter 9).

4. Auxiliary feed pumps start (See Chapter 6).

5. Emergency diesel start (See Chapter 8).

6. Feedwater isolation (See Chapter 10).

7. Containment ventilation isolation valve and damper actuators (See Chapter 6).

8. Main steam line isolation valve actuators (See Chapter 10).

9. Containment spray pump and valve actuators (See Chapter 6).

10. Control room isolation (See Chapter 9).

11. Auxiliary building isolation and Auxiliary Building Gas Treatment actuation (See Chapter 6&9).

12. Emergency Gas Treatment System (See Chapter 6).

If an accident is assumed to occur coincident with a station electrical blackout, the Engineered Safety Features loads must be sequenced onto the diesel generators to prevent overloading them. This sequence is discussed in Chapter 8. The design conforms to 1971 GDC 35.

7.3.1.1.5 Support Systems

The following systems are required for support of the Engineered Safety Features:

1. Essential Raw Cooling Water - Heat Removal (See Chapter 9).

2. Component Cooling Water Systems - Heat Removal (See Chapter 9).

3. Electrical Power Distribution Systems (See Chapter 8).

4. Auxiliary Control Air System (See Chapter 9).

5. Heating, Ventilating and Air Conditioning Systems (See Chapter 9).

7.3.1.2 Design Bases Information

The functional diagrams presented in Figure 7.2.1-1, sheets 5, 6, 7, 8, 14, 17, 18, and 19 provide a graphic outline of the functional logic for the Engineered Safety Features Actuation System. Requirements for the Engineered Safety Features System are given in Chapter 6. Given below is the design bases information requested in IEEE 279-1971 Reference 2.

7.3.1.2.1 Generating Station Conditions

The following are examples of Condition III and IV events requiring protective action:

1. Primary System Accidents

   a. Rupture in small pipes or cracks in large pipes
   b. Rupture of a reactor coolant pipe (loss of coolant accident)
   c. Steam generator tube rupture

2. Secondary System Accidents

   a. Minor secondary system pipe breaks resulting in steam release rates equivalent to a single dump, relief or safety valve
   b. Rupture of a major steam pipe

7.3.1.2.2 Generating Station Variables

The following list summarizes the generating station variables required to be monitored by the Engineered Safety Features Actuation System during each accident identified in the preceding section. Post accident monitoring requirements are given on Tables 7.5.1 and 7.5.2.

1. Primary System Accidents
   a. Pressurizer pressure
   b. Containment pressure (not required for Steam Generator tube rupture)

2. Secondary System Accidents
   a. Pressurizer pressure
   b. Steam line pressures

c. Steam line pressure rate
d. Reactor coolant average temperature (T_{avg})
e. Containment pressure

7.3.1.2.3 Spatially Dependent Variables

The only variable sensed by the Engineered Safety Features Actuation System which has spatial dependence is reactor coolant narrow range hot leg temperature. The effect on the measurement is negated by taking multiple samples from the reactor coolant hot leg and electronically averaging these samples in the process protection system.

7.3.1.2.4 Limits, Margins and Levels

Prudent operational limits, available margins and setpoints before onset of unsafe conditions or requiring protective action are discussed in Chapter 15 and the Technical Specifications. (Refer also to Subparagraph 7.1.2.1.9)

7.3.1.2.5 Abnormal Events

The malfunctions, accidents, or other unusual events which could physically damage protection system components or could cause environmental changes are as follows:

1. Loss of coolant accident (See Sections 15.3 and 15.4)
2. Steam breaks (See Sections 15.3 and 15.4)
3. Earthquakes (See Chapter 3 and Chapter 2)
4. Fire (See Subsection 9.5.1)
5. Explosion (Hydrogen buildup inside containment) (See Section 15.4)
6. Missiles (See Section 3.5 and 10.2.3)
7. Flood (See Chapters 2 and 3)

7.3.1.2.6 Minimum Performance Requirements

Minimum performance requirements are as follows:

1. System response times:

   The Engineered Safety Features actuation system response time, or time delay, is defined as the interval required for the Engineered Safety Features sequence to be initiated subsequent to the point in time that the appropriate variables(s) exceed setpoint(s). The delay time includes sensor, process and logic (digital) delay plus, the time delay associated with tripping open the reactor trip breakers, although the reactor trip (on Engineered Safety Feature Actuation Signal) theoretically occurs before or simultaneously with Engineered Safety Features sequence initiation (See Figure 7.2.1-1, Sheet 8). The ESFAS response time values are provided in Table 7.3.1-4.

   The design of the alternating current distribution system in conjunction with the worst-case accident conditions introduces a potential five-second delay in achieving minimum equipment operating voltage for 480-volt safety-related loads with offsite power available. This potential delay results from the worst-case automatic tap changer movement on the common station service transformers. The response times shown in Table 7.3.1-4 support surveillance test conditions with the onsite power system at normal voltage levels. The accident analysis supports an additional five-second duration for safety related equipment that is affected by the potential delay in achieving adequate voltage.

2. System accuracies are described in "Westinghouse Setpoint Methodology for Protection Systems, Sequoyah Units 1 and 2," WCAP 11239 for the following:

   a. Pressurizer low pressure
   b. Steam line pressure
   c. T_{avg}
   d. Containment pressure signal

3. Ranges of sensed variables to be accommodated until conclusion of protection action is assured:

   Typical ranges required in generating the required actuation signals for loss of coolant protection are given:

a. Pressurizer pressure	1700 to 2500 psig
b. Containment pressure (Ice Condenser System)	-1 to 15 psig

   Typical ranges required in generating the required actuation signals for steam break protection are given:

a. T_{avg}	530 to 630°F
b. Steam line pressure	0 to 1200 psig
c. Containment pressure (Ice Condenser System)	-1 to 15 psig

7.3.2 Analysis

7.3.2.1 Failure Mode and Effects Analyses

Failure mode and effects analysis have been performed on ESF systems equipment within the Westinghouse scope of supply. The results verify that these systems meet protection system single failure criteria as required by IEEE-279. The Sequoyah ESF systems, although not identical to those systems analyzed, are designed to equivalent safety design criteria.

Safety related equipment in the scope of TVA is reviewed for failure modes and effects, but is not documented in a separate report.

7.3.2.2 Compliance With Standards and Design Criteria

Discussion of the NRC General Design Criteria is provided in various sections of Chapter 7 where a particular GDC is applicable. Compliance with certain IEEE Standards is presented in Paragraphs 7.1.2.5, 7.1.2.6, 7.1.2.7, and 7.1.2.9. Compliance with Regulatory Guide 1.22 is discussed in Paragraph 7.1.2.8. Compliance with Regulatory Guide 1.11 is discussed in Paragraph 6.2.4.1 and 6.2.4.3. The discussion given below shows that the Engineered Safety Features Actuation System complies with IEEE 279-1971 (Reference 2).

Evaluation of Compliance with IEEE-279, 1971, Reference 2

7.3.2.2.1 Single Failure Criteria

The discussion presented in Subparagraph 7.2.2.2.3 (Item 1) is applicable to the Engineered Safety Features Actuation System, with the following exception.

In the Engineered Safety Features, a loss of instrument power will call for actuation of Engineered Safety Features equipment controlled by the specific comparator that lost power (except for containment spray and automatic switchover from the Refueling Water Storage Tank to the Containment Sump for pump suction following a Safety Injection). The actuated equipment must have power to comply. The power supply for the protection systems is discussed in Chapter 8. For containment spray, the final bistables are energized to trip to avoid spurious actuation. In addition, manual containment spray requires simultaneous actuation of two manual controls. There are two sets (2 switches/set) of manual containment spray controls available. This is considered acceptable because spray actuation on high-high containment pressure signal provides automatic initiation of the system via protection channels meeting the criteria in Reference 2. Moreover, all Engineered Safety Features equipment (valves, pumps, etc.) can be individually manually actuated from the control board. Hence, a third mode of containment spray initiation is available. The design conforms to 1971 GDC 21 and 23.

7.3.2.2.2 Equipment Qualification

The ability of equipment inside containment which is required for post loss of coolant accident operation to function in the adverse environment associated with the loss of coolant accident or incontainment steam break has been evaluated in Reference 4 and Section 3.11.

7.3.2.2.3 Channel Independence

The discussion presented in Subparagraph 7.2.2.2.3 (Item 4) is applicable. The Engineered Safety Features outputs from the solid state logic protection cabinets are redundant, and the actuations associated with each train are energized up to and including the final actuators by the separate AC power supplies which power the logic trains.

7.3.2.2.4 Control and Protection System Interaction

The discussions presented in Subparagraph 7.2.2.2.3 (Item 5) are applicable.

7.3.2.2.5 Capability for Sensor Checks and Equipment Test and Calibration

The discussions of system testability in Subparagraph 7.2.2.2.3 (Item 6) are applicable to the sensors, process circuitry, and logic trains of the Engineered Safety Features Actuation System.

The following discussions cover those areas in which the testing provisions differ from those for the Reactor Trip System:

Testing of Engineered Safety Features Actuation Systems

The Engineered Safety Features Systems are tested to provide assurance that the systems will operate as designed and will be available to function properly in the unlikely event of an accident. WCAP 7705, Reference 6, discusses Engineered Safety Features test cabinets that are typical of the Sequoyah Plant and is referenced for information only. The testing program meets the requirements of Regulatory Guide 1.22 as discussed in Paragraph 7.1.2.8 and Criteria 21, 37, 40 and 43 of the 1971 GDC. The program is as follows:

1. Prior to initial plant operations, Engineered Safety Features System tests were conducted.

2. Subsequent to initial startup, Engineered Safety Features System tests are conducted in accordance with Technical Specifications.

3. During on-line operation of the reactor, all of the Engineered Safety Features process and logic circuitry are fully tested. In addition, testable Engineered Safety Features final actuators are tested.

4. During normal operation, the operability of testable final actuation devices of the Engineered Safety Features Systems is tested by manual initiation from the control room.

Reference 7 documents a methodology to be used to justify revisions to the technical specifications. The methodology consists of the deterministic and numerical evaluation of the effects of particular technical specification changes with consideration given to such things as safety, equipment requirements, human factors and operation impacts. The technical specification revisions evaluated were increased test and maintenance times, less frequent surveillance and testing in bypass.

Performance Test Acceptability Standard for the "S" (Safety Injection Signal) and for the "P" (the Automatic Demand Signal for Containment Spray Actuation) Actuation Signals Generation

During reactor operation, the basis for Engineered Safety Features Actuation Systems acceptability is the successful completion of the overlapping tests performed on the Reactor Trip and the Engineered Safety Features Actuation Systems. Process checks verify operability of the sensors. Checks of process indications verify the operability of the process circuitry from the input of these circuits through to and including the logic input relays. Solid State logic testing checks the digital signal path from and including logic input relay contacts through the logic matrices and master relays and performs continuity tests on the coils of the output slave relays. Final actuator testing verifies operability of those devices which require safeguards actuation and which can be tested without causing plant upset. Operation of the final devices is confirmed by control board indication or visual observation that the appropriate pump motor breakers close and automatic valves have completed their travel.

The basis for acceptability for the Engineered Safety Features interlocks is control board indication of proper receipt of the signal upon introducing the required input at the appropriate setpoint.

Frequency of Performance of Engineered Safety Features Actuation Tests

Refer to the Technical Specifications for system tests and test frequencies.

Engineered Safety Features Actuation Test Description

The following sections describe the testing circuitry and procedures for the on-line portion of the testing program. The guidelines used in developing the circuitry and procedures are:

1. The test procedures must not involve the potential for damage to any plant equipment.

2. The test procedures must minimize the potential for accidental tripping.

3. The provisions for on line testing must minimize complication of engineered safety features actuation circuits so that their reliability is not degraded.

Description of Initiation Circuitry

Several systems comprise the total Engineered Safety Features System, the majority of which may be initiated by different process conditions and be reset independently of each other. Refer to Figure 7.2.1-1 for functions and auxiliary support systems and their initiating signals.

Each function is actuated by a logic circuit which is duplicated for each of the two redundant trains of Engineered Safety Features initiation circuits.

The output of each of the initiation circuits consists of a master relay which drives slave relays for contact multiplication as required. The logic, master, and slave relays are mounted in the solid state logic protection cabinets designated Train A, and Train B respectively, for the redundant counterparts. The master and slave relay circuits operate various pump and fan motor circuit breakers or starters, motor operated valve contactors, solenoid operated valves, emergency generator starting, etc.

Process Testing

Process testing is identical to that used for reactor trip circuitry and is described in Paragraph 7.2.2.2.3. Briefly, in the process racks, a portable Man-Machine-Interface (MMI) Unit is used together with a rack mounted test panel to facilitate testing. Administrative control requires, during comparator testing, that the comparator output be put in a trip condition which disconnects and thus de-energizes (operates) the comparator output relays in Train A and Train B cabinets. This of necessity, is done on one channel at a time. Status lights and single channel trip alarms in the main control room verify that the bistable relays have been de-energized and the bistable outputs are in the trip mode. An exception to this is containment spray, which is energized to actuate 2/4 and changes to 2/3 when one channel is in test.

Solid State Logic Testing

After the individual channel process testing is complete, the logic matrices are tested as described in 7.2.2.2.3 (6). During logic testing of one Train, the other Train can initiate the required Engineered Safety Features function. For additional details, see Reference 3.

Actuator Testing

At this point, testing of the initiation circuits through operation of the master relay and its contacts to the coils of the slave relays has been accomplished. Slave relays do not operate because of the reduced voltage.

The actuation components are tested during plant shutdown. Overlap testing between the slave relays and actuation devices completes the ESFAS test.

Time Required for Testing

It is estimated that process testing can be performed at a rate of several channels per hour. Logic testing can be performed in less than 30 minutes.

Summary

The procedures described in this section provide capability for checking completely from the process signal to the logic cabinets and from there to the individual pump and fan motor circuit breakers or starters, valve contactors, pilot solenoid valves, etc. including all field cabling actually used in the circuitry called upon to operate for an accident condition.

The procedures require testing at various locations.

1. Process testing and verification of comparator setpoint are accomplished at process racks. Verification of comparator relay operation is done at the main control room status lights.

2. Logic testing through operations of the master relays and low voltage application to slave relays is done at the logic rack test panel.

3. Testing of pumps, fans and valves will be a function of control room operator availability.

Testing During Shutdown

Emergency Core Cooling System actuation tests are performed as required in the Technical Specifications (normally at each major fuel reloading). With the Reactor Coolant System pressure less than or equal to 350 psig and temperature less than or equal to 350°F, a test safety injection signal is applied to initiate operation of the system. The safety injection and residual heat removal pumps are made inoperable for this test.

Containment spray system actuation tests are performed as required in the Technical Specifications (normally at each major fuel reloading). The tests are performed one train at a time with the isolation valves in the spray supply lines and the containment sump suction lines blocked closed and the appropriate valves in the recirculation path to the RWST open. The tests are initiated by tripping the normal actuation instrumentation.

Periodic Maintenance Inspections

The maintenance procedures for the engineered safety feature actuation system which follow may be accomplished in any order. The frequency will depend on the operating conditions and requirements of the reactor power plant. If any degradation of equipment operation is noted, either mechanically or electrically, remedial action is taken to repair, replace, or readjust the equipment. Optimum operating performance must be achieved at all times.

Typical maintenance procedures include the following:

1. Check cleanliness of exterior and interior surfaces where accessible.

2. Check all fuses for corrosion.

3. Inspect for loose or broken control knobs and burned out indicator lamps.

4. Inspect for rust, moisture and condition of cables and wiring.

5. Mechanically check all connectors and terminal boards for looseness, poor connection, or corrosion.

6. Inspect the components of each assembly for signs of overheating or component deterioration.

7. Perform complete system operating check.

The balance of the requirements listed in Reference 2 (Paragraphs 4.11 through 4.22) are discussed in Subparagraph 7.2.2.2.3. Paragraph 4.20 receives special attention in Section 7.5.

7.3.2.2.6 Manual Initiation of Protective Action

The manual initiation of reactor trip, safety injection, containment isolation A, containment spray (along with containment isolation B and containment ventilation isolation), and diesel generator start are all accomplished on the system level. However, the manual initiation of both steamline isolation, and switchover from injection to recirculation following a loss of primary coolant accident are performed at the component level only, so that the initiation of these two systems is not specifically designed to meet Section 4.17 of IEEE 279-1971.

The main steam isolation valves are included in the plant design to mitigate the consequences resulting from steam line breaks, and protection logic is provided in the plant design to automatically close the valves when necessary.

The inadvertent manual closure of any single MSIV or the simultaneous closure of all MSIVs both create Condition II faults. If all valves are closed simultaneously when the plant is operating at full power, a loss-of-load accident will result with a consequent primary and secondary side pressure increase, reactor trip and secondary side safety valve release. In the event that only one valve closes on inadvertent manual actuation when the plant is operating at full power, the steam flow in the other loops will increase in an attempt to restore full power steam flow. The non-symmetric steam flow can cause an increase in reactor power due to the non-symmetric loop temperatures and to the moderator temperature coefficient of reactivity. Consequently margins to DNB are reduced.

Since remote individual closure of the steam line isolation valves from the control room is required for operational reasons, it is not felt that putting additional manual capabilities which can lead to the inadvertent closure of all steam stop valves is in the direction of reactor safety.

There are four individual main steam isolation valve momentary control switches (one per loop) mounted on the control board. Each switch when actuated will isolate one of the main steam lines.

The manual operations performed at the component level for switchover from safety injection to cold leg recirculation following a loss of primary coolant accident are described in Table 6.3.2-4.

7.3.2.3 Further Considerations

In addition to the considerations given above, a loss of one train of instrument air or loss of one train of component cooling water to vital equipment has been considered. Neither the loss of one train of instrument air nor the loss of one train of cooling water can cause safety limits as given in the SQN Technical Specifications to be exceeded or prevent the mitigation of an accident.

Safety related systems that use instrument air to perform their functions generally are designed to assume their safe condition upon loss of instrument air (e.g., isolation dampers). However, all systems are redundant and each counterpart supplied from an independent instrument air supply. The following systems use instrument air to perform their required functions: (1) control bay heating, ventilation, and air conditioning system; (2) auxiliary building gas treatment system; (3) containment vacuum relief system; (4) emergency gas treatment system; (5) turbine driven auxiliary feedwater system; and (6) motor driven auxiliary feedwater level control system.

7.3.2.4 Summary

The effectiveness of the Engineered Safety Features Actuation System is evaluated in Chapter 15, based on the ability of the system to contain the effects of Condition III and IV faults, including loss of coolant and steam line break accidents. The Engineered Safety Features Actuation system parameters are based upon the component performance specifications which are given by the manufacturer or verified by test for each component. Appropriate factors to account for uncertainties in the data are factored into the constants characterizing the system.

The Engineered Safety Features Actuation system must detect Condition III and IV faults and generate signals which actuate the Engineered Safety Features. The system must sense the accident condition and generate the signal actuating the protection function reliably and within a time determined by and consistent with the accident analyses in Chapter 15.

Much longer times are associated with the actuation of the mechanical and fluid system equipment associated with Engineered Safety Features. This includes the time required for switching, bringing pumps and other equipment to speed and the time required for them to take load. Consideration is given these times in the accident analysis (Chapter 15).

Operating procedures require that the complete Engineered Safety Features Actuation System normally be operable. However, redundancy of system components is such that the system operability assumed for the safety analyses can still be met with certain instrumentation channels out of service. Channels that are out of service are to be placed in the tripped mode or bypass mode. See section 7.2 for more detail on the use of bypasses.

7.3.2.4.1 Loss of Coolant Protection

By analysis of loss of coolant accident and in system tests it has been verified that except for very small coolant system breaks which can be protected against by the charging pumps followed by an orderly shutdown, the effects of various loads of coolant accidents are reliably detected by the low pressurizer pressure; the Emergency Core Cooling System is actuated in time to prevent or limit core damage. (Refer to Section 15.3.1.)

For large coolant system breaks the passive accumulators inject first, because of the rapid pressure drop. This protects the reactor core during the unavoidable delay associated with actuating the active Emergency Core Cooling System phase. (Refer to Section 15.4.1.)

High containment pressure also actuates the Emergency Core Cooling System. Therefore, emergency core cooling actuation can be brought about upon sensing this other direct consequence of a primary system break; that is the protection system detects the leakage of the coolant into the containment.

Containment spray will provide additional emergency cooling of containment and also limit fission product release upon sensing elevated containment pressure (high-high) to mitigate the effects of a loss of coolant accident.

The delay time between detection of the accident condition and the generation of the actuation signal for these systems is assumed to be about 1.0 second; well within the capability of the protection system equipment. However, this time is short compared to that required for startup of the fluid systems. The analyses in Chapter 15 show that the diverse methods of detecting the accident condition and the time for generation of the signals by the protection systems and time for initiation of protective action are adequate to provide reliable and timely protection against the effects of loss of coolant.

7.3.2.4.2 Steam Break Protection

The Emergency Core Cooling System is also actuated in order to protect against a steam line break. About 2.0 seconds elapses between sensing low steamline pressure and generation of the actuation signal. Analysis of steam break accidents assuming this delay for signal generation shows that the Emergency Core Cooling system is actuated in time to limit or prevent further core damage for steam break cases. There is a reactor trip but the core reactivity is further reduced by the highly borated water injected by the Emergency Core Cooling System.

Additional protection against the effects of steam break is provided by feedwater isolation which occurs upon actuation of the Emergency Core Cooling System. Feedwater line isolation is initiated in order to prevent excessive cooldown of the reactor.

Additional protection against a steam break accident is provided by closure of all steam line isolation valves in order to prevent uncontrolled blowdown of all steam generators. The generation of the protection system signal (about 2.0 seconds) is again short compared to the time to close the fast acting steam line isolation valves.

In addition to actuation of the Engineered Safety Features, the effect of a steam break accident also generates a signal resulting in a reactor trip on overpower or following Emergency Core Cooling System actuation. However, the core reactivity is further reduced by the highly borated water injected by the Emergency Core Cooling System.

The analyses in Chapter 15 of the steam break accidents and an evaluation of the protection system instrumentation and channel design shows that the Engineered Safety Features Actuation Systems are effective in preventing or mitigating the effects of a steam break accident.

7.3.2.4.3 <u>Response to IE Information Notice 79-22</u>

TVA has performed a systematic (matrix) evaluation of the environmental effects resulting from high energy pipe breaks inside and outside containment upon nonsafety-related systems. Specifically, safety features required to mitigate the consequences of high energy pipe break and those required to obtain and maintain a safe shutdown following such an event were evaluated to determine if a single inappropriate actuation of an interfacing nonsafety-related system could unacceptably affect the required safety feature. TVA's conclusion is that although there is a possibility for disruptive signals to be generated, these are in every case acceptable because the operator will always have sufficient indication and time to take corrective action. Where appropriate, operating instructions have been modified as an additional precaution to preclude the event or to alert the operator to the possibility of the event.

<u>Methodology</u>

The following approach was used in analyzing the potential for disruption of required safety features by the consequential inappropriate actuation of interfacing nonsafety systems.

1. Required safety features for LOCA, main steam and feedwater, and other postulated high energy pipe rupture events were identified from the appropriate safe shutdown logic diagram. These required features were screened against a list of plant systems to determine if, functionally, sufficient interface existed between the required feature and the system to merit further evaluation. That is, without regard for the credibility of the event a single spurious actuation was postulated to occur anywhere within the system under consideration. As this spurious actuation was postulated, the question was asked, is there sufficient interface between the system and the required safety feature so that functionally there is potential for an unacceptable condition to exist. (See Table 7.3.2-1 for potential interaction matrix.)

2. All cases identified as potentially unacceptable in step one were subjected to an individual evaluation for credibility and acceptability. All nontrivial cases are discussed in the results.

<u>Results</u>

RCS Inventory and Pressure Control

The pressurizer PORVs might be subject to inappropriate opening due to environmental effects which could exist from high energy pipe breaks inside containment. Such inappropriate opening has been judged to be acceptable because (1) adequate annunciation is provided to alert the operator to the event, (2) adequate time is available for operator action, and (3) the control system design is such that operator action is possible.

RCS inventory and pressure control could also be jeopardized by inappropriate control circuit actuations which would lead to a reactor coolant pump (RCP) seal failure. Control system modifications have been made to both the component cooling water system, which supplies cooling to the pumps thermal barrier and to the chemical and volume control system (CVCS), which supplies seal injection water to assure seal integrity in the presence of fire-induced

spurious control system actuations. In that these modifications would also render the seals immune to damage due to pipe break induced inappropriate actuations, this feature was judged to be assured without further evaluation.

Steam Generator Inventory and Pressure Control

The control system for the SG power operated relief valves (PORVs), contained within the Distributed Control System (DCS), could be affected by high energy pipe breaks in the main steam valve room. This inappropriate opening is considered to be acceptable because (1) adequate annunciation is provided to alert the operator to the event, (2) adequate time is available for operator action, and (3) the control system design assures that the operator can override the inappropriate open signal. For a steamline break downstream of the flow restrictor coupled with a spurious opening of a steam generator power operated relief valve and its failure to close the steamline break analysis performed for a break upstream of the flow restrictor is bounding. Note: The design of the replacement steam generators includes an integral flow limiter in the main steam nozzle, which eliminates the potential for a main steam line break upstream of the flow restrictor.

An inappropriate opening of a main steam isolation valve bypass valve would defeat steam generator isolation. Normally the solenoids for these valves are deenergized (by handswitch position) after the valves are closed during plant startup.

ECCS Response

An inappropriate actuation of the reactor building auxiliary flow and equipment drain sump pump could jeopardize long term ECCS response by pumping water out of the ECCS active sump. This actuation is considered to be acceptable because (1) adequate indication is provided to alert the operator to the event, (2) adequate time is available for operator action, and (3) control system design is such that operator action is possible.

A number of other control circuits whose inappropriate actuation has the potential to disrupt ECCS response have been modified or de-energized as discussed in Section 7.6.6. In that this action would also prevent environmentally induced inappropriate actuations, these control systems were not evaluated further.

Other Safety Features

Inappropriate control system actuations within the Essential Raw Cooling Water (ERCW) system has the potential to disrupt a number of required Safety features. This system had been previously evaluated for unacceptable fire-induced inappropriate actuation. A number of cases were discovered where an inappropriate actuation would cause unacceptable load imbalance within the system. The modifications taken to preclude such fire-induced actuations would also make the control systems immune to pipe break environmental effects. Hence, the system was considered to be acceptable without further evaluation.

Additional Considerations

The study thus far has considered the system being evaluated as a target in the zone of influence of the postulated high energy pipe break. There are two cases where this evaluation has made use of previous efforts to control the zone of influence of the postulated event. The events, which are identified in the SQN pipe break analysis, are a RHR break in the 690 ft. elevation of the Auxiliary Building, and a break along the route of the auxiliary boiler steam line in the Auxiliary Building. Trainized temperature sensors have been provided to alert the operator of an adverse environment within the RHR pipe chase.

Conclusion

The conclusion of this evaluation is that a safe shutdown can be achieved at SQN even if a postulated accident is compounded by environmentally induced inappropriate control system actuation.

TABLE 7.3.1-3

INTERLOCKS FOR ENGINEERED SAFETY FEATURES ACTUATION SYSTEM

Designation	Input	Function Performed
P-4	Reactor trip	Actuates turbine trip Provides Feedwater Isolation Signal on T_{avg} below setpoint Prevents opening of main feedwater valves which were closed by safety injection or high steam generator water level Allows manual block of the automatic reactuation of safety injection
P-11	2/3 Pressurizer pressure below setpoint	Allows manual block of safety injection actuation on low pressurizer pressure signal. Allows manual block of safety injection and steamline isolation on low steamline pressure. Steamline isolation on high negative rate steamline pressure is permitted when this manual block is accomplished.
	2/3 Pressurizer pressure above Setpoint	Defeats manual block of safety injection actuation. Defeats manual block of safety injection and steamline isolation on low steamline pressure and defeats steamline isolation on high negative rate steamline pressure. Provides auto-open signal to SIS cold leg accumlator valves.
P-12	2/4 Low-Low T_{avg} below setpoint	Blocks condenser steam dump valves. Allows manual bypass of steam dump block for the cooldown condenser dump valves only. (Note) For the use of additional steam dump valves below the P-12 interlock, please refer to Section 10.4.4.3.
	3/4 low-low T_{avg} above setpoint	Defeats the manual bypass of steam dump block
P-14	2/3 Steam generator Hi-Hi water level above setpoint on any steam generator	Provides feedwater isolation signal Actuates turbine trip

TABLE 7.3.1-4 (Sheet 4)

NOTES

1. Diesel generator starting and sequence loading delays included. Response time limit includes opening of valves to establish SI path and attainment of discharge pressure for centrifugal charging pumps, SI and RHR pumps.

2. This isolation, accompanied by a reactor trip, is accomplished by closure of redundant valves in the piping to each steam generator and tripping of the main feedwater pumps. The air to open, spring to close, FW regulator valves will close within 7.0 seconds. The motor-operated containment FW isolation valves will close within 7.5 seconds. The FW bypass control valves will close within 8.0 seconds. The FW isolation response time, which includes closure time and all electronic delays of the FW regulator valves, the startup valves bypassing the FW regulator valves, and the FW isolation valves will be less than nine seconds.

3. The following valves are exceptions to the response times shown in the table and will have the values listed in seconds for the initiating signals and function indicated:

Valves:	FCV-26-240, -243	
Response times:	2.d.	21 (8) (15) / 31 (9)
	3.d.	22 (8) (15)
	6.d.	21 (8) (15) / 31 (9)
Valves:	FCV-61-96, -97, -110, -122, -191, -192, -193, -194	
Response times:	2.d.	31 (8)
	3.d.	32 (8)
	6.d.	31 (8)
Valve:	FCV-70-143	
Response times:	2.d.	61 (8) (15) / 71 (9)
	3.d.	62 (8) (15)
	6.d.	61 (8) (15) / 71 (9)

4. On 2/3 any Steam Generator

5. On 2/3 in 2/4 Steam Generator

6. Radiation detectors for Containment Ventilation Isolation may be excluded from Response Time Testing.

7. Diesel generator starting and sequence loading delays not included. Offsite power available. Response time limit includes opening and closing of valves to establish SI path and attainment of discharge pressure for centrifugal charging pumps.

8. Diesel generator starting and sequence loading delays not included. Response time limit includes operating time of valves.

9. Diesel generator starting and sequence loading delays included. Response time limit includes operating time of valves.

10. The response time for loss of voltage is measured from the time the diesel start signal is initiated until the time full voltage is restored by the diesel. The response time for degraded voltage is measured from the time the load shedding signal is generated, either from the degraded voltage or the SI enable timer, to the time full voltage is restored by the diesel. The response time of the timers is covered by the requirements on their setpoints.

TABLE 7.3.1-4 (Sheet 5)

11. The provisions of Technical Specification SR 3.0.4 are not applicable for entry into MODE 3 for the turbine-driven Auxiliary Feedwater Pump.

12. The following valves are exceptions to the response times shown in the table and will have the values listed in seconds for the initiating signals and the function indicated:

Valves:	FCV-67-89, -90, -105, -106	
Response times:	7.b.	75 (8) (15) / 85 (9)
Valve:	FCV-70-141	
Response times:	7.b.	70 (8) (15) / 80 (9)

13. Containment purge valves only. Containment radiation monitor valves have a response time of 6.5 seconds or less.

14 Does not include Trip Time Delays. Response times noted include the transmitters, Eagle-21 process protection cabinets, solid state protection cabinets, and actuation devices (up to and including pumps). This reflects the response times necessary for THERMAL POWER in excess of 50% RTP.

15. The response time shown is for system/valve response with normal equipment operating voltage available during periodic testing. Additional margin is included in the analysis to account for potential delays in achieving minimum equipment operating voltage.

16. The Essential Raw Cooling Water system 6.9 kv pumps are exceptions to the response times shown in the table and will have the values listed in seconds for the initiating signals and the function indicated:

Essential Raw Cooling Water System Pumps

Response times:	2.g.	65.0 (8) / 75.0 (9)
	3.g.	65.0 (8) / 75.0 (9)
	6.g.	65.0 (8) / 75.0 (9)

7.4 SYSTEM REQUIRED FOR SAFE SHUTDOWN

The process signals and information necessary for safe shutdown are available from instrumentation channels that are associated with major systems in both the primary and secondary sides of the Nuclear Steam Supply System. These channels are normally aligned to serve a variety of operational functions, including startup and shutdown as well as protective functions.

The instrumentation and control capability which is identified as being required for maintaining safe shutdown of the reactor is by definition, the minimum under nonaccident conditions. This capability will permit the necessary operations that will:

1. Prevent the reactor from achieving criticality in violation of the Technical Specifications and

2. Provide an adequate heat sink such that design and safety limits are not exceeded.

The designation of systems that can be used for maintaining a safe shutdown by providing the necessary functions depends on identifying those systems which provide the following capabilities:

1. Boration.

2. Residual heat removal.

Discussions of the systems required for a safe shutdown, which are identified in Section 7.4.1, together with the applicable codes, criteria, and guidelines are contained in other sections of the Safety Analysis Report and the Fire Protection Report (see 9.5.1).

7.4.1 Description

7.4.1.1 Control Room Availability

The main control room is located in the Control Building, which is a Seismic Category I Structure, at elevation 732. The Main Control Room Ventilation System, is described in detail in Section 9.4.1, is designed to maintain habitability in accordance with GDC-19 during essentially all conditions.

Extensive fire in the Main Control Room or Control Building could, however, force its evacuation. In that unlikely event, control will be transferred to the Auxiliary Control Station located in the Auxiliary Building after tripping the reactor. The auxiliary controls provide a capability to bring the units to and maintain them at a safe shutdown condition. Auxiliary controls are discussed below and in the Fire Protection Report (see 9.5.1).

The construction materials used in the main control room are noncombustible. The main control boards are of steel and the internal surface is painted with a fire-retardant paint. Electrical wiring is flame resistant as shown by the vertical flame test as described in the Insulated Power Cable Engineer's Association, IPCEA, Publications and the American Society for Testing Materials, ASTM D 470-64T.

For details on the habitability systems of the main control room, see Section 6.4.

7.4.1.2 Auxiliary Controls

In case it becomes necessary to evacuate the main control room due to fire or smoke, the capability exists to establish and maintain the reactor(s) in a safe shutdown condition from locations outside the Main Control Room. This capability is discussed in the Fire Protection Report (See 9.5.1).

Each auxiliary control function is designed with a transfer switch to disconnect it from the main control room. Placing the transfer switch in the local operating position will give an annunciating alarm in the control room and will turn off the motor control position lights on the control room panel. For certain systems the purpose of this transfer switch is to prevent actuation of the system due to a spurious signal caused by fire. Any exceptions to the above are evaluated and documented on design criteria SQN-DC-V-2.17 and SQN-DC-V-12.2.

7.4.1.3 Systems Available for Hot Shutdown

System and instrumentation required for fire safe shutdown is described in the Fire Protection Report (see 9.5.1).

To achieve and maintain hot shutdown for various nonaccident reactor conditions, essential control functions are provided both inside and outside the main control room for the following systems:

	System	FSAR Reference Section
1.	Reactor Coolant System	Chapter 5
2.	Chemical and Volume Control System	Section 9.3.4
3.	Residual Heat Removal System	Section 5.5.7
4.	Component Cooling System	Section 9.2.1
5.	Main Steam System	Section 10.3
6.	Ventilation System	Section 9.4
7.	Essential Raw Cooling Water System	Section 9.2.2
8.	Auxiliary Feedwater System	Section 10.4.7.2
9.	Diesel Generators	Chapter 8

In addition to the functions indicated above, the turbine may be tripped in the main control room or at the turbine; the reactor may be tripped in the main control room, the 480V MG set breakers, or at the reactor trip switchgear; and all automatic systems (unless damaged by fire) continue functioning as discussed in Section 7.3.

7.4.1.3.1 Main Controls

The indicators and controls available in the main control rooms are discussed in Section 7.1.4.

7.4.1.3.2 Auxiliary Controls

The indicators and controls available outside of the main control room are described in this section.

1. Reactor Coolant (RC) System

   The following information is available to the operator in the auxiliary control room:

   a. RC temperature.
   b. Pressurizer pressure.
   c. Pressurizer level.
   d. Pressurizer relief tank level (Unit 2 only).
   e. Pressurizer relief tank pressure.

Controls for the RC pumps, the oil-lift pumps, the valves necessary to vent the pressurizer, and the safety related pressurizer heaters are available outside of the main control room.

2. Chemical and Volume Control System

The following functions and equipment are available to the operator from outside the main control room:

a. Charging and letdown flow.
b. Demineralizer bypass.
c. Divert flow to the holdup tank.
d. Charging pumps.
e. Boric acid tank flow.
f. Seal flow.

3. Residual Heat Removal (RHR) System

To achieve and maintain hot shutdown, the only function required of this system is to ensure closure of the RHR isolation valves.

4. Component Cooling System (CCS)

Controllers for the following functions and equipment are located outside the main control room:

a. The main CCS pumps.
b. The booster pumps.
c. Header flow control valves.
d. Diversion valves to the component coolers.

5. Main Steam System

The steam generator pressures are displayed in the auxiliary control room. The steam flow to the auxiliary feed pump turbine, the operation of the power relief valves, and the cessation of blowdown and sampling can be controlled from the panels outside the main control room.

6. Ventilation System

The containment pressure is displayed on auxiliary control panels for both units.

The controllers needed to control the lower compartment cooler units, the control rod driver cooler units, and the recirculation valves are located on panels outside the main control room.

7. Essential Raw Cooling Water (ERCW) System

From outside of the main control room, the operator has control of the following:

a. ERCW pumps.
b. Header flow.
c. Header isolation.
d. Header pressure.
e. Header valves.
f. Cooler discharge flow valves.

8. Auxiliary Feedwater (AFW) System

   Panels outside the main control room contain the displays and controls for the following equipment and functions:

   a. AFW pumps.
   b. ERCW supply to AFW isolation valves.
   c. Steam generator level control.
   d. AFW pump discharge pressure.
   e. Steam generator levels.
   f. AFW flow to each steam generator.
   g. Total turbine-driven pump header flow.

   The steam generator levels are provided by two channels of instrumentation.

9. Diesel Generators

   The operator has the ability to initiate emergency start and emergency stop of the diesel generators from outside the main control room.

7.4.1.4 Systems Available for Cold Shutdown

The systems available to achieve and maintain hot shutdown are available also for cold shutdown.

7.4.1.4.1 Main Controls

The indicators and controls available in the main control room are discussed in Section 7.1.4.

7.4.1.4.2 Auxiliary Controls

In addition to the functions that are available outside the main control room discussed in Section 7.4.1.3.2, the operator is provided with control of the following RHR functions and equipment:

1. RHR valves from the RCS.
2. RHR pumps and miniflow.
3. RHR header and cross-tie flow.
4. RHR flow and temperature.

To achieve cold shutdown the operator must be able to defeat the safety injection signal trip circuit and close the accumulator isolation valves or vent the accumulators to decrease their pressure. The instrumentation and controls for certain systems may require some modification or repair in order that their functions may be performed outside the control room. Note that the plant design does not preclude attaining the cold shutdown conditions from outside the control room. An assessment of plant conditions can be made in order to attain cold shutdown. During such time the plant could be safely maintained at hot shutdown condition.

7.4.1.5 Additional Systems Available Outside the Main Control Room

The following systems are not required for safe shutdown but are provided with controls both inside and outside the main control room so essential functions can be maintained:

1. Containment Spray System, Section 6.2.2.
2. Safety Injection System, Section 6.3.
3. Waste Disposal System, Chapter 11.

7.4.1.5.1 Main Controls

The indicators and controls available in the main control room are discussed in Section 7.1.4.

7.4.1.5.2 Auxiliary Controls

1. Containment Spray System

   The controls for the containment spray pumps, the spray header flow valves, and the supply valves are available outside the main control room.

2. Safety Injection System

   From panels located outside the main control room, the following functions and equipment can be controlled:

   a. Accumulator tank pressure.
   b. Accumulator tank level.
   c. Flow to the cold legs of the RC System.
   d. Accumulator tank to RCDT flow.
   e. Flow to the RHR heat exchangers.
   f. SIS pumps.
   g. Flow from the refueling water storage tank.
   h. Flow to the CCP injection tank.
   i. Containment sump discharge.

3. Waste Disposal System

   The Gaseous and Liquid Processing Systems panels are local panels located in the Auxiliary Building. The sump pump and isolation valves are controlled from panels in the vicinity of the auxiliary control room.

7.4.2 Analysis

Hot shutdown is a stable plant condition, automatically reached following a plant shutdown. The hot shutdown condition can be maintained safely for an extended period of time either automatically or manually. In the unlikely event that access to the control room is restricted, the plant can be safely kept at hot shutdown or taken to cold shutdown by the use of the monitoring indicators and the controls listed in Sections 7.4.1.3 and 7.4.1.4. These indicators and controls are provided outside as well as inside the control room.

The safety evaluation of the maintenance of a shutdown from the main control room has included consideration of the accident consequences that might jeopardize safe shutdown conditions. The accident consequences that are germane are those that would tend to degrade the capabilities for boration, adequate supply for auxiliary feedwater and residual heat removal.

The results of the accident analyses are presented in Chapter 15. Of these, the following produce the most severe consequences that are pertinent:

1. Uncontrolled boron dilution.
2. Loss of normal feedwater.
3. Loss of external electrical load and/or turbine trip.
4. Loss of all alternating current power to the station auxiliaries (station blackout).

It is shown by these analyses that safety is not compromised by these incidents with the associated assumptions being that the instrumentation and controls indicated in Section 7.1.4 are available to control and/or monitor shutdown. These available systems will allow a maintenance of hot shutdown even under the accident conditions listed above which would tend toward a return to criticality or a loss of heat sink.

Fire-Safe shutdown Analysis is discussed in the Fire Protection Report (see 9.5.1).

7.5 SAFETY-RELATED DISPLAY INSTRUMENTATION FOR POSTACCIDENT MONITORING (PAM)

7.5.1 Description

7.5.1.1 System Description

Post Accident Monitoring (PAM) instrumentation is required to monitor plant and environment conditions during and following design basis Condition II, III and IV faults as described in FSAR Chapter 15. PAM will enable the Main Control Room (MCR) operating staff (operator) to take preplanned manual actions, provide information on whether critical safety functions are being accomplished, provide information for potential or actual breach of the barriers to fission product release, provide information of individual safety systems, and provide information on the magnitude of the release of radioactive materials.

Table 7.5-2 lists the process information required at the initiation of an accident, during the course of an accident, and until the unit is in cold shutdown following an accident. The variables were selected through a systematic evaluation of parameters required for the mitigation of design basis events, a comprehensive review of the Emergency Instructions (EIs), Function Restoration Guidelines (FRGs), and Condition II, III and IV faults in Chapter 15 of the FSAR. In some cases, the EIs and FRGs address mitigation of events which may extend beyond the design basis of the plant. Instrumentation used for beyond design basis events may be exempted from being PAM instrumentation. Table 7.5-2 furnishes the 5 appropriate variable classification types/categories for each variable description. PAM variable types/categories were determined using the guidance given in U.S. NRC Regulatory Guide 1.97 R2.

7.5.1.2 Variables Types

Five (5) classifications of variable types, A, B, C, D, and E were identified to provide the PAM instrumentation. Those classifications meet the PAM classification contained in Regulatory Guide 1.97 R2. These five classifications are not mutually exclusive, in that, a given variable (or instrument) may be included in one or more types. When a variable is included in more than one of the classifications, the equipment monitoring this variable meets the more stringent qualification category requirements as noted in Table 7.5-1.

Type A Variables

Those variables that provide primary information to the MCR operators to allow them to take preplanned manually controlled actions for which no automatic action is provided and that is required for safety systems to accomplish their safety functions for Chapter 15 design basis events.

Type B Variable

Those variables that provide information to indicate the accomplishment of critical safety functions.

Type C Variable

Those variables that provide information to indicate the potential for being breached or the actual breach of the barriers to fission product release. The barriers to fission product release are fuel cladding, reactor coolant pressure boundary, and primary reactor containment.

Type D Variable

Those variables that provide information to indicate the operation of individual safety systems and other systems important to safety.

Type E Variable

Those variables used in determining the magnitude of the release of radioactive materials and for continuously assessing such releases.

7.5.1.3 Variables Categories

The five types of variables are functionally classified into three (3) qualification categories (1, 2, and 3) according to the safety function provided by that variable. Description of the three categories are given below. Table 7.5-1 briefly summarizes the qualification criteria of the three designated categories.

The differentiation in the 3 categories was made in order that importance of information hierarchy could be recognized in specifying accident monitoring instrumentation. Category 1 instrumentation has the highest pedigree and should be utilized for information which is essential to the Main Control Room operating staff in order for them to determine if the plant critical safety functions are being performed. Category 2 and 3 instruments are of lesser importance in determining the state of the plant and do not require the same level of operational assurance.

The primary differences between category requirements are in the qualification, application of single failure, power supply and display requirements. Category 1 requires class 1E, seismic and environmental qualification, the application of a single failure criteria, utilization of emergency standby power and continuous display. Category 2 requires emergency standby power and environmental qualification, but does not require class 1E qualification or the application of the single failure criteria. Category 2 requires, in effect, a rigorous performance verification for a single instrument channel. Category 3 does not require qualification, single failure criteria, emergency standby power or an immediately accessible display.

7.5.2 Design Basis

7.5.2.1 Selection Criteria

Type A variables are key variables and are designated Category 1. Type B and C variables are determined to be either a key or a backup variable depending on their particular usage. Those variables determined to be key shall be classified as Category 1 except for those classified as Category 2 in accordance with the specific guidance presented in Regulatory Guide 1.97, Table 2. Most backup variables are considered Category 3. The type D and E variables determined to be key shall be classified as Category 2 except for those classified as Category 1 in accordance

with the specific guidance presented in Regulatory Guide 1.97, Table 2. Most backup variables are considered Category 3. Differences between this general guidance and the variables given in Table 7.5-2 are addressed in the deviations (reference 3, 5, and 12).

The variable categories were determined through, (1) the guidance given in Regulatory Guide 1.97, Table 2, (2) a review of the SQN Emergency Instructions and Functional Restoration Guidelines and, (3) a safety analysis performed for the FSAR Chapter 15 design basis accidents. These three steps insure that sufficient instrumentation is available to the operator to keep the plant in a safe condition under accident scenarios.

7.5.2.2 Design Criteria

7.5.2.2.1 Category 1 Variables

A. Redundant Class 1E qualified continuous indication of these variables has been provided. Qualification applies from the sensor to the display. The variables have been provided with a minimum of two independent channels (PAM 1 and PAM 2) for monitoring each variable. These two channels of two diverse or redundant variables allow the operator to deduce actual plant conditions.

   Where failure of a channel would present ambiguous or confusing information to the operator, preventing the operator from taking action or misleading the operator, an additional (PAM 3) channel has been provided. The PAM 3 channel may be an additional (redundant) or an independent channel to monitor a different variable that bears a know relationship to the multiple channels (diverse). The third channel has been qualified to the same requirements as the first two channels. Table 7.5-2 lists the redundancy requirements for each Category 1 variable.

B. PAM instrumentation has components and cables environmentally qualified and installed to function in plant conditions for which they are expected to operate. Qualification is in accordance with 10 CFR 50.49 using the guidance described in NUREG 0588 in accordance with RG 1.89.

C. PAM instrumentation is designed to function after a design basis seismic event.

D. Transmission of signals from PAM Category 1 devices to non-qualified equipment is only through an isolation device qualified to the same requirements as Category 1. No credible failure at the output of the isolation device prevents the monitoring channel from meeting its minimum performance requirements.

E. Category 1 instrumentation is capable of operating independently of offsite power, and is normally backed up by batteries. The instrumentation can be backed up by the emergency diesel generators if shown through analysis that the indication is not required by the operator during the time for the diesels to come up to speed and tie on to the Auxiliary Power System. The physical separation between redundant channels has been preserved in field wiring by combining outputs from Train A or channels from instrumentation cabinets I or III into the PAM 1 channels. The redundant PAM 2 channels are from Train B or channels from instrumentation cabinets II or IV.

F. Category 1 analog variables are trended on the plant computer system. In addition to the plant computer system, a hardwire recorder for at least one instrument loop of the variable has been provided when the trending of Category 1 variables enhances the operators' ability to cope with mitigating various design basis events. To increase reliability, the power supplies for these recorders must be arranged so that no single failure will result in the loss of both the plant computer system and recorder trending. The notes in Table 7.5-2 show which variables require a trend recorder. The trending portion of the PAM channel has met Category 1 qualification requirements unless isolation has been provided. Where isolation exists, the trending portion of the PAM channel has met Category 2 requirements.

G. Category 1 variables follow quality assurance requirements as described in Chapter 17 for safety related devices.

7.5.2.2.2 Category 2 Variables

A. Redundant or Class 1E circuitry is not required for Category 2 variables. However, the parent system may require the instrumentation to be classified 1E for non-PAM functions. Where this instrumentation has been used to provide PAM Category 2 indication, the Class 1E qualification applies from the sensor through the isolator/buffer. The display need not meet Class 1E requirements.

B. PAM instrumentation has components and cables environmentally qualified and installed to the plant conditions for which they are expected to operate. Nondivisional and Class 1E PAM instrumentation located in a harsh environment has been qualified in accordance with 10 CFR 50.49 using the guidance described in NUREG 0588. Mild environment Category 2 components do not have any special qualification requirements.

C. There are no specific requirements for seismic operability. However, specific system requirements above that required for PAM may exist. In those cases, the most restrictive qualification level applies. In addition, components are designed and mounted such that they do not have an adverse effect on safety systems during a seismic event.

D. Category 2 instruments are powered from highly reliable power sources, not necessarily divisional power, and are diesel generator or battery backed.

E. Potential plant release point effluent radioactivity monitors, area radiation monitors, and associated instrumentation are trended on a MCR recorder or on the plant computer system.

F. Category 2 instrumentation located in a harsh environment follow quality assurance requirements as described in Chapter 17 for safety related devices.

7.5.2.2.3 Category 3 Variables

A. PAM instrumentation is high-quality commercial grade equipment. No redundancy, qualification, or signal isolation is required.

B. Category 3 PAM loops are powered from normal station power supplies (such as, non-divisional power).

C. Components are designed and mounted such that they do not have an adverse effect on safety systems during a design basis seismic event. Instruments that are not part of a safety related system are not seismically qualified unless Sequoyah's FSAR invokes seismic requirements for the associated system.

D. The meteorology monitors are trended on the plant computer system.

7.5.2.3 General Requirements

7.5.2.3.1 Display Requirements

Category 1 parameters are displayed on individual devices located in the Main Control Room.

Category 2 and 3 devices are normally either displayed on individual instruments located in the Main Control Room or processed for display by the plant computer system.

Portable or postaccident sampling devices are not displayed in the Main Control Room. In addition, a limited number of Category 2 and 3 devices are displayed on local panels if the following guidelines are met:

1. The information displayed is of a non-critical or diagnostic nature.

2. The local panel display is accessible under accident conditions.

3. The information can be retrieved in a time frame necessary to support the operator's action.

4. The parameter changes slowly such that only infrequent updates are needed.

Human factors principles have been used in determining the type and location of the displays. To the extent practical, the same instruments were used for accident monitoring as are used for the normal operations of the plant to enable the operators to use instruments which they are most familiar during accident situations. To the extent practical, monitoring instrumentation is from sensors that directly measure the desired variables. Indirect measurements are made only when it can be shown by analysis to provide equivalent or unambiguous information. The PAM parameters have associated required accident ranges. The minimum required ranges are given in Table 7.5-2. Typically, the range of the instrumentation is sufficient to keep the indication on scale at all times. Where the required range of monitoring instrumentation results in a loss of instrumentation sensitivity or accuracy in the normal operating range by using a single instrument (such as radiation monitors), multiple instruments are used to encompass the entire required range. Where two or more instruments are needed to cover a particular range, overlapping of instrument spans have been provided to ensure one of the two instruments will be on scale at all times.

7.5.2.3.2 Identification

The Category 1 and 2 displays are uniquely identified on the Main Control Board so that the operator can easily discern that they are intended for use under accident conditions. PAM Category 1 display devices have been identified with a nameplate with black background, white letters and the symbol C1 inscribed on the nameplate. PAM Category 2 variable display devices (which are not also PAM Category 1) have been identified with a nameplate with a white background, black letters with the symbol C2 inscribed on its nameplate.

Category 1 indicators are identified on the control diagrams, drawing series 47W610, as P1 and P2 (as well as P3 when a third redundant channel is required) respectively to denote each redundant train of instrumentation.

7.5.3 Analysis

For Condition II, III and IV events sufficient duplication of information is provided to ensure that the minimum information required is available. The information is part of the operational monitoring of the plant which is under surveillance by the operator during normal plant operation. This is functionally arranged on the Main Control Board to provide the operator with a ready understanding and interpretation of plant conditions.

The variables identified in Table 7.5-2 were selected on the basis of sufficiency and availability during and subsequent to an event for which they are necessary.

Redundant Class 1E sensors are provided to develop the necessary information to enable the required manual functions to be performed following a Condition IV event. These sensors are environmentally and seismically qualified.

Range and accuracy requirements are determined through the analysis of Condition II, III or IV events as described in FSAR Chapter 15. The display system meets the following requirements.

a. The range of the readouts extends over the maximum expected range of the variables being measured.

b. The combined indicated accuracies are within the errors used in the safety analysis.

As described throughout FSAR Section 7.5, SQN meets the intent of NRC Regulatory Guide 1.97, R2. Any deviations from the Regulatory Guide have been identified to the NRC (References 3, 4, and 5) and have been accepted by the NRC (References 10 and 11).

Other information systems such as the plant computer are integrated with the PAM instrumentation described in this section. In order to provide the operator adequate information to prevent and/or cope with events, those displays have been included in Human Factors engineering review.

7.5.4 Tests and Inspections

7.5.4.1 Programs

Services, testing and calibration programs are performed on at least an 18 month or refueling outage intervals for category 1 variables to maintain the capability of the monitoring instrumentation with one exception. The category 1 AFW Flow, AFW LCV Position, and SG level variables are calibrated at a frequency in accordance with the Surveillance Frequency Control Program (SFCP). For those instruments where the required interval between testing is less than the normal interval between station shutdowns, a capability for testing during operation is provided. Services, testing and calibration programs for category 2 and 3 variables may exceed the 18 month or refueling outage intervals based on guidance provided within Reference 1.

7.5.4.2 Removal of Channels from Service

Whenever a means for removing channels from service are included in the design, the design facilitates administrative control for such removal. The system is designed to permit at least one channel to remain operable when required during power operation. During service removal, the active parts of the channel need not continue to meet the single failure criteria. As such, monitoring systems comprised of two redundant channels are permitted to violate the single failure criterion during channel bypass. The bypass time interval allowed for category 1 variables is specified in the plant technical specifications.

7.5.4.3 Administrative Control

The design facilitates administrative control of the access to all setpoint adjustments, module calibration adjustments and test points.

TABLE 7.5-1

SUMMARY OF QUALIFICATION CRITERIA
FOR POSTACCIDENT MONITORING

Criteria	Category 1	Category 2	Category 3
Redundancy	Yes	N/A	N/A
EQ	Per 10 CFR 50.49 as described in SQN FSAR Chapter 3	Equipment in harsh environment same as Category 1; N/A for equipment in mild environment	N/A
Seismic	Must function after seismic event as described in Chapter 3	N/A	N/A
QA	Yes - as given in Chapter 17 for safety related devices	Yes - for all items requiring EQ above; No - for the remainder	N/A
Power Supply	Class 1-E as described in Chapter 8	Non-1E instrument power	Non-1E
Physical Separation	Yes - per design basis of the plant	N/A	N/A
Electrical Separation	Yes - Non-1E circuit inter-faces are through qualified isolation devices	N/A	N/A
Indication	Hardwired Indicator	Indicator, computer or indication light	Indicator, computer, indicating light, or alarm
Special Labeling on MCR Board	Yes	Yes	No
Testing and Maintenance	Yes	Yes	Yes
Isolation Device Accessibility	Yes	N/A	N/A
Trending	All analog variables trended on the plant computer are qualified to Category 2 requirements	Recorder or computer Rad monitors and associated instru-ments; N/A for the remainder	Plant computer system for meterological; N/A for the remainder

7.6 ALL OTHER SYSTEMS REQUIRED FOR SAFETY

7.6.1 Instrumentation and Control Vital Power Supply Systems

7.6.1.1 Description

The following is a description of the Instrumentation and Control Vital Power Supply System: (See Chapter 8 for description of Vital Alternating-Current (AC) System)

a. Each unit has four inverters, and four distribution panels. Each inverter is connected independently to one distribution panel.

b. The inverters provide a source of 120V, 60 Hz power for the operation of the nuclear steam supply system instrumentation. This power is derived from the 480V AC, 3Φ, 60 Hz distribution system (preferred power supply), or the station batteries which assure continued operation of instrumentation systems in the event of a station blackout. The inverters have a static switch which automatically transfers between the inverter output and a regulated bypass source in the event of overload or system malfunction. The bypass source is derived from the same 480V source as the inverter.

c. Each of the four distribution panels may be connected to a separate backup source of 120V AC power. Each channel has a spare inverter which can be manually aligned to replace the unit 1 or Unit 2 inverter.

7.6.1.2 Functional Performance Requirements

The functional performance requirements for the Vital Power Supply system are: To supply reliable and continuous regulated single phase AC power to all instrumentation and control equipment required for plant safety.

7.6.1.3 Analysis

There are four independent batteries (plus one spare) and battery chargers. Each battery is attached to a bus serving one inverter per unit plus one spare inverter shared between units. Since not more than one inverter per unit is connected to the same bus, a loss of a single bus can only affect one of the four inverters per unit. In addition, each of the four distribution panels is connected to a different source of backup 120V AC power. Each distribution panel can receive power from the 120V AC backup source under operator control. The inverters have a static switch which automatically transfers between the inverter output and a different regulated bypass source in the event of overload or system malfunction without interrupting power to the load. In addition, each of the four distribution panels can be transferred under operator control to a spare inverter.

Therefore, no single failure in the Instrumentation and Control Vital Power Supply System or its associated power supplies can cause a loss of power to more than one of the redundant loads.

The loss of the inverter’s alternating-current or direct-current inputs are alarmed in the control room, as is the loss of an inverter's output. There are no inverter breaker controls on the control board, as no manual transfers are necessary in the event of loss of the 480V AC preferred power source.

Physical separation and provisions to protect against fire are discussed in Chapter 8 and the Fire Protection Report (see 9.5.1).

Based on the scope definitions presented in Reference 1 (IEEE 308- September, 1971), Reference 2 (IEEE 279-1971), and References 3 (IEEE 338-1971), the criteria which are applicable to the Instrumentation and Control Vital Power Supply System are IEEE 308-Sept., 1971 and Regulatory Guide 1.6 (March, 1971). Availability of this system is continuously indicated by the operational status of the system and is verified by periodic testing as discussed in sections 8.3.1.1 and 8.3.2.1.

7.6.2 Residual Heat Removal Isolation Valves

7.6.2.1 Description

There are two motor-operated gate valves as shown in Figure 5.5.7-1 in series in the inlet line from the Reactor Coolant System to the Residual Heat Removal System. They are normally closed and are only opened for residual heat removal after Reactor Coolant System pressure and system temperature has been reduced to acceptable levels. (See Chapter 5 for details of the Residual Heat Removal System). They are the same type of valve and motor operator as those used for accumulator isolation, but they differ in their controls and indications in the following respect:

The pump suction isolation valve adjoining the Reactor Coolant System is interlocked with a pressure signal to prevent it from opening whenever the system pressure is greater than the acceptable level. There are also interlocks which prevent the valve from opening unless the RWST suction valve and containment sump isolation valve are fully closed. During normal plant operation, power is removed from the valve control circuit to prevent inadvertent opening of the valve. Valve status indication is provided at the control switch on the Main Control Board at all times. The other pump suction isolation valve, adjoining the Residual Heat Removal System, is similarly interlocked to prevent opening whenever the system pressure is greater than the acceptable level.

When aligning for residual heat removal operations, power is restored to the valve and it is opened from the control switch on the Main Control Board. Annunciation to warn against RHR system overpressurization is provided to the operator by a high RHR suction pressure alarm. This alarm is actuated from any one of two pressure switches located on the RHR common header suction piping.

Additional overpressure protection is provided by an RHR suction valve misalignment logic that will also actuate the Main Control Room high suction pressure alarm. This logic will actuate the alarm whenever one of the two suction valves is moved from its closed seat while the other valve remains closed. This will provide the alarm to alert a misalignment but will not provide a nuisance alarm when both valves are opened for RHR operation.

7.6.2.2 Analysis

Based on the scope definitions presented in Reference 2 (IEEE 279-1971) and Reference 3 (IEEE-338, 1971), these criteria do not apply to the Residual Heat Removal Isolation Valve interlocks; however, in order to meet NRC requirements and because of the possible severity of

the consequences of loss of function, the requirements of IEEE-279 will be applied with the following comments.

1. For the purpose of applying IEEE 279-1971, to this circuit, the following definitions will be used.

   a. Protection System

      The two valves in series and all components of their open interlocking.

      Utilization of operator action in response to the high suction pressure/suction valve position - mismatch alarm is based upon the Westinghouse generic analysis described in WCAP-11736 as confirmed by a comparison analysis of Sequoyah as documented in Calculation SQN-SQS2-0097.

   b. Protective Action

      The manual initiation and maintenance of Residual Heat Removal System isolation from the Reactor Coolant System for Reactor Coolant System pressures above residual heat removal design pressure.

2. IEEE-279, Paragraph 4.10: The requirement for on-line test and calibration capability is applicable only to the actuation signal (pressure channel from P403 in Process Protection Set II and pressure channel from P405 in Process Protection Set III) and not to the isolation valves, which are required to remain closed during power operation.

3. IEEE-279, Paragraph 4.15: This requirement does not apply, as the setpoints are independent of mode of operation and are not changed.

Environmental qualification of the valves and wiring are discussed in Section 3.11.

7.6.3 Refueling Interlocks

A functional description of the refueling system equipment covered in Section 9.1 includes a discussion of the interlocks which are provided on the refueling equipment to prevent damage to the fuel assemblies. Although there are no electrical interlocks associated with the spent fuel bridge and the fuel handling tools, there are electrical interlocks employed by the manipulator crane and the fuel transfer system.

The following are the electrical interlock functions on the manipulator crane: (Although these interlocks are not specifically designed to meet IEEE 279-1971 (Reference 2), the following discussions considers the compliance of the electrical interlocks with the provisions of individual sections of IEEE 279).

1. Electrical movement of the bridge or trolley is permissible only when the fuel is withdrawn completely into the outer mast. Two position indicating switches wired in series for the fuel withdrawn interlock are provided. When the gripper is disengaged (no fuel), the redundant switches are bypassed, and bridge or trolley movement is permitted.

2. The solenoid valve cuts off air to the operating cylinder gripper except when the weight indicator shows there is no fuel assembly suspended from the gripper. This is to prevent the operator from opening the gripper and dropping the fuel. An independent mechanical locking device as redundant protection for the associated interlock is provided.

3. The hoist electric drive is operable only when the gripper position switches show that the gripper is either fully engaged or disengaged. This interlock is to prevent a fuel assembly from being lifted if the gripper has hung up in a partially engaged position. A monitoring circuit to notify the operator of failure of the associated interlock circuit is provided.

4. Hoist electric drive in the up direction is prevented if the primary load cell indicates an excessive load. This interlock protects the fuel assembly from excessive loading if it becomes hung up during withdrawal. The primary load cell which can be bypassed is backed up by a second excessive weight switch (set above the primary) that is completely independent of the primary circuit and cannot be bypassed. This meets the single failure criteria of Section 4.2 of IEEE 279-1971 Standard. The primary load cell does have a scale change switch that is accessible to the operator. Both interlocking functions of the load cell (one involving the hoist drive in the up direction and the other cutting off air to the operating cylinder gripper) have redundant back up, one back up being a mechanical locking device for the solenoid valve, and the other back up being a switch which cannot be bypassed for the load cell.

For all the above four interlock functions associated with the manipulator crane the appropriate provisions required by sections 4.13 (Indication of Bypass) and 4.14 (Access to Means of Bypass) of IEEE 279 are specified.

5. The bridge, trolley, and hoist are mutually interlocked to prevent operation of more than one mode at a time. This interlock function is not considered safety-related because, although it is not good practice to do so, it is not necessarily hazardous to operate more than one mode at a time.

6. The bridge and trolley drives are interlocked to prevent movement that could cause collision of the mast with the guide studs, stored internals or walls. This interlock function is not considered safety-related because the consequences of failure would not cause damage to a fuel assembly in the machine. The fuel assembly is carried inside the outer mast which is a 16 inch O.D., 3/4 inch wall pipe.

The following are the electrical interlock functions on the fuel transfer system:

1. Both lifting frames must be in the horizontal position before the conveyor car can be moved.

2. The conveyor car must be against its travel limit stops before the lifting frames can be operated. This interlock is to make sure the fuel container on the conveyor car, is properly positioned before an attempt is made to raise it.

3. The manipulator crane must be over the core or the gripper must be at the top stop position before the lifting frame can be operated. This interlock is to prevent the operator from lowering the transfer system fuel container while the manipulator crane is in the process of inserting or removing a fuel assembly.

For the above interlock functions associated with the Fuel Transfer System, the appropriate provisions required by section 4.14 of IEEE 279 are specified.

7.6.4 DELETED BY AMENDMENT 8

7.6.5 Loose Part Detection System (LPDS)

System Description

The Loose Part Detection System consists of sensors capable of detecting acoustic disturbances within the reactor coolant pressure boundary, associated cabling, amplifiers, and a data acquisition system. Two sensors are located at each natural collection region on the exterior surface of the reactor coolant boundary (e.g., reactor vessel upper and lower plenum and each of the steam generator reactor coolant inlet plenums). Should a sensor or sensor channel fail at one of these natural collection regions, the failed sensor or channel can be removed from service with the remaining sensor or channel providing loose part monitoring coverage for that area. The online sensitivity of the system is capable of detecting a metallic loose part that weighs from 0.25 to 30 lbs. and impacts with a kinetic energy of 0.5 ft-lb on the inside surface of the reactor coolant pressure boundary within 3 feet of a sensor.

The data acquisition portion of the system has an automatic and a manual mode of operation. The manual mode allows users to view system operation, to set alarm discrimination parameters, and to perform diagnostic tests. The automatic mode provides continuous monitoring for loose part events, displays real time system status, and the ability to record raw data for later analysis. The automatic mode also provides filtering to prevent false loose part alarms. The system also allows for manual inhibiting of a channel's alarm functions.

The LPDS is capable of performing its function following all seismic events, up to and including the Operating Basis Earthquake (OBE), that do not require plant shutdown. While recording equipment may not function without maintenance following the seismic event, the audio or visual alarm capability will remain functional. Portions of the system located within containment are compatible with the operating environment and consistent with minimum maintenance requirements and low-failure rates.

7.6.6 Spurious Actuation Protection for Motor Operated Valves

The design of Sequoyah Nuclear Plant is such that the failure of any single valve to operate on demand cannot result in the loss of capability to perform a system safety function. However, in the case of possible inadvertent valve misalignment, the following motor operated valves have been identified as valves whose spurious operation could result in the loss of a system safety function.

FCV 63-1	FCV 63-67	FCV 63-98
FCV 63-3	FCV 63-72	FCV 63-118
FCV 63-5	FCV 63-73	FCV 63-156
FCV 63-8	FCV 63-80	FCV 63-157
FCV 63-11	FCV 63-93	FCV 63-172
FCV 63-22	FCV 63-94	

Means have been provided to preclude such spurious misalignment. The design consists of modified control circuits for these valves to ensure that no single failure will be able to energize

the opening or closing coils for the valve operator. The design utilizes contacts which are wired before and after each opening and closing coil. Figure 7.6.6-1 is a typical schematic, isolation of the opening and closing coils is provided by contacts R11-R12, R21-R22, L21-L22, and L31-L32.

In addition, single failure has been considered on the part of the operator. For FCV-63-1, 22, 67, 80, 98, and 118 operating instructions specify the removal of valve actuator power during normal operation. After removal of power, valve position indication is still provided to the operator (from a separate control power circuit). The design for the remaining valves includes easy access, clear protective covers attached to the main control board panel over each respective control room switch. The operator would be required to open this protective cover before he operates the control switch.

7.6.7 Interlocks for RCS Pressure Control During Low Temperature Operation

The basic function of the RCS overpressure mitigation system during low temperature operation is discussed in Section 5.2.2.4. The function of this actuation logic is to continuously monitor RCS temperature and pressure conditions when the actuation logic is manually unblocked at a temperature below the arming setpoint. The monitored system temperature signals are processed to generate the reference pressure limit program which is compared to the actual measured system pressure. This comparison will provide an actuation signal to cause the PORV to automatically open if necessary to prevent pressure conditions from exceeding allowable limits. See Figure 7.6.7-1 for the block diagram showing the interlocks for RCS pressure control during low temperature operation.

As shown on this figure, the station variables required for this interlock are channelized as follows:

1. Protection Set I

   a. Wide Range RCS Temperature from Hot Legs and Cold Legs.

2. Protection Set II

   a. Wide Range RCS Temperature from Hot Legs and Cold Legs.

3. Protection Set III

   a. Wide Range RCS System Pressure.

4. Non-Divisional

   a. Wide Range RCS System Pressure.

The wide range temperature signals, as inputs to the Low Temperature Over Pressure System (LTOPS) contained within the plant Distributed Control System (DCS) in Processing Groups 12 and 13, continuously monitor RCS temperature conditions. Whenever plant operation is at a temperature below the arming setpoint and the system is manually armed, LTOPS provides RCS overpressure protection. In Protection Set I, the RCS hot leg and cold leg wide range temperature channels supply through an isolation device continuous analog input to DCS auctioneering logic, which is located in the DCS Processing Group 13. The lowest reading will be selected and input to a function generator which calculates the reference limit program considering the plant's allowable pressure and temperature limits. Also available from Protection Set III is the wide range RCS system pressure signal which is sent through an isolation device to DCS Processing Group 13. The reference pressure from the DCS function generator is compared to the actual RCS system pressure monitored by the wide range pressure channel.

The error signal derived from the difference between the reference pressure and the actual measured pressure will first annunciate a main control board alarm whenever the actual measured pressure approaches, within a predetermined amount, the reference pressure. On a further increase in measured pressure, the error signal will generate an annunciated actuation signal. The actuation signal available from Processing Group 13 will control the Train A PORV whenever the system is manually armed. Above this manual interlock, the normal pressure protection system (as discussed in Section 5.2) ensures that the system pressure temperature limitations are not exceeded. This manual interlock prevents unnecessary system actuation at normal RCS operating conditions as a result of a failure in the process sensors.

The monitored generating station variables that generate the actuation signal for the Train B PORV are processed in a similar manner. In the case of the Train B PORV, the reference temperature is generated in DCS Processing Group 12 from the lowest auctioneered wide range hot leg and cold leg temperature. The auctioneering device derives its inputs from the RCS wide range temperature in Protection Set II and the actual measured pressure signal is available from a non-divisional transmitter. Therefore, the generating station variables used for the Train B PORV are derived from a source that is independent of the Sets from which generating station variables used for the Train A PORV are derived. The error signal derivation itself used for the actuation signals is available from the Processing Group 13.

Upon manual arming and receipt of the actuation signal, the actuation device will automatically cause the PORV to open. Upon sufficient RCS inventory letdown, the operating RCS pressure will decrease, clearing the actuation signal. Removal of this signal causes the PORV to close.

7.6.7.1 Analysis of Interlocks

Many criteria presented in IEEE 279-1971 and IEEE 338-1971 standards do not apply to the interlocks for RCS pressure control during low temperature operation because the interlocks do not perform a protective function but rather provide automatic pressure control at low temperatures as a backup to the operator. However, although IEEE-279 criteria do not apply, some advantages of the dependability and benefits of an IEEE-Std-279 design have occurred by including the pressure (A train only) and temperature signal elements as noted above in the Protection Sets and by organizing the control of the two PORVs into dual channels wherever practical. Either of the two PORVs can accomplish the RCS pressure control function.

The design of the low temperature interlocks for RCS pressure control is such that pertinent features include:

1. No credible failure at the output of the protection set racks, after the output leaves the racks to interface with the interlocks, will prevent the associated protection system channel from performing its protective function because such outputs that leave the racks go through an isolation device as shown in Figure 7.6.7-1.

2. Testing capability for elements of the interlocks within (not external to) the overpressure mitigation system is consistent with the testing principles and methods discussed in Section 7.2.2.2.3.

3. A loss of offsite power will not defeat the provisions for an electrical power source for the interlocks because these provisions are through onsite power which is described in Sections 8.3 and 7.6.1.

7.6.8 Liquid Level Monitoring Systems

Two types of level measurement systems used inside containment are described below along with the particular application:

7.6.8.1 Steam Generator Water Level Instrumentation

An open column reference leg is used for steam generator (SG) level measurement. The instrument is connected to the SG process by a condensate chamber at the upper tap. The liquid in the reference leg will be at essentially ambient temperature.

Steam Generator Narrow Range Water Level Safety Functions

- Turbine trip and feedwater isolation on high-high steam generator water level
- Reactor trip on low-low steam generator water level
- Auxiliary feedwater pump initiation on low-low steam generator water level
- Post-accident monitoring function
- SG level control for AFW following an accident

Steam Generator Wide Range Water Level Safety Function

- Post-accident monitoring function

7.6.8.2 Pressurizer Water Level Instrumentation

A sealed reference leg is used for pressurizer level measurement. For additional information, see Section 7.2.1.1.5 and 7.2.2.3.4.

Pressurizer Water Level Safety Function

- Reactor trip on high water level
- Post-accident monitoring function

7.6.9 Switchover from S.I. to Recirculation Following LOCA

For the discussion on switchover from the S.I. mode to the recirculation mode, refer to Section 6.3.2.2, and for the switchover logic functions, see Figure 7.6.9-1.

7.6.10 In-core Instrumentation - Thermocouples

The In-core Thermocouple System provides information on the core outlet temperatures at selected core locations.

The thermocouple installation is discussed in section 4.2 and 4.4.

Thermocouple readings are monitored by redundant microprocessors which also monitor reactor coolant wide-range temperature and pressure. The microprocessors output the following information:

1. In-core reactor temperature
2. Wide range reactor coolant temperature
3. Wide range reactor coolant pressure
4. Saturation or subcooling margin of the reactor coolant in °F based on hottest in-core temperature, hottest RCS hot-leg temperature or average of all in-core temperatures.

The microprocessors output this information to the redundant control room indicators and recorders and Items 1-3 above to the Plant Computer System.

7.7 CONTROL SYSTEMS NOT REQUIRED FOR SAFETY

Much of the Plant Control System is contained within the Plant Distributed Control System (DCS).

The general design objectives of the Plant Control Systems (PCS) are:

1. To establish and maintain power equilibrium between primary and secondary system during steady-state unit operation.

2. To constrain operational transients so as to preclude unit trip and reestablish steady-state unit operation.

3. To provide the reactor operator with monitoring instrumentation that indicates all required input and output control parameters of the systems and provides the operator the capability of assuming manual control of the system.

7.7.1 Description

The PCS described in this section perform the following functions:

1. Reactor Control System

   a. Enables the nuclear plant to accept a step load increase or decrease of 10 percent and a ramp increase or decrease of 5 percent per minute within the load range of 15 percent to 100 percent without reactor trip, steam dump, or pressurizer relief actuation subject to possible xenon limitations.

   b. Maintains reactor coolant average temperature T_{avg} within prescribed limits by creating the bank demand signals for moving groups of full length rod cluster control assemblies during normal operation and for operational transients. The T_{avg} control also supplies a signal to pressurizer level control, and steam dump control.

2. Rod Control System

   a. Provides for reactor power modulation by manual or automatic control of full-length control rod banks in a preselected sequence and for manual operation of individual banks.

   b. Systems for Monitoring and Indicating

      (1) Provide alarms to alert the operator if the required core reactivity shutdown margin is not available due to excessive control rod insertion.

      (2) Display control rod position.

      (3) Provide alarms to alert the operator in the event of control rod deviation exceeding a preset limit.

3. Plant Control System Interlocks

   a. Prevent further withdrawal of the control banks when signal limits are approached that predict the approach of a DNBR limit or kW/ft limit.

b. Inhibit automatic turbine load change as required by the Nuclear Steam Supply System.

4. Pressurizer Pressure Control

a. Maintains or restores the pressurizer pressure to the design pressure $\pm$ 35 lb/in^2 (which is well within reactor trip and relief and safety valve actuation setpoint limits) following normal operational transients that induce pressure changes by control (manual or automatic) of heaters and spray in the pressurizer. Also provides steam relief by controlling the power relief valves.

5. Pressurizer Water Level Control

a. Establishes, maintains, and restores pressurizer water level within specified limits as a function of the average coolant temperature. Changes in level are caused by coolant density changes induced by loading, operational, and unloading transients. Level changes are provided by means of charging flow control (manual or automatic). Maintaining coolant level in the pressurizer within prescribed limits by actuating the charging system and/or isolating the letdown system thus provides control of the reactor coolant water inventory.

6. Steam Generator Water Level Control

a. Establishes and maintains the steam generator water level to within predetermined physical limits during normal operating transients.

b. Restores the steam generator water level to within predetermined limits at unit trip conditions. Regulates the feedwater flow rate such that under operational transients the heat sink for the Reactor Coolant System does not decrease below a minimum. Steam generator water inventory control is manual or automatic through use of feedwater control valves.

7. Steam Dump Control

a. In conjunction with the Rod Control System, permits the nuclear plant to accept a sudden 50 percent loss of net load without incurring reactor trip. Steam is dumped to the condenser as necessary to accommodate excess power generation in the reactor during turbine load reduction transients.

b. Provides the capability to remove stored energy and residual heat following a reactor trip to bring the plant to equilibrium no load conditions without actuation of the steam generator safety valves.

c. Maintains the plant at no load conditions and permit a manually controlled cooldown of the plant.

8. In-Core Instrumentation

Provides information on the neutron flux distribution.

7.7.1.1 Reactor Control System

The Reactor Control System enables the nuclear plant to make load changes automatically including the acceptance of step load increase or decrease of 10 percent and ramp increase or decrease of 5 percent per minute within the load range of 15 percent to 100 percent without reactor trip, steam dump, or pressure relief - subject to possible xenon limitations. The system is also capable of restoring coolant average temperature to within the programmed temperature deadband following a change in load. Manual control rod operation may also be performed.

The Reactor Control System controls the reactor coolant average temperature by regulation of control rod bank position. The reactor coolant loop average temperatures are determined from hotleg and coldleg measurements in each reactor coolant loop. There is an average coolant temperature (T_{avg}) computed for each loop, where:

$$T_{avg} = \frac{Thot + Tcold}{2}$$

The error between the programmed reference temperature (based on turbine impulse chamber pressure) and the highest of the average measured temperatures (which is processed through a lead-lag compensation unit (contained within the DCS)) from each of the reactor coolant loops constitutes the primary control signal as shown in general on Figure 7.7.1-1 and in more detail on the functional diagrams shown in Figure 7.2.1-1 Sheet 9. The system is capable of restoring coolant average temperature to the programmed value following a change in load. The programmed coolant temperature increases linearly with turbine load from zero power to the full power condition. The T_{avg} also supplies a signal to pressurizer level control and steam dump control and rod insertion limit monitoring.

An additional control input signal is derived from the reactor power versus turbine load mismatch signal. This additional control input signal improves system performance by enhancing response and reducing transient peaks.

7.7.1.2 Rod Control System

7.7.1.2.1 Full Length Rod Control System

The shutdown banks are always in the fully withdrawn position during normal operation, and are moved to this position at a constant speed by manual control prior to criticality. A reactor trip signal causes them to fall by gravity into the core. There are four shutdown banks.

The control banks are the only rods that can be manipulated under automatic control. Each control bank is divided into two groups to obtain smaller incremental reactivity changes per step. All rod control cluster assemblies in a group are electrically paralleled to move simultaneously. There is individual position indication for each rod cluster control assembly.

When the turbine load reaches approximately 15 percent of rated load, the operator may select the "AUTOMATIC" mode, and control rod motion is then controlled by the reactor control systems. A permissive interlock C-5 (see Table 7.7.1-1) derived from measurements of turbine impulse chamber pressure prevents automatic control when total turbine load is below

15 percent. In the "AUTOMATIC" mode, the rods are withdrawn (or inserted) in a predetermined programmed sequence by the automatic programming equipment. The manual and automatic controls are further interlocked with the control interlocks (see Table 7.7.1-1).

The full length Rod Control System receives rod speed and direction signals from the T_{avg} control system (contained within the DCS). The automatic rod speed demand signal varies over the corresponding range of 5 to 45 inches per minute (8 to 72 steps/minute) depending on the magnitude of the error signal. The rod direction demand signal is determined by the positive or negative value of the error signal. Manual control is provided to move a control bank in or out at a prescribed fixed speed.

Power to rod drive mechanisms is supplied by two motor generator sets operating from two separate 480 volt, 3-phase buses. Each generator is the synchronous type and is driven by a 150-horsepower induction motor. The alternating current power is distributed to the rod control power cabinets through the two series connected reactor trip breakers. A detailed discussion of the electrical power distribution is contained in Reference 3.

The variable speed full length rod control system rod drive programmer affords the ability to insert small amounts of reactivity at low speed to accomplish fine control of reactor coolant average temperature about a small temperature deadband, in addition to coarse control at high speed. A summary of the rod cluster control assembly sequencing characteristics is given below.

1. Two groups within the same bank are stepped such that the relative position of the groups will not differ by more than one step.

2. The control banks are programmed such that withdrawal of the banks is sequenced and overlapped in the following order: Control Bank A, Control Bank B, Control Bank C, and then Control Bank D. The programmed insertion sequence is the opposite of the withdrawal sequence, i.e., the last control bank withdrawn (Bank D) is the first control bank inserted.

3. The control bank withdrawals are programmed such that when the first bank reaches a preset position, the second bank begins to move out simultaneously with the first bank (e.g., overlap). When the first bank reaches the top of the core, it stops, while the second bank continues to move toward its fully withdrawn position. When the second bank reaches a preset position, the third bank begins to move out, and so on. This withdrawal sequence continues until the unit reaches the desired power level. The control bank insertion sequence is the opposite.

4. Overlap between successive control banks is adjustable between 0 to 50 percent (0 and 115 steps), with an accuracy of $\pm$ 1 step.

7.7.1.2.2 Part Length Rod Control System

Part length control rods are not installed in the Sequoyah Nuclear Plant.

7.7.1.3 Plant Control Signals for Monitoring and Indicating

7.7.1.3.1 Monitoring Functions Provided by the Nuclear Instrumentation System

The power range channels are important because of their use in monitoring power distribution in the core and verifying it is within specified safe limits. They are used to measure reactor power level, axial power imbalance, and radial power imbalance. Suitable alarms are derived from these signals as will be described below. Basic power range signals are:

1. Total current from a power range detector (four signals from separate detectors); these detectors are vertical and have an active length of 10 feet.

2. Current from the upper half of each power range detector (four signals).

3. Current from the lower half of each power range detector (four signals).

Derived from these basic signals are the following (including standard signal processing for calibration):

4. Indicated nuclear flux (four).

5. Indicated axial flux imbalance, derived from upper half flux minus lower half flux (four).

Alarm functions derived are as follows:

6. Deviation (maximum minus minimum of four) in indicated nuclear power.

7. Upper radial tilt (maximum to average of four) on upper-half currents.

8. Lower radial tilt (maximum to average of four) on lower-half currents.

Provision is made to continuously record, on strip charts on the control board, the 8 ion chamber signals, i.e., upper and lower currents for each detector. Nuclear power and axial unbalance is selectable for recording as well. Indicators are provided on the control board for nuclear power and for axial power imbalance.

A comprehensive discussion of the Nuclear Instrumentation System can be found in Reference 2.

7.7.1.3.2 Rod Position Monitoring of Full Length Rods

Two separate systems are provided to sense and display control rod position as described below:

1. Analog Rod Position Indication System (RPIS)

   Analog System - An analog signal is produced for each rod cluster control assembly by a linear variable transformer.

   Direct continuous readout of every rod cluster control assembly position is presented to the operator by individual meter indications without need for operator selection or switching to determine rod position. A rod bottom (rod drop) alarm is provided.

Unit Operation With an Inoperable RPIS Indicator

The malfunction of an indicator in the RPIS is addressed by controls established in the technical specifications. The controls include requirements to use the moveable incore detectors to verify the position of the affected rod whenever an indicator is inoperable. This action may be periodically repeated for the duration of the period the indicator is inoperable. A second action is available in the technical specifications to address the malfunction of an indicator for an extended period of time (referred to as the extended action in this discussion). The options provided by the extended action allows for continued operation in a situation where the component causing the indicator to be inoperable is inaccessible due to operating conditions (adverse radiological or temperature environment). In this situation, repair of the indicator cannot occur until the unit is in an operating mode that allows access to the failed components. The primary purpose for this option is to prevent unnecessary wear on the incore detectors due to repeated use over an extended period.

Implementation of the extended action involves the monitoring of test points associated with the control rod drive mechanism affected by the inoperable indicator. During the use of the extended action signal cables are connected to the control rod drive mechanism circuitry test points on a temporary basis to monitor the operation and timing of the lift coil and the stationary gripper coil to provide the instrumentation for the monitoring of the position of the affected rod in the MCR.

A variation of the extended action exists for shutdown rods with an Inoperable RPIS Indicator. This is because there is different monitoring criteria and operational function for a shutdown rod vs. a control rod. A shutdown bank has no automatic reactivity control function other than the ability to insert into the core from an automatic signal from SSPS and is only moved manually during periodic rod movement verification surveillances, and during plant startup and shutdown. This manual movement is considered intended rod movement, and not unintended rod movement. During normal plant operation, when the shutdown banks are withdrawn and not manually being moved, monitoring of test points for stationary gripper voltage displayed in the MCR for the affected rod is sufficient to determine whether unintended rod movement has occurred (i.e. loss of power to gripper). As a conservative measure, to further ensure unintended rod motion is not possible, the lift coil disconnect switch will be administratively controlled in the open position for the affected rod. It is not considered necessary to monitor the lift coil and various rod motion timing sequences, since these are associated with intended manual movement of the shutdown rods.

2. Demand Position Indication System (DPIS)

   The DPIS counts pulses generated in the Rod Drive Control System to provide a readout of the demanded bank position.

   The DPI and RPI Systems are separate systems; each serves as backup for the other. Operating procedures require the reactor operator to compare the demand and (actual) readings upon recognition of any apparent malfunction. Therefore, a single failure in rod position indication does not in itself lead the operator to take erroneous action in the operation of the reactor.

The DPIS is described in detail in Reference 4.

7.7.1.3.3 Control Bank Rod Insertion Monitoring

When the reactor is critical, the normal indication of reactivity status in the core is the position of the control bank in relation to reactor power (as indicated by the Reactor Coolant System ΔT) and coolant average temperature. Control bank rod insertion limits (RIL) maintain sufficient shutdown margin and provide a limit on the maximum inserted rod worth in the unlikely event of a hypothetical rod ejection, and limits rod insertion such that acceptable nuclear peaking factors are maintained. The rod insertion limits for each control rod bank are documented in the Core Operating Limits Report (COLR).

1. The "low" alarm alerts the operator of control rod bank RIL.

2. The "low-low" alarm alerts the operator a control rod bank has reached the RIL.

The purpose of the control bank rod insertion monitor (contained within the DCS) is to give warning to the operator of excessive rod insertion. The low alarm activates prior to the control bank reaching the rod insertion limit. Operators take action to address the excessive rod insertion and restore shutdown margin. The low-low alarm activates when the control rod bank has reached the RIL. Operators take action to restore margin and ensure Control Bank Insertion Limits Technical Specification requirements are met.

An upper limit is applied to the low and low-low control rod bank insertion alarms to limit nuisance alarms. The upper limit is set above the control bank D RIL at full power, ensuring the control bank D alarm input activates the control rod bank insertion alarms throughout the full range of power.

Since the amount of shutdown reactivity required for the design shutdown margin following a reactor trip increases with increasing power, the allowable rod insertion limit position increases (rods are withdrawn further) with increasing power. Two parameters which are proportional to power are used as inputs to the control bank rod insertion monitor: the ΔT between the hot leg and the cold leg, which is a direct function of reactor power; and T_{avg}, which is programmed as a function of power. The control bank rod insertion monitor calculates the RIL and the alarms for each control rod bank as follows:

$$\mathrm{Z_{RIL}} = \mathrm{K_1}\ (\Delta T)_{auct} + \mathrm{K_2}(T_{avg})_{auct} + \mathrm{K_3}$$

Where

Z_{RIL}	=	Rod insertion limit for affected control bank
$(\Delta T)_{auct}$	=	Highest ΔT of all loops
$(T_{avg})_{auct}$	=	Highest T_{avg} of all loops
K_1, K_2, K_3	=	Constants set to calculate Z_{RIL} in accordance with the COLR RIL

Below the upper limit, the control rod bank demand position (Z) is compared to Z_{RIL} as follows:

If $\mathrm{Z} = \mathrm{Z_{RIL}} + \mathrm{K_4}$ a low alarm is actuated (K_4 is the alarm margin to RIL)

If $\mathrm{Z} = \mathrm{Z_{RIL}}$ a low - low alarm is actuated

Since the highest values of T_{avg} and ΔT are chosen by auctioneering, a conservatively high representation of power is used in the control rod bank insertion limit calculation.

Figure 7.7.1-2 shows a block diagram representation of the control rod bank insertion monitor and alarms. The monitor is shown in more detail on the functional diagrams shown in Figure 7.2.1-1, Sheet 9. In addition to the rod insertion monitor for the control banks, an alarm system is provided to warn the operator if any shutdown rod cluster control assembly leaves the fully withdrawn position.

Rod insertion limits are established by:

1. Establishing the allowed rod reactivity insertion at full power consistent with the purposes given above.

2. Establishing the differential reactivity worth of the control rods when moved in normal sequence.

3. Establishing the change in reactivity with power level by relating power level to rod position.

4. Linearizing the resultant limit curve. All key nuclear parameters in this procedure are measured as part of the initial and periodic physics testing program.

Any unexpected change in the position of the control bank under automatic control, or a change in coolant temperature under manual control, provides a direct and immediate indication of a change in the reactivity status of the reactor. In addition, samples are taken periodically of coolant boron concentration. Variations in concentration during core life provide an additional check on the reactivity status of the reactor, including core depletion.

7.7.1.3.4 Rod Deviation Alarm

The demanded and measured rod position signals are displayed on the control board. They are also monitored by the plant computer which provides an audible alarm whenever an individual rod position signal deviates from the other rods in the bank by a preset limit. The alarm is set in accordance with plant technical specifications.

Figure 7.7.1-3 is a block diagram of the rod deviation comparator and alarm system.

7.7.1.3.5 Rod Bottom Alarm

A rod bottom signal for the full-length rods bistable in the analog RPIS as described in Reference 4 generates the "ROD BOTTOM ROD DROP" alarm.

7.7.1.4 Plant Control System Interlocks

The listing of the Plant Control System Interlocks, along with the description of their derivations and functions, is presented in Table 7.7.1-1. It is noted that the designation numbers for these interlocks are preceded by "C". The development of these logic functions is shown in the functional diagrams (Figure 7.2.1-1, Sheets 9 to 16).

7.7.1.4.1 Rod Stops

Rod stops are provided to prevent abnormal power conditions which could result from excessive control rod withdrawal initiated by either a control system malfunction or operator violation of administrative procedures.

Rod stops are the C_1, C_2, C_3, C_4, and C_5 control interlocks identified in Table 7.7.1-1. The C_3 rod stop derived from over-temperature ΔT and the C_4 rod stop, derived from overpower ΔT are also used for turbine runback, which is discussed below.

7.7.1.4.2 Automatic Turbine Load Runback

Automatic turbine load runback is initiated by an approach to an overpower or overtemperature condition. This will prevent high power operation that might lead to an undesirable condition which, if reached, will be protected by reactor trip.

Turbine load reduction is initiated by either an overtemperature or overpower ΔT signal. Two out of four coincidence logic is used.

Inhibit relays are included in the C_3 and C_4 interlock control circuits to prevent turbine runback in the event of a loss of 120V AC Vital Power to the Overtemperature Delta T or Overpower Delta T separation relays.

A rod stop and turbine runback are initiated when

$$\Delta T > \Delta T_{rod\ stop}$$

for both the overtemperature and the overpower condition.

For either condition in general

$$\Delta T_{rod\ stop} = \Delta T_{setpoint} - B_p$$

where

B_p= a setpoint bias

where ΔT setpoint refers to the overtemperature ΔT reactor trip value and the overpower ΔT reactor trip value for the two conditions.

The turbine runback is repeated until ΔT is equal to or less than $\Delta T_{rod\ stop}$.

This function serves to maintain an essentially constant margin to trip.

7.7.1.5 Pressurizer Pressure Control

The Reactor Coolant System pressure is controlled by using either the heaters (in the water region) or the spray (in the steam region of the pressurizer) plus steam relief for large transients. The electrical immersion heaters are located near the bottom of the pressurizer. A portion of the heater group is proportionally controlled to correct small pressure variations. These variations are due to heat losses, including heat losses due to a small continuous spray. The remaining (backup) heaters are turned on when the pressurizer pressure-controlled signal demands approximately 100 percent proportional heater power. Pressurizer Pressure Control is contained within the plant Distributed Control System (DCS).

The spray nozzles are located on the top of the pressurizer. Spray is initiated when the pressure-controlled spray demand signal is above a given setpoint. The spray rate increases proportionally with increasing spray demand signal until it reaches a maximum value.

Steam condensed by the spray reduces the pressurizer pressure. A small continuous spray is normally maintained to reduce thermal stresses and thermal shock and to help maintain uniform water chemistry and temperature in the pressurizer.

Power relief valves limit system pressure for large positive pressure transients. In the event of a large load reduction, not exceeding the design plant load rejection capability, the pressurizer power-operated relief valves might be actuated for the most adverse conditions, e.g., the most negative Doppler coefficient, and the minimum incremental rod worth. The relief capacity of the power-operated relief valves is sized large enough to limit the system pressure to prevent actuation of high pressure reactor trip for the above condition. See Figure 7.2.1-1 sheet 11.

7.7.1.6 Pressurizer Water Level Control

The pressurizer operates by maintaining a steam cushion over the reactor coolant. As the density of the reactor coolant changes due to changes in reactor coolant temperature, the steam water interface moves to absorb the variations with relatively small pressure disturbances.

The water inventory in the Reactor Coolant System is maintained by the Chemical and Volume Control System. During normal plant operation, the charging flow varies to produce the flow demanded by the pressurizer water level controller (contained within the DCS). The pressurizer water level is programmed as a function of coolant average temperature, with the highest average temperature being used.

The pressurizer water level decreases as the load is reduced from full load. This is a result of coolant contraction following programmed coolant temperature reduction from full power to low power. The programmed level is designed to match as nearly as possible the level changes resulting from the coolant temperature changes. A block diagram of the Pressurizer Water Level Control System is shown on Figure 7.2.1-1 sheet 11.

To permit manual control of pressurizer water level during startup and shutdown operations, the charging flow can be manually regulated from the main control room.

7.7.1.7 Steam Generator Water Level Control

Each steam generator is equipped with a three-element feedwater flow control system which maintains a programmed water level which is a function of turbine load. The three-element Feedwater Control (FWC) System regulates the feedwater valve by continuously comparing the feedwater flow signal, the water level signal, the programmed level, and the pressure compensated steam flow signal.

The steam generator water level signal provided to the feedwater control system is derived from a median signal selector in the Feedwater DCS (Distributed Control System) which accepts the three narrow range level signal inputs for each steam generator and selects the median signal. Upon failure of one level channel, the average of the remaining two is used for control.

For the feedwater flow input signals, the two feedwater flow channels for each feedwater line are used to develop an average to control its respective feedwater regulating valve. The average of the other feedwater flows to the other steam generators is used as a “voter” so that should one of the feedwater flow channels fail, the voter signal would cause the control system to select the remaining channel that is closest to the voter signal value for continued automatic control. The system will alarm indicating the channel had failed. The voter signal only helps in determining the signal health between the two individual feedwater flow channels for a particular steam generator and is not the control signal.

For the steam flow input signals, the two steam flow channels for each steam line are used to develop an average steam flow signal to control its respective feedwater control valve. The average of the other steam generator's feedwater flows (the same "voter" signal used for FW flows describe above) is also used as a voter so that should one steam flow channel signal fail outside a predetermined limit, that signal quality is set to BAD, and the remaining steam flow channel alone would be used in the FW regulating valve control. An alarm would annunciate indicating that the steam flow channel had failed. The steam flow voter is not used as the controlling signal.

In the event that both feedwater flow signals or both steam flow signals from one steam generator fail while at power, three element flow control is no longer available for that steam generator FW flow control valve. The DCS will sense that either the validated feedwater flow or validated steam flow control signals have failed, and will cause that feedwater regulating valve to transfer control to single

element, level input only, type of automatic control. This is an interim type of control in that it gives the operator time to evaluate FW stability and to take manual action as necessary to avoid an automatic reactor trip. Single element control, though less stable than three element control, can be utilized as needed until three element flow control can be re-established.

The turbine driven main feedwater pumps' speeds are varied to maintain a programmed pressure differential between the steam header and the feed pump discharge header. The speed controller continuously compares the actual ΔP with a programmed ΔP. For these variables, steam pressure header and feedwater pressure header, three transmitter signals are used for each which input into the DCS. For normal control, the median signal is selected for each variable. Should one channel fail, the remaining steam or feedwater pressure channels then would be averaged and used for control. The ΔP setpoint is developed from the average of the steam flows from all four steam generators.

Continued delivery of feedwater to the steam generators is required as a sink for the heat stored and generated in the reactor following a reactor trip and turbine trip. An override signal closes the feedwater valves when the average coolant temperature is below a given temperature and the reactor has tripped. This signal also trips the main FW pumps when the FW Isolation Valves are tripped. Manual override of the FWC System is available at all times.

A block diagram of the Steam Generator Water Level Control System is shown in Figures 7.2.1-1 sheets 13 and 14.

7.7.1.8 Steam Dump Control (SDC) Systems

The Sequoyah Plant has a 50 percent loss of net load capability, the steam dump steam flow capacity is 40 percent of full load steam flow at full load steam pressure. The 10 percent loss of load is handled directly by the Rod Control System. The automatic SDC System, contained within the DCS, is able to accommodate this abnormal load rejection and to reduce the effects of the transient imposed upon the Reactor Coolant System. By bypassing main steam directly to the condenser, an artificial load is thereby maintained on the Primary System. The Rod Control System can then reduce the reactor temperature to a new equilibrium value without causing overtemperature and/or overpressure conditions.

If the difference between the reference T_{avg} (T_{ref}) based on turbine impulse chamber pressure and the lead/lag compensated auctioneered T_{avg} exceeds a predetermined amount, and the control interlock (C7) is satisfied, a demand signal will be provided to actuate the SDC System to maintain the RC System temperature within control range until a new equilibrium condition is reached.

To prevent actuation of steam dump on small load perturbations, an independent load rejection sensing circuit is provided. This function is performed by an independent DCS processing group. This circuit senses the rate of decrease in the turbine load as detected by the turbine impulse chamber pressure. Control interlock (C7) is provided to unblock the dump valves when the rate of load rejection exceeds a preset value corresponding to a 10 percent step load decrease.

A block diagram of the SDC System is shown on Figure 7.7.1-4.

7.7.1.8.1 Load Rejection Steam Dump Controller

This circuit prevents large increase in reactor coolant temperature following a large, sudden load decrease. The error signal is a difference between the lead/lag compensated auctioneered T_{avg} and the T_{ref} which is based on turbine impulse chamber pressure.

The T_{avg} signal is the same as that used in the RC System. The lead/lag compensation for the T_{avg} signal is to compensate for lags in the plant thermal response and in valve positioning. Following a sudden load decrease, T_{ref} is immediately decreased and T_{avg} tends to increase, thus generating an immediate demand signal for steam dump. Steam dump terminates as the error comes within the maneuvering capability of the control rods.

7.7.1.8.2 Reactor Trip Steam Dump Controller

Following a reactor trip, the load rejection steam dump controller is defeated and the reactor trip steam dump controller becomes active. Since control rods are not available in this situation, the demand signal is the error signal between the lead/lag compensated auctioneered T_{avg} and the no load T_{ref}. When the error signal exceeds a predetermined setpoint the dump valves are tripped open in a prescribed sequence. As the error signal reduces in magnitude indicating that the RC System is T_{avg} being reduced toward the reference no load value, the dump valves are modulated by the reactor trip controller to regulate the rate of removal of decay heat and thus gradually establish the equilibrium hot standby condition.

The error signal determines whether a group of valves is to be tripped open or modulated open. In either case, they are modulated when the error is below the trip-open setpoints.

7.7.1.8.3 Steam Header Pressure Controller

Residual heat removal is maintained by the steam generator pressure controller (manually selected) which controls the amount of steam flow to the condensers. This controller operates a portion of the same steam dump valves to the condensers which are used during the initial transient following turbine and reactor trip or load rejection.

7.7.1.9 In-Core Instrumentation

7.7.1.9.1 Thermocouples

See Section 7.6.10.

.

7.7.1.9.2 Movable Neutron Flux Detector Drive System

Miniature fission chamber detectors can be remotely positioned in retractable guide thimbles to provide flux mapping of the core. See Reference 5 for neutron flux detector parameters. The stainless steel detector shell is welded to the leading end of helical wrap drive cable and to stainless steel sheathed coaxial cable. The retractable thimbles, into which the miniature detectors are driven, are pushed into the reactor core through conduits which extend from the bottom of the reactor vessel down through the concrete shield area and then up to a thimble seal table.

The thimbles are closed at the leading ends, are dry inside, and serve as the pressure barrier between the reactor water pressure and the containment atmosphere. Mechanical seals between the retractable thimbles and the conduits are provided. During reactor operation, the retractable thimbles are stationary. They are extracted downward from the core during refueling to avoid interference within the core. A space above the seal table is provided for the retraction operation.

The drive system for the insertion of the miniature detectors consists basically of drive assemblies, 5-path rotary transfer operation selector assemblies, and 10-path rotary transfer selector assemblies, as shown in Figure 7.7.1-5. These assemblies are described in Reference 5. The drive system pushes hollow helical wrap drive cables into the core with the miniature detectors attached to the leading ends of the cables and small diameter sheathed coaxial cables threaded through the hollow centers back to the ends of the drive cables. Each drive assembly consists of a gear motor which pushes a helical wrap drive cable and a detector through a selective thimble path by means of a special drive box and includes a storage device that accommodates the total drive cable length.

The leakage detection and gas purge provisions are discussed in Reference 5. The carbon dioxide gas purge feature is not used at Sequoyah.

Manual isolation valves (one for each thimble) are provided for closing the thimbles. When closed, the valve forms a 2500-lb/in^{2}g barrier. The manual isolation valves are not designed to isolate a thimble while a detector/drive cable is inserted into the thimble. The detector/drive cable must be retracted to a position above the isolation valve prior to closing the valve.

A small leak would not prevent access to the isolation valves and thus a leaking thimble could be isolated during a hot shutdown. A large leak might require cold shutdown for access to the isolation valve.

7.7.1.9.3 Control and Readout Description

The Control and Readout System provides means for inserting the miniature neutron detectors into the reactor core and withdrawing the detectors while plotting neutron flux versus detector position. The Control System consists of two sections, one physically mounted with the drive units, and the other contained in the control room. Limit switches in each transfer device

provide feedback of path selection operation. Each gear box drives an encoder for position feedback. One 5-path operation selector is provided for each drive unit to insert the detector in one of five functional modes of operation. A 10-path rotary transfer assembly is a transfer device that is used to route a detector into any one of up to ten selectable paths. A common path is provided to permit cross calibration of the detectors.

The control room contains the necessary equipment for control, position indication, and flux recording for each detector. Additional panels are provided for such features as drive motor controls, core path selector switches, plotting and gain controls.

A "flux-mapping" consists, briefly, of selecting (by panel switches) flux thimbles in given fuel assemblies at various core quadrant locations. The detectors are driven to the top of the core and stopped automatically. An x-y plot (position versus flux level) is initiated with the slow withdrawal of the detectors through the core from top to a point below the bottom. In a similar manner other core locations are selected and plotted. Each detector provides axial flux distribution data along the center of a fuel assembly. Various radial positions of detectors may then be compared to obtain a flux map for a region of the core.

The thimbles are distributed nearly uniformly over the core with about the same number of thimbles in each quadrant. The number and location of these thimbles have been chosen to permit measurement of local to average peaking factors to an accuracy of ± 5 percent (95 percent confidence). Measured nuclear peaking factors will be increased by 5 percent to allow for this accuracy. If the measured power peaking is larger than acceptable, reduced power capability will be indicated.

Operating plant experience has demonstrated (Reference 6) the adequacy of the in-core instrumentation in meeting the design bases stated.

7.7.1.10 Control Board

The control board functional layout is shown on Figure 7.1.4-1.

Control board switches and associated lights are furnished in modules. Modules provide a degree of physical protection for the switches, associated lights, and wiring.

The control board layout is based on operator ease in relating the control board devices to the physical plant and in determining at a glance the status of related equipment. This is referred to as providing a functional layout. Within the boundaries of a functional layout, modules are arranged in columns of control functions associated with separation trains defined for the reactor protection and engineered safeguards systems. TVA approved wire is used within the module and between the module and the first termination point.

Modular train column wiring is formed into wire bundles and carried to metal wireways (gutters). Gutters are run into metal vertical wireways (risers). The risers are the interface between field wiring and control board wiring. Risers are arranged to maintain the separated routing of the field wire trays.

Mutually redundant safety train wiring is routed so as to maintain a minimum of six-inch air separation between wires associated with different trains. Where such air separation is not

available, barriers are provided in lieu of air space. A device such as braided sheath material (known as shielding and bonding cable) is used to provide a barrier in lieu of the 6-inch dimension. An example of this sheath material is Belden Braid. When this sheath material is used to provide physical separation, it is sized and secured to the wire bundle.

In order to maintain separation between wiring associated with different trains, mutually redundant safety train wiring is not terminated on a single device. Backup manual actuation switches link the separate trains by mechanical means to provide greater reliability of operator action for the manual reactor trip function and also for the manual ESF actuations. The linked switches are themselves redundant so that operation of either set of linked switches will actuate Safety Train A and Safety Train B simultaneously. For example, the manual reactor trip circuit will have an "A" train switch and a "B" train switch in different board locations not linked in any way. The "A" train switch may be linked mechanically to a backup "B" train switch, and similarly for the "B" train switch linked with a backup "A" train switch.

7.7.1.11 Comparison of Plant Control (PC) Systems with the Donald C. Cook Station

The functional design of the Sequoyah Nuclear Plant Control Systems is basically the same as that employed on the Donald C. Cook installation. The Steam Dump Control System differs because of optional control features.

Each unit of the Donald C. Cook Station has the capability for accepting up to a 100 percent net load rejection via steam dump without reactor trip, whereas each unit of the Sequoyah Station has a 50 percent net load rejection without trip via steam dump. Each station employs a Rod Control System that assumes a step change of 10 percent of the load. The steam dump capacity of Sequoyah is 40 percent of full load steam at full load steam pressure, whereas the steam dump capacity of Donald C. Cook is 85 percent which is provided by additional steam dump valves plus additional logic to trip open these valves on large differences between auctioneered T_{avg} and T_{ref}. The steam dump capacity of 40 percent of the Sequoyah Station, is sufficient to maintain the steam pressure below the steam generator relief valve setpoint in the event of a turbine trip.

In translating the functional requirements in control equipment during the detailed design of the plant, there may be minor changes in actual hardware. Specific functional requirements are, however, accomplished with the same reliability as on the Donald C. Cook design.

7.7.1.12 Anticipated Transients Without Scram (ATWS) Mitigating System Actuation Circuitry (AMSAC)

The design of the AMSAC system shall comply with 10 CFR 50.62 "Requirements for Reduction of Risk from ATWS Events for Light-Water-Cooled Nuclear Power Plants." The function of AMSAC is to mitigate the effects of an ATWS by providing alternate means of tripping the main turbine and actuating auxiliary feedwater (AFW) flow independent from the reactor protection system (RPS). AMSAC actuation will mitigate a common mode failure within RPS upon detection of low-low steam generator levels existing in three-out-of-four steam generators coincident with plant power levels above approximately 40 percent. This actuation will prevent reactor coolant system (RCS) over-pressurization, maintain fuel integrity, and meet 10 CFR 100 radiation release requirements.

ASMAC is not required to be evaluated within the plant design basis and therefore, is not addressed in FSAR Chapters 4.0 and 15.0.

Safety Requirements

The AMSAC system has no safety-related requirements, as per the ATWS final rule (10 CFR 50.62), but its implementation shall be such that it will not degrade the RPS, the AFW system or other safety-related systems.

Redundancy

There are no redundancy requirements for the AMSAC system, however, appropriate coincidence logic shall be utilized to avoid inadvertent actuation.

Electrical Independence Requirements

AMSAC input and output signals shall be isolated from the RPS, AFW, and other safety-related systems with isolation devices.

Seismic Requirements

Seismic qualification for the AMSAC system is not required. However, the AMSAC system shall be designed so as not to degrade the seismic qualification of other plant systems for which seismic qualification is required.

7.7.2 Analysis

The Plant Control Systems are designed to assure high reliability in any anticipated operational occurrences. Equipment used in these systems is designed and constructed to maintain a high level of reliability.

Proper positioning of the control rods is monitored in the control room by bank arrangements of the individual position column meters for each rod cluster control assembly. A rod deviation alarm alerts the operator of a deviation of one rod cluster control assembly from the other rods in that bank position. There are also insertion limit monitors with visual and audible annunciation. A rod bottom alarm signal is provided to the control room for each full length rod cluster control assembly. Four long ex-core ion chambers also detect asymmetrical flux distribution indicative of rod misalignment.

Overall reactivity control is achieved by the combination of soluble boron and rod cluster control assemblies. Long-term regulation of core reactivity is accomplished by adjusting the concentration of boric acid in the reactor coolant. Short-term reactivity control for power changes is accomplished by the Plant Control System which automatically moves rod cluster control assemblies. This system uses input signals including neutron flux, coolant temperature, and turbine load.

The Plant Control Systems will prevent an undesirable condition in the operation of the plant that, if reached, will be protected by reactor trip. The description and analysis of this protection is covered in Section 7.2. Worst case failure modes of the Plant Control Systems are postulated in the analysis of off-design operational transients and accidents covered in Chapter 15, such as the following:

1. Uncontrolled rod cluster control assembly withdrawal from a subcritical condition.

2. Uncontrolled rod cluster control assembly withdrawal at power.

3. Rod cluster control assembly misalignment.

4. Loss of external electrical load and/or turbine trip.

5. Loss of all alternating current power to the station auxiliaries (station blackout).

6. Excessive heat removal due to feedwater system malfunctions.

7. Excessive load increase.

8. Accidental depressurization of the Reactor Coolant System.

These analyses do show that a reactor trip setpoint is reached in time to protect the health and safety of the public under these postulated incidents and that the resulting coolant temperatures produce a DNBR well above the limiting value. Thus, there will be no cladding damage and no release of fission products to the Reactor Coolant System under the assumption of these postulated worst case failure modes of the Plant Control System.

7.7.2.1 Separation of Protection and Control Systems

In some cases it is advantageous to employ control signals derived from individual protection channels through isolation amplifiers contained in the protection channel. As such, a failure in the control circuitry does not adversely affect the protection channel. Accordingly, this failure mode meets the requirements of GDC 23 (1971 Criteria). Test results have shown that a short circuit, or the application of 118 volts alternating current or 140-volts direct current on the isolated output portion of the circuit (is the nonprotection side of the circuit) will not affect the input (protective) side of the circuit.

Where a single random failure can cause a control system action that results in a generating station condition requiring protective action and can also prevent proper action of a protection system channel designed to protect against the condition, the remaining redundant protection channels are capable of providing the protective action even when degraded by a second random failure. This meets the applicable requirements of Section 4.7 of IEEE-279.

7.7.2.2 Response Considerations of Reactivity

Reactor shutdown with control rods is completely independent of the control functions since the trip breakers interrupt power to the full length rod drive mechanisms regardless of existing

control signals. The design is such that the system can withstand accidental withdrawal of control groups or unplanned dilution of soluble boron without exceeding acceptable fuel design limits. Thus the design meets the applicable requirements of GDC 21 (1971 Criteria).

No single electrical or mechanical failure in the rod control system could cause the accidental withdrawal of a single rod cluster control assembly from the partially inserted bank at full power operation. The operator could deliberately withdraw a single rod cluster control assembly in the control bank; this feature is necessary in order to retrieve a rod, should one be accidentally dropped. In the extremely unlikely event of simultaneous electrical failures which could result in single withdrawal, rod deviation would be displayed on the plant annunciator, and the rod position indicators would indicate the relative positions of the rods in the bank. Withdrawal of a single rod cluster control assembly by operator action, whether deliberate or by a combination of errors, would result in activation of the same alarm and the same visual indications.

Each bank of control and shutdown rods in the system is divided into two groups of up to four or five* mechanisms each. The rods comprising a group operate in parallel through multiplexing thyristors. The two groups in a bank move sequentially such that the first group is always within one step of the second group in the bank. A definite schedule of actuation or deactuation of the stationary gripper, movable gripper, and lift coils of a mechanism is required to withdraw the rod cluster control assembly attached to the mechanism. Since the four stationary grippers, movable grippers, and lift coils associated with the rod cluster control assemblies of a rod group are driven in parallel, any single failure which could cause rod withdrawal would affect a minimum of one group of rod cluster control assemblies. Mechanical failures are in the direction of insertion, or immobility.

The identified multiple failure involving the least number of components consists of open circuit failure of the proper 2 out of 16 wires connected to the gate of the lift coil thyristors. The probability of open wire (or terminal) failure is 0.016×10^{-6} per hour by MIL HDB217A. These wire failures would have to be accompanied by failure or disregard of the indications mentioned above. The probability of this occurrence is therefore too low to have any significance.

Concerning the human element, to erroneously withdraw a single rod cluster control assembly, the operator would have to improperly set the bank selector switch, the lift coil disconnect switches, and in-hold-out switch. In addition, the three indications would have to be disregarded or ineffective. Such series of errors would require a complete lack of understanding and administrative control. A probability number cannot be assigned to a series of errors such as these.

The RPI System provides direct visual displays of each control rod assembly position. The plant computer alarms for deviation of rods from their banks. In addition, a rod insertion limit monitor provides low and low-low alarms that are audible and visual to warn the operator of an approach to an abnormal condition due to dilution. The low and low-low control bank rod insertion alarms alert operators to take action to restore margin. The facility reactivity control systems are such that acceptable fuel damage limits will not be exceeded even in the event of a single malfunction of either system.

An important feature of the Control Rod System is that insertion is provided by gravity fall of the rods.

---

* U1 is permitted to operate with the location H-8 Control Rod Assembly removed during U1C24 and U1C25. Therefore it will have groups of up to four in all banks of the Control and Shutdown rods.

*U2 is permitted to operate with the location H-8 Control Rod Assembly removed during Unit 2 Cycle 24 (U2C24) and Cycle 25 (U2C25). Therefore, Unit 2 will have groups of up to four in all banks of the Control and Shutdown rods.

In all analyses involving reactor trip, the single, highest worth rod cluster control assembly is postulated to remain untripped in its full out position.

One means of detecting a stuck control rod assembly is available from the actual rod position information displayed on the control board. The control board position readouts, one for each full length rod, gives the plant operator the actual position of the rod in steps. The indications are grouped by banks (e.g., Control Bank A, Control Bank B, etc.) to indicate to the operator the deviation of one rod with respect to other rods in a bank. This serves as a means to identify rod deviation.

The plant computer monitors the actual position of all rods. Should a rod be misaligned from the other rods in that bank by more than 15 inches, the rod deviation alarm is actuated.

Misaligned rod cluster control assemblies are also detected and alarmed in the control room via the Flux Tilt Monitoring System which is independent of the plant computer.

Isolated signals derived from the Nuclear Instrumentation System are compared with one another to determine if a preset amount of deviation of average power has occurred. Should such a deviation occur, the comparator output will operate a bistable unit to actuate a control board annunciator. This alarm will alert the operator to a power imbalance caused by a misaligned rod. By use of individual rod position readouts, the operator can determine the deviating control rod and take corrective action.

Thus the design of the Plant Control Systems meets the applicable requirements of GDC 13 and GDC 25 (1971 Criteria).

The Rod System can compensate for the reactivity effects of fuel/water temperature changes accompanying power level changes over the full range from full load to no load at the design maximum load rate of change. Automatic control of the rods is, however, limited to the range of approximately 15 percent to 100 percent of rating.

The Boron System (by the use of administrative measures) will maintain the reactor in the cold shutdown state irrespective of the disposition of the control rods.

The Rod System can compensate for xenon burnout reactivity transients over the allowed range of rod travel. Xenon burnout transients of larger magnitude must be accommodated by boration or by reactor trip (which eliminates the burnout). The Boron System is discussed in section 9.3.4.

The overall reactivity control achieved by the combination of soluble boron and rod cluster control assemblies meets the applicable requirements of GDC 26 (1967 Criteria).

7.7.2.3 Step Load Changes Without Steam Dump

The Plant Control System restores equilibrium conditions, without a trip, following a $\pm$ 10 percent step change in load demand, over the 15 to 100 percent power range for automatic control. Steam dump is blocked for load decrease less than or equal to 10 percent. A load demand greater than full power is prohibited by the turbine control load limit devices.

The Plant Control System minimizes the reactor coolant average temperature deviation during the transient within a given value and restores average temperature to the programmed setpoint. Excessive pressurizer pressure variations are prevented by using spray and heaters and power relief valves in the pressurizer.

The Control System will limit nuclear power overshoot to acceptable values following a 10 percent increase in load to 100 percent.

7.7.2.4 Loading and Unloading

Ramp loading and unloading of 5 percent per minute can be accepted over the 15 to 100 percent power range under automatic control without tripping the plant. The function of the Control System is to maintain the coolant average temperature as a function of turbine-generator load.

The coolant average temperature increases during loading and causes a continuous insurge to the pressurizer as a result of coolant expansion. The sprays limit the resulting pressure increase. Conversely, as the coolant average temperature is decreasing during unloading, there is a continuous outsurge from the pressurizer resulting from coolant contraction. The pressurizer heaters limit the resulting system pressure decrease. The pressurizer water level is programmed such that the water level is above the setpoint for heater cutout during the loading and unloading transients. The primary concern during loading is to limit the overshoot in nuclear power and to provide sufficient margin in the overtemperature ΔT setpoint.

7.7.2.5 Load Rejection Furnished by Steam Dump System

When a load rejection occurs, if the difference between the required temperature setpoint of the Reactor Control System and the actual average temperature exceeds a predetermined amount, a signal will actuate the steam dump to maintain the Reactor Control System temperature within control range until a new equilibrium condition is reached.

The reactor power is reduced at a rate consistent with the capability of the Rod Control System. Reduction of the reactor power is automatic. The steam dump flow reduction is as fast as rod cluster control assemblies are capable of inserting negative reactivity.

The Rod Control System can then reduce the reactor temperature to a new equilibrium value without causing overtemperature and/or overpressure conditions. The steam dump steam flow capacity is 40 percent of full load steam flow at full load steam pressure.

The steam dump flow reduces proportionally as the control rods act to reduce the average coolant temperature. The artificial load is therefore removed as the coolant average temperature is restored to its programmed equilibrium value.

The dump valves are modulated by the reactor coolant average temperature signal. The required number of steam dump valves can be tripped quickly to stroke full open or modulate, depending upon the magnitude of the temperature error signal resulting from loss of load.

7.7.2.6 Turbine-Generator Trip With Reactor Trip

Whenever the turbine-generator unit trips at an operating power level above 50 percent power, the reactor also trips. The unit is operated with a programmed average temperature as a

function of load, with the full load average temperature significantly greater than the equivalent saturation pressure of the safety valve setpoint. The thermal capacity of the Reactor Control System is greater than that of the secondary system, and because the full load average temperature is greater than the no load temperature, a heat sink is required to remove heat stored in the reactor coolant to prevent actuation of steam generator safety valves for a trip from full power. This heat sink is provided by the combination of controlled release of steam to the condenser and by makeup of cold feedwater to the steam generators.

The Steam Dump System is controlled from the reactor coolant average temperature signal whose setpoint values are programmed as a function of turbine load. Actuation of the steam dump is rapid to prevent actuation of the steam generator safety valves. With the dump valves open, the average coolant temperature starts to reduce quickly to the no load setpoint. A direct feedback of temperature acts to proportionally close the valves to minimize the total amount of steam which is bypassed.

Following the turbine trip, the feedwater flow is cut off when the average coolant temperature decreases below a given temperature or when the steam generator water level reaches a given high level.

Additional feedwater makeup can then be controlled manually to restore and maintain steam generator water level while assuring that the reactor coolant temperature is at the desired value. Residual heat removal is maintained by the steam header pressure controller (manually selected) which controls the amount of steam flow to the condensers. This controller operates a portion of the same steam dump valves to the condensers which are used during the initial transient following turbine and reactor trip.

The pressurizer pressure and water level fall rapidly during the transient because of coolant contraction. The pressurizer water level is programmed so that the level following the turbine and reactor trip is adequate to protect the pressurizer heaters. At low pressurizer level, letdown isolates, the heaters are deenergized, and the Chemical and Volume Control System will increase charging flow to restore water level in the pressurizer. Heaters are then turned on to restore pressurizer pressure to normal.

The Steam Dump and Feedwater Control Systems are designed to prevent the average reactor coolant temperature from falling below the core design allowable cooldown temperature following the trip (rods at the insertion limit) to ensure adequate reactivity shutdown margin without emergency borating. If the Steam Dump and Feedwater Control Systems cools the average reactor coolant temperature below allowable, emergency boration will be administratively initiated.

TABLE 7.7.1-1
PLANT CONTROL SYSTEM INTERLOCKS

Designation	Derivation	Function
C-1	1/2 Neutron flux (intermediate range) above setpoint	Blocks automatic and manual control rod withdrawal
C-2	1/4 Nuclear Power (power range) above setpoint	Blocks Automatic and manual control rod withdrawal
C-3	2/4 Overtemperature ΔT above setpoint	Blocks automatic and manual control rod withdrawal
		Actuates turbine runback via load reference
		Defeats remote load dispatching
C-4	2/4 Overpower ΔT above setpoint	Blocks automatic and manual control rod withdrawal
		Actuates turbine runback via load reference
		Defeats remote load dispatching
C-5	1/1 Turbine impulse chamber pressure below setpoint	Defeats remote load dispatching
		Blocks automatic control rod withdrawal
C-7	1/1 Time derivative (absolute value) of Turbine impulse chamber pressure (decrease only) above setpoint	Makes steam dump valves available for either tripping or modulation
C-8	Turbine trip, 2/3 emergency trip header pressure below set point or 4/4 turbine valves closed	Indicates anticipatory reactor trip if above P-9
	No turbine trip, 2/3 emergency trip header pressure above set point and 1/4 turbine-inlet line stop valves not closed	
C-9	*1/2 condenser pressure above setpoint or All Circulation water pump breakers open	Blocks steam dump to condenser
C-11	1/1 Bank D control rod position above setpoint	Blocks automatic rod withdrawal

*Median of three condenser pressures above setpoint, or all circulation water pump breakers open.

APPENDIX 7A

INSTRUMENTATION INDENTIFICATIONS AND SYMBOLS

LIST OF CONTENTS

LIST OF FIGURES

APPENDIX 7A - INSTRUMENTATION IDENTIFICATIONS AND SYMBOLS

A standard set of instrumentation symbols and identifications is provided in this appendix to aid in the interpretation of the figures reproduced from TVA drawings.

The identification and symbols include the following designation:

1. Instrument identification letters.

2. Process system numbers.

3. Flow and control diagram symbols.

4. Basic instrumentation and radiation symbols.

5. Basic digital logic symbols.

7A.1 IDENTIFICATION SYSTEM

Each instrument is identified by a series of letters and numbers to designate the function, the process system, and the control loop.

7A.1.1 Functional Identification

The functional identification of an instrument consists of letters from Table I in Figure 7A-1 and generally includes one uppercase first letter covering the measured or initiating variable; and one or more uppercase succeeding letters covering the function of the individual instruments. The exceptions to this rule are as follows:

1. The use of chemical symbols, e.g., pH, Cu, Na, as a first-letter entity to better identify some of the measured variables.

2. The use of An and Px in the succeeding letters to identify analyzer and power supply, respectively.

7A1.1.1 Principal Function

The functional identification of an instrument is made according to the principal function and not according to the construction. Thus, a differential-pressure transmitter used for flow measurement is identified as an FT, not a PdT. A pressure indicator and a pressure switch connected to the output of a pneumatic level transmitter is identified as LI and LS, respectively. (Note: An instrument identified may also have secondary purposes, i.e., a signal originating from a pressure transmitter that is proportional to pressure may also be used as an inferred measurement of temperature).

7A.1.1.2 Measured Variable

In an instrument loop, the first letter of the functional identification indicates the measured (initiating) or the inferred variable and the manipulated variable. Thus, a control valve varying

flow according to the dictates of a level controller is an LCV, not an FCV. Also, if two or more measured variable signals are combined to control a particular variable, the instrument processing the combined signals is identified in accordance with the controlled variable (i.e., cascade control).

7A.1.1.3 Readout or Passive Functions

The one or more succeeding letters of the functional identification designates one or more readout or passive functions, or output functions, or both. The readout or passive functional letters, such as R for recording and I for indicating, follow the first letter in sequence. The output functional letters, such as C for control and S for switch, follow these in sequence except that output letter C (control) shall precede output letter V (valve) and O (operator), e.g., HCV, a hand-actuated control valve. However, if there are no readout or passive functional letters, then the output functional letters follow the first letter in sequence.

7A.1.1.4 Modifying Letters

Modifying letters may modify either a first letter or the succeeding letters, as applicable. However, modifying letters, if used, are interposed so that they are placed immediately following the letter they modify except letter S for solenoid which precedes output letter V (valve), e.g., FSV designates a solenoid-actuated flow valve.

7A.1.1.5 Tagging Symbols

An instrument tagging designation on a control diagram may be drawn with as many circular tagging symbols as there are measured variables or outputs. Thus, a recorder charting temperature and flow may be identified by two tangent circles where possible, one inscribed TR-3-31 and the other FR-3-31. The instrument then would be designated TR/FR-3-31.

7A.1.1.6 Special Identifying Letters

The measured variable letter X (special), has been included in Table I of Figure 7A-1 to cover unlisted variables that are used to a limited extent. It may also be used for an instrument function. Therefore, the letter may have any number of meanings as a first letter and any number of meanings as a succeeding letter.

Any first letter, if used in combination with the modifying letter, e.g., d (differential), represents, as shown on Table I for pressure differential, a new and separate measured variable, and the combination shall be treated as a first-letter entity. Thus, instruments PdI and PI measure two different variables, namely, differential pressure and pressure.

7A.1.1.7 Pilot Lights

A pilot light that is part of an instrument loop is identified by a first letter Z (zone or position), followed by a succeeding letter, I or A (I - indicating, A - alarm). A pilot light that serves only as position indication associated with hand switches need not be identified.

7A.1.2 System Identification

The system identification of an instrument uses a number assigned to the process system of which the instrument is a part. Each process system, e.g., boiler feedwater, extraction, reactor water cleanup, has been assigned a system identification number.

7A.1.2.1 Identification Numbers

The system identification numbers are listed in Table II in Figure 7A-2. The system identification number follows the "succeeding letters" of the functional identification letters and is separated from them by a hyphen.

7A.1.2.2 Instruments Common to Multiple Process Systems

If an instrument is common to two or more process systems, it is assigned to the one for which it is performing its principal function. If no principal function can be determined, it is assigned to the process system having the lowest system identification number.

7A.1.3 Loop Identification

The control loop identification of an instrument generally uses a number assigned to the control loop of which the instrument is a part. There may be one or many instrument control loops in a process system. However, each control loop has a unique number. The control loop numbering sequence begins with 1, starting generally at the first measurement or control point of each process system.

7A.1.3.1 Instruments Common to Multiple Control Loops

If an instrument is common to two or more control loops, it is assigned to the loop for which it is performing its principal function. If no principal function can be determined, it is assigned to the loop having the lowest loop identification number.

7A.1.3.2 Multiple Instruments with a Common Function

If a given loop has more than one instrument with the same functional identification, a suffix letter or number is appended to the loop number, e.g., FCV-3-10A, FCV-3-10B.

7A.2 SYMBOLS

The symbols used to depict the instrumentation on flow, control, and logic diagrams and other drawings are illustrated in the following figures:

Figure 7A-3 - Flow and control diagram symbols

Figure 7A-4 - Basic instrumentation and radiation symbols

Figure 7A-5 - Application of basic instrumentation symbols

Figure 7A-6 - Digital logic symbols

The flow diagram symbols for valves, valve operators, and miscellaneous devices most frequently used by TVA are shown in Figure 7A-3.

7A.2.1 Instrument Symbol

The circular symbol, shown in Figure 7A-4, is the basic instrumentation symbol. It is used to depict the instrument proper and most other instrumentation items. Also, it is used as a "flag" to enclose identifications and point out items such as valves, which have their own pictorial symbols. Typical applications of the instrumentation symbols are shown in Figure 7A-5.

8.0 ELECTRIC POWER

8.1 INTRODUCTION

8.1.1 Utility Grid and Interconnections

The Tennessee Valley Authority (TVA) is a corporation of the United States Government serving the State of Tennessee and parts of six other states in the southeast on the boundaries of Tennessee. TVA is interconnected with electric power companies to the north, west, south, and east of its service area. As shown in Figure 8.1.1-1, the TVA grid consists of interconnected hydro plants, fossil-fueled plants, combustion turbine plants, and nuclear plants supplying electric energy over a transmission system consisting of various voltages up to 500-kV.

The Sequoyah Nuclear Plant is located 18 miles northeast of Chattanooga, Tennessee, on the west bank of the Tennessee River, six miles east of Soddy-Daisy, Tennessee. The plant is connected into a strong transmission grid supplying large load centers. One of the two nuclear units is connected to the 500-kV transmission system and one is connected to the 161-kV transmission system. The two systems are interconnected at Sequoyah through a 1200 MVA, 500-161-kV transformer bank.

8.1.2 Plant Electrical Power System

For Unit 1and 2, the plant electric power system consists of the main generator, the generator circuit Breaker (GCB), the unit station service transformers, the common station service transformers, the main bank transformers, the diesel generators, the batteries, and the electric distribution system as shown in Figures 8.1.2-1 and 8.1.2-2. The main generator supplies electrical power through isolated-phase buses to the main bank transformers and the unit station service transformers. During normal operations the auxiliary power is typically supplied by unit power through the unit station service transformers. During startup and shutdown the auxiliary power is typically supplied by the 500-kV system through the main bank and unit station service transformers for Unit 1 and the 161-kV system through the main bank and unit station service transformers for Unit 2. During startup, shutdown, and normal operations auxiliary power may be supplied by the 161-kV system through the common station service transformers.

The standby onsite power is supplied by four diesel generators. The power to the 6.9-kV common boards is supplied by the 161-kV system through the common station service transformers.

The safety objective for the power system is to furnish adequate electric power to ensure that safety loads function in conformance with design criteria and bases.

The safety objective has been accomplished by: (1) establishing design criteria and bases that conform to regulatory documents and accepted design practice, and (2) implementation of these criteria and bases in a manner that assures a system design and a constructed plant which satisfies safety requirements. The applicable documents governing the design are shown in Subsection 8.1.5.

Figure 8.1.2-1 depicts the plant auxiliary power distribution system that receives AC power from either the Unit 1 or 2 nuclear power unit, the two independent preferred (offsite) power circuits, and four diesel-generator standby (onsite) power sources and distributes it to both safety-related and nonsafety-related loads in the plant. The two preferred circuits have access to the TVA transmission network which in turn has multiple interties with other transmission networks.

The major safety-related loads for each nuclear unit are divided electrically into two redundant load groups. Each redundant load group of each unit has access to a standby (onsite) source and to each of the two preferred (offsite) sources. Due to a number of shared systems, two (must be the same train) out of four diesels and load groups are required to provide all safety functions for each unit. The offsite and onsite power systems are described in Sections 8.2 and 8.3.

Figure 8.1.2-2 depicts the vital AC and DC control power distribution systems that connect four 125V batteries, four battery chargers and eight 120V AC inverters with their respective safety-related loads. The 125V DC distribution system is a safety-related system which receives power from four independent battery chargers and four 125V DC batteries and distributes it to safety-related (and non-safety related) loads of both units. The 120V AC distribution system is also a safety-related system which receives power from eight independent inverters and distributes it to the safety-related (and non-safety related) loads of both units. These systems are described in Sections 8.2 and 8.3.

8.1.3 Safety-Related Loads

Major loads requiring electric power to perform their safety function are listed in Table 8.1.2-1.

8.1.4 Design Bases

The design bases for the electric power system are listed below.

Offsite (Preferred) Power System

(1) Each of the two offsite power circuits supplying electric power from the transmission network to the onsite electric distribution system shall have sufficient capability and capacity, and be available in sufficient time following a loss of all onsite alternating current power and the other offsite electric power circuit, to assure that specified acceptable fuel design limits and design conditions of the reactor coolant pressure boundary are not exceeded. One of the two circuits shall be available to supply the plant safety loads within a few seconds following a loss-of-coolant accident to assure that core cooling, containment integrity, and other vital safety functions are maintained.

(2) The two offsite power circuits (not including the switchyard) shall be designed and located to be physically independent so as to minimize, to the extent practical, the likelihood of their simultaneous failure under operating and postulated accident and environmental conditions.

Onsite (Standby) Power Systems

(1) The onsite power systems shall be designed to provide sufficient capacity to assure that acceptable fuel design limits and design conditions of the reactor coolant pressure boundary are not exceeded as a result of anticipated operational occurrences and that the core is cooled and containment integrity and other vital functions are maintained in the event of postulated accidents in one unit and to safely shutdown the other unit.

(2) The onsite power systems shall be designed to perform their safety functions assuming a single failure.

(3) The onsite power systems shall be located within Category I structures so that they are protected from natural phenomena.

(4) The onsite power systems shall be designed to perform their safety function considering the effects of the following events:

(a) postulated accident environment

(b) fires

(c) accident-generated missiles

(d) fire protection system operation

(e) accident-generated flooding, sprays, or jets

(f) single act, event, component, failure, or circuit fault that could cause multiple equipment malfunctions.

(5) The onsite power systems shall be designed to permit appropriate surveillance, periodic inspection, and testing of important areas and features to assess the continuity of the systems and the condition of their components.

(6) The onsite standby AC power sources shall be designed to be automatically initiated in the event of an accident signal or a loss of offsite power.

Onsite DC Power System

(1) The vital batteries have adequate capacity for a period of 30 minutes, without chargers, to provide the necessary DC power to perform the required safety functions in the event of a postulated accident in one unit and to safely shutdown the other unit, assuming a single failure.

The 30 minute criteria is used to justify battery sizing. This timeframe is an acceptable time to demonstrate the adequacy of the vital battery system by the safety analysis of the station in accordance with IEEE Std 308-1971.

(2) The vital batteries have adequate capacity, with load shedding, for a period of four hours, without chargers, to provide the necessary DC power to maintain both reactors at hot shutdown, assuming the loss of all AC power sources.

(3) The vital battery chargers have adequate capacity to simultaneously supply the combined demands of the steady-state loads and to restore the battery from the design discharge state to the design charged state.

8.1.5 Design Criteria and Standards

Although the design of the electric power system for the Sequoyah Nuclear Plant preceded the publication of several of the standards and regulatory guides referenced below, it is TVA's belief that the design meets the intent of those standards and guides.

8.1.5.1 Design Criteria

(1) IEEE Std 279-1971, IEEE Standard Criteria for Protection Systems for Nuclear Power Generating Stations.

(2) IEEE Std 308-1971, IEEE Standard Criteria for Class IE Electric Systems for Nuclear Power Generating Stations.

(3) Criterion Nos. 1, 2, 3, 4, 5, 17, and 18, NRC General Design Criteria Nuclear Power Plants (10 CFR 50, Appendix A, July 7, 1971).

(4) AEC Quality Assurance Criteria for Nuclear Power Plants (10 CFR 50, Appendix B, June 26, 197l).

8.1.5.2 NRC Regulatory Guides

(1) Regulatory Guide No. 1.6, Rev. 0, Independence Between Redundant Standby (Onsite) Power Sources and Between Their Distribution Systems.

(2) Regulatory Guide No. 1.9, Rev. 0, Selection of Diesel Generator Set Capacity for Standby Power Supplies.

(3) Regulatory Guide No. 1.32, Rev. 2, Use of IEEE Std 308-1971, "Criteria for Class IE Electric Systems for Nuclear Power Generating Stations."

(4) Regulatory Guide 1.29, Rev. 0, Seismic Design Classification.

(5) Regulatory Guide 1.81, Rev. 1, Shared Emergency and Shutdown Electric Systems for Multi-Unit Nuclear Power Plants.

(6) Branch Technical Position EICSB 7, Shared Emergency Electric Power Systems for Multi-Unit Generating Station.

(7) Regulatory Guide 1.106, Rev. 1, "Thermal Overload Protection for Electric Motors on Motor Operated Valves"

(8) Regulatory Guide 1.155, RO, Station Blackout

8.1.5.3 Other Standards and Guides

(1) IEEE No. 317-1971, IEEE Standard for Electric Penetration Assemblies in Containment Structures for Nuclear Fueled Power Generating Stations.

(2) IEEE No. 323-1971, IEEE Trial-Use Standard: General Guide for Qualifying Class IE Electric Equipment for Nuclear Power Generating Stations.

TABLE 8.1.2-1 (Sheet 1)

MAJOR SAFETY LOADS AND FUNCTIONS

Safety Loads	Typical Safety Function	Power
Centrifugal Charging Pumps	Provide ECCS	6900V AC
Safety Injection Pumps	Provide ECCS	6900V AC
Residual Heat Removal Pumps	Remove reactor heat during a shutdown condition and ECCS	6900V AC
Containment Spray Pumps	Provide containment cooling	6900V AC
Essential Raw Cooling Water Pumps	Provide cooling water for CCS and other safety systems	6900V AC
Auxiliary Feedwater Pumps	Provide secondary side SG inventory	6900V AC
Pressurizer Heater Backup Group	Provide heat for maintaining adequate pressure in the primary coolant system	6900/480V AC
Component Cooling System Pumps	Provide cooling water to the NSSS equipment and safety systems	480V AC
Spent Fuel Pit Pumps	Cooling spent fuel pit pool	480V AC
Fire Pumps	Provide AFW during flood	480V AC
Reactor Lower Compart-ment Cooling Fans	Provide adequate cooling to the lower containment during post accident periods	480V AC
Containment Air Return Fans	Return air from upper to lower containment to reduce pressure after a LOCA and prevent excessive hydrogen buildup in pocketed areas	480V AC
Safety-Related Air Conditioning	Control air temperature	480V AC
Ventilation System	Controls air temperature and radiological conditions	480V AC & 125V DC
Vital Battery Chargers	Maintain 125V vital batteries at proper charge level	480V AC
Vital Inverter	Supplies power to the vital instrument buses	480V AC or 125V DC
Hydrogen Recombiner	Control hydrogen concentration	480V AC
Motor Control Centers	Provide power for small motors, fans, MOV's, heaters, and small pumps	480V AC
Solid-State Pro-tection System	Shuts reactor down whenever an unsafe parameter is sensed.	120V AC

TABLE 8.1.2-1 (Sheet 2)

MAJOR SAFETY LOADS AND FUNCTIONS

Safety Loads	Typical Safety Function	Power
Nuclear Instrument System	Monitors reactor power level for reactor control and trip logic	120V AC
Auxiliary Relay Racks	Auxiliary relays for process control	120V AC & 125V DC
Power Switchgear	Control power for power switchgear	125V DC
Reactor Trip Switchgear	Trips reactor	125V DC
Diesel Generator Control	Remote control of diesel generators	125V DC
Auxiliary Feed Turbine	Control power of auxiliary feed pump turbine	125V DC
Solenoid Valves	Controls flow through safety related valves (may use pneumatic valves with solenoid pilots)	125V DC & 120V AC

8.2 OFFSITE POWER SYSTEM

8.2.1 Transmission Network Description

The Sequoyah Nuclear Plant is connected into a strong existing transmission network supplying large load centers. One unit is connected into the 500-kV transmission network and the other unit is connected into the 161-kV transmission system. The two systems are interconnected at Sequoyah through a 1200-MVA, 500-161-kV intertie transformer bank. Preferred electric power to the emergency buses and to start up and shut down the generating units at the Sequoyah Nuclear Plant is supplied by two physically and electrically independent circuits from the Sequoyah 161-kV or 500-kV switchyard through separate transformers to the onsite electrical distribution system, (refer to Figure 8.2.1-1).

For Unit 1 and 2, the normal power supply to the emergency buses is typically supplied by unit power through the unit station service transformers (USSTs). For Unit 1, the normal power supply to start up and shut down the generator is typically supplied by the 500-kV system through the main bank transformers and USSTs. For Unit 2, the normal power supply to start up and shut down the generator is typically supplied by the 161-kV system through the main bank transformers and unit station service transformers. Power to the emergency buses and to start up or shut down the generating unit may be supplied by the common station service transformers (CSSTRs).

Five 500-kV transmission lines connect one generating unit into the 500-kV system. Except in the vicinity of Sequoyah Nuclear Plant, the lines are on rights of way which are sufficiently wide to preclude the likelihood of failure of one line causing failure of another.

The 161-kV switchyard is the terminus for the second nuclear unit, the 500-kV intertie transformer bank and eight 161-kV transmission lines. Four 161-kV transmission lines terminate on each bus section. Two fuseless 84 MVAR 161-kV capacitor banks are tied to the 161-kV switchyard through double bus-tie breakers. Each bank is independently switched. These capacitors provide reactive voltage support for the 161-kV offsite system. Of the eight 161-kV transmission lines emanating from the Sequoyah 161-kV switchyard, one connects to TVA's Chickamauga Hydro Plant; one connects to TVA's Watts Bar Hydro Plant; and six connect to 161-kV substations that are an integral part of the 161-kV transmission network. Nine hydro plants, one fossil-fueled plant, and one nuclear plant are located within a sixty-mile radius from the Sequoyah Nuclear Plant. These plants are strongly connected through the 161-kV and 500-kV transmission networks to Sequoyah and have an installed capacity of more than 4000 MVA.

The transmission line structures of the 161-kV and 500-kV systems are designed to withstand medium loading conditions as specified in The Bureau of Standards Handbook No. 10 (National Electrical Safety Code Part 2).

To reduce the total number of acres of easement right of way required for the line connections to the Sequoyah Nuclear Plant, a number of the 161-kV lines are constructed on double circuit towers and, also, on common wide right of way. The 161-kV switchyard is designed with two main bus sections and is arranged so that the supply to the onsite power system, as well as the connections to the generator and 500-161-kV intertie transformer bank is maintained to one bus section for a failure of the other section. Four of the 161-kV lines terminate on one bus section and connect to Hiwassee, East Cleveland, VW Chattanooga, and Falling Water 161-kV substations. The other four 161-kV transmission lines terminate on the other bus section and connect to Hiwassee and Concord 161-kV substations and Chickamauga and Watts Bar Hydro Plants.

To make the thirteen line connections into Sequoyah, a number of lines must cross each other. When lines of different voltages cross, the higher voltage line crosses over the lower voltage line. Crossings similar to these are common throughout the TVA service area.

The Bradley 500-kV Line crosses over the Sequoyah-Moccasin 161-kV Transmission Line. Assuming the 500-kV line falls at the crossover point, this will result in the loss of both the 500-kV and 161-kV lines. The four remaining 500-kV connections at Sequoyah and the seven remaining 161-kV connections will stay in service.

The Sequoyah-Hiwassee 500-kV Transmission Line crosses under the Widows Creek 500-kV Line, the Franklin 500-kV Line, and the Watts Bar No. 1 Line. If one of the three physically higher lines fall, this will result in the loss of two 500-kV lines. Three 500-kV connections and eight 161-kV connections will stay in service.

The 161-kV transmission line crossover at Sequoyah in the 161-kV transmission grid system consists of the Concord No. 1 line crossing under the following five connections from Sequoyah. They are Hiwassee 2, Hiwassee 1, Chickamauga No. 1, Watts Bar Hydro, and East Cleveland. Only two of the 161-kV transmission lines would be involved if either of the five aforementioned lines were to fall. Those lines remaining in service will be five 500-kV connections and six 161-kV connections.

The Tennessee Valley Region is located in a high thunderstorm frequency area and interruptions due to lightning do occur. Most interruptions are momentary in duration and have no significant effect on the operation of TVA's network of lines. The lightning performance for the transmission lines connected to the 161- and 500-kV switchyards at Sequoyah indicates that for the period January 1, 1994, through December 31, 1998, there were twenty-one 500-kV line interruptions and twenty 161-kV line interruptions attributed to lightning. Of these interruptions, six 500 kV and no 161-kV interruptions resulted in outages in excess of one minute.

Localized heavy conductor icing has occurred on some of TVA's transmission lines in years past. TVA's lines are designed to withstand these heavy icing conditions and no mechanical failures have occurred due to icing of any of the lines being connected into Sequoyah.

Several of the existing transmission lines that will be connected into Sequoyah do traverse fairly rugged terrain. Construction across this type terrain is not unusual for TVA transmission lines. Conductor spans in excess of 2,000 feet are fairly common and construction of spans of this magnitude are handled routinely. The longest spans which normally require the tallest transmission towers are river crossing spans. The 3,400 foot river crossing span on the Watts Bar-Sequoyah 500-kV lines is the longest span in the lines being connected into Sequoyah. The overhead ground wire in this span is marked with aircraft hazard markers and the transmission line towers are lighted for aeronautical protection.

TVA's transmission lines are designed and constructed to eliminate damaging conductor vibrations. Conductor galloping is a phenomenon which normally occurs on lines constructed of small conductors during conductor icing conditions in conjunction with a continuous low velocity wind. Since TVA's higher voltage lines utilize larger conductors, galloping on them is extremely rare and is no threat to the safe operation of the lines being connected into Sequoyah.

8.2.1.1 Preferred Power System

The intent of GDC 17 has been implemented in the design of the Preferred Power System by providing two physically and functionally independent circuits for energizing safety related load groups. This section identifies these two circuits and describes the general provisions made to achieve functional independence between them. Paragraphs 8.2.1.2 through 8.2.1.4 describe measures taken to provide physical independence between them. The Preferred Power System

can be identified by reference to Figures 8.1.2-1, 8.2.1-1, and 8.2.1-2. The Preferred Power System consists of: two main bank transformers; six 24-kV isolated phase buses; four 24-6.9-kV unit station service transformers; four 6.9-kV unit station service transformer buses; three 161-6.9-kV CSSTR's (A and C, energized spare B); a 6.9-kv start board; four 6.9-kV start buses; eight 6.9-kV unit boards; four 6.9-kV shutdown boards; and all overhead conductors, buses, cable, and distribution equipment that interconnect the off-site power circuits with the 6.9-kV shutdown boards. The Preferred Power System is supplied power by way of either the plant 161-kV or 500-kV switchyard. The combination of Unit 1 and 2 main bank transformers, USSTs, 24-kV isolated phase buses, and 6.9-kV unit station service transformer buses comprise one qualified independent off-site power circuit.

Figures 8.1.2-1 and 8.2.1-1 indicate the functional arrangement of the two independent circuits which derive power from either the 161-kV or 500-kV switchyard and deliver it to the individual 6.9-kV Unit Boards. Power is then routed by two independent circuits from the 6.9-kV Unit Boards to the 6.9-kV Shutdown Boards within each unit.

The components comprising the Preferred Power System have been arranged to provide sufficient independence (both physical and functional) to minimize the likelihood of simultaneous outage of both preferred circuits.

Functional independence has been achieved by providing separate control circuits, powered by separate DC sources. The single line diagrams of these non-safety related 250V DC Systems are included as Figures 8.2.1-3 and 8.2.1-4.

8.2.1.2 Transmission Lines, Switchyard, and Transformers

The eight 161-kV and the five 500-kV lines connecting the plant with the TVA transmission network are indicated functionally on Figure 8.2.1-1. The onsite transmission line arrangement is shown on Figure 8.2.1-2 and the offsite transmission line routing in the vicinity of the switchyard is shown on Figure 8.2.1-5. These lines are routed to minimize the likelihood of their simultaneous failure.

The physical separation of the most widely spaced transmission lines at a point on a circle with a radius of one mile from the plant center exceeds 1/4 mile as shown on Figure 8.2.1-5, which meets the separation requirement from Regulatory Guide 1.155 (NU-MARC 87-00).

Physical arrangement of the equipment is shown on Figure 8.2.1-2. Normally, total functional independence is not maintained in the switchyard itself, due to the fact that all bus sections are electrically connected together. However, in the event of an electrical fault, electrical separation is established in a few cycles by circuit breaker operation. The fault isolation and bus transfer scheme is designed to permit automatic fault isolation while still maintaining multiple connections from the 161-kV and 500-kV switchyard to the grid. Thus, both independent circuits providing preferred power will remain energized. Switchyard control and functional independence is further discussed in Paragraph 8.2.1.5.

It is also possible to isolate the incoming circuit associated with a CSSTR from the other incoming transmission lines. This makes it possible to functionally isolate the transformer on a single hydro unit either at the Watts Bar or Chickamauga Hydro Station, which itself has been isolated from the grid.

Location of the CSSTRs and CCW cooling tower transformers is shown on Figure 8.2.1-2. Physical separation between CSSTRs A, B, and C is a minimum of 65 feet, centerline-to-centerline and 35 feet between closest parts. No missile barrier is required between the CSSTRs to protect one transformer in the event of a failure of the other transformer. The physical arrangement is based on TVA's experience and the analysis of previous failures on transformers with similar construction. A fire is the major concern relative to a transformer failure. In addition to the physical separation, automatic fire protection has been provided as

described in the Fire Protection Report (see 9.5.1). Also, the yard area is covered with a thick layer of loose limestone gravel which is designed to limit the spread of transformer oil should a transformer tank rupture. Therefore, these three design features provide the necessary protection to minimize to the extent practical the likelihood of the simultaneous failure of the common station service transformers under operating and postulated accident conditions. The primary voltage is 161-kV, rated 33/44/55MVA, OA/FA/FOA at 55°C.[1] The secondary voltage is 6.9-kV, and each is rated 24/32/40MVA, OA/FA/FOA at 55°C. CSSTR's A, B, and C are equipped with automatic high speed load tap changers.

---

[1]Cooling modes associated with different ratings are as follows:
OA - Oil to air cooling
FA - Oil to forced air cooling
FOA - Forced oil to forced air cooling

Common station service transformer D and CCW cooling tower transformers A and B are also connected to the 161-kV switchyard. These transformers supply power to non-essential non-safety-related balance-of-plant loads that provide no safety-related functions. The rest of this chapter discusses only the A, B, and C CSSTR's unless specifically noted otherwise.

The location of the unit station service transformers is shown on Figure 8.2.1-2. The USSTs and the CSSTRs are located outside the west and south wall of the turbine building, respectively. Distance mitigates the effect of fire and missiles resulting from the failure of the USSTs on the availability of the CSSTRs. In addition, the yard area below the USSTs is covered with a thick layer of loose limestone gravel which is designed to limit the spread of transformer oil should a transformer tank rupture. Therefore, the design features provide the necessary protection to minimize to the extent practical the likelihood of the simultaneous failure of the unit station service transformers and common station service transformers under operating and postulated accident conditions. The primary voltage of the USSTs is 22-kV. The secondary voltage is 6.9-kV, and each is rated 24/32/40MVA, ONAN/ONAF/ONAF at 55ºC[2]. The USSTs are equipped with automatic high speed load tap changers.

---

[2]Cooling modes associated with the different ratings are as follows:
ONAN - Oil to air cooling
ONAF - Oil to forced air cooling

8.2.1.3 Arrangement of the Start Buses, Start Board, and Unit Boards

From the low-voltage side of each common station service transformer, two 6.9-kV buses supply the 6.9-kV start board. The 6.9-kV buses from CSSTR C are underground cable. The 6.9-kV buses from CSSTRs A and B maintain 65 feet center-to-centerline separation to their convergence at the start board. These buses then connect to the start bus normal or alternate breakers. The design of the start board conforms to ANSI C 37.20 "Standard for Switchgear Assemblies Including Metal-Enclosed Bus," (including Section 20-6.2.2 of this standard which defines the requirements for barriers) and is classified as outdoor metal-clad switchgear. The breakers at the 6.9-kV start board are electrically operated, horizontal drawout type, with stored energy mechanisms. The breakers supply the start buses which feeds the 6.9-kV unit boards and 6.9-kV common boards. These circuit breakers have a continuous rating of 3,750 amperes, an insulation system for 13.8-kV, and interrupting rating of 50,000 amperes, and a momentary rating of 80,000 amperes. The circuit breakers are utilized at 6.9-kV and there is sufficient margin between the application and the rating of these circuit breakers.

Each start bus is enclosed by a grounded bus housing. The start buses consist of two insulated 6 x 1/2 inch aluminum channels per phase for 4000A busduct section; two insulated 4 x 3/4 inch aluminum bars per phase for 3000A busduct sections; two insulated 4 inch by 3/4 inch aluminum bars per phase for the 2000A busduct section, and one insulated 4 inch by 1/4 inch copper bar per phase for the 1200A busduct section; and two 8 inch by 1/2 inch aluminum bars per phase for part of 4000A buses 1A, 1B, and 2B. The outdoor portion of 1A, 2A, 1B, and 2B are one insulated 10 x 1/2 inch copper bar per phase. 4000A buses C1 and C2 (from CSSTR C to the start board) consist of 9-750MCM per phase underground cables. The bus segment between the start bus and CSSTRs A and B are one insulated 10 x ½ inch copper bar per phase. Each three-phase circuit is separately enclosed in a metal bus housing. The separation with two intervening grounded metal barriers, makes the start buses independent with respect to fault propagation. Protection from natural phenomena, other than GDC 2 events, vehicle collision, missile impact, and falling structures is best provided by minimizing the length of run and careful routing. The position of the bus relative to the turbine building wall, as shown in Figure 8.2.1-2, provides protection for almost 180 degrees from all such non-GDC 2 hazards. The turbine building structure is designed to withstand tornado wind loadings which are greater than that of the offsite power system.

There is no normal vehicular access (except for maintenance) to the vicinity of the start buses. The short length of the buses provides a minimum cross-section for missile impact, while the inherent strength of the bus housing, and supporting structure assures a high probability of surviving a non-GDC 2 missile impact in the unlikely event that it would occur.

The 6.9-kV start buses enter the turbine building spaced approximately 10 feet centerline-to-centerline and continue on this spacing across the building.

The 6.9-kV unit boards are indoor, metal-clad switchgear with electrically operated, horizontal drawout breakers with stored energy mechanisms and are mounted on floor El. 701'-2" between the two start buses. The 6.9-kV common boards are the same type switchgear as the 6.9-kV unit boards and are mounted on floor El. 732'-0" above the two start buses. The start buses are tapped at appropriate places to enter the unit boards supply breakers through the tops of the boards and the common boards supply breakers through the bottoms of the boards. The normal and alternate supply breakers for each board are separated along the length of the board by several load feeder breakers.

The unit station service transformers are located in the transformer yard, west of the turbine building and directly under the delta section of the isolated-phase main generator bus. The unit station service buses are of outdoor construction until they enter the turbine building where the construction changes to indoor type. After entering the turbine building, the unit station service buses are routed to the appropriate supply breakers in the 6.9-kV unit boards and 6.9-kV common boards, entering through the tops of the 6.9-kV unit boards and the bottoms of the 6.9-kV common boards. The unit station service buses routed to the 6.9-kV common boards have a section removed.

All of the station service buses (unit and common) are nonventilated, nonsegregated, metal-clad dripproof construction referenced in ANSI C37.20. In addition, the outdoor portions are weatherproof and equipped with 120V 1-phase heaters to prevent condensation inside the bus conductor insulation or supporting insulators. All buses are provided with gas-resistant seals at entry to a piece of switchgear. At the penetration of an outside building wall, the buses are provided with a 2 hour rated firestop.

It is the TVA position that the offsite power system is not required to withstand the design basis phenomena of GDC 2. An onsite electrical power system is provided, consistent with the requirement of GDC 17, for this purpose.

8.2.1.4 <u>Arrangement of Switchyard Control and Relaying Panels</u>

Figure 8.2.1-6 shows the physical arrangement of the relay and main control rooms where the relay, control, and 250V dc control power distribution panels are located.

The protective and auxiliary relays for CSSTR's A, B, and C are parts of two separate groups of duplex relay boards located in the relay room. The switchboard wire used for wiring in the relay and control boards is insulated with cross-linked polyethylene.

The control switches, indicating lights, and indicating instruments associated with the two CSSTR supplied offsite power circuits are located on panels 5, 4, and 2 of the electrical control board (ECB) in the main control room. Circuit A controls are on ECB panel 5, circuit C on ECB panel 4, and circuit B on ECB panel 2. The control board panels are of unitary construction with full side panels and rear doors.

For Unit 1 and 2, the control switches and indicating instruments associated with the USST supplied power circuit are located on panel 1M1 and 2M1 of the unit control board in the main control room.

The control switches for the 161-kV power circuit breakers and motor-operated disconnect switches are mounted together with the corresponding indicating lights on the benchboard part of each panel. The control switches for the 6900V start bus feeders and associated indicating meters are located above the switches on the vertical part of the board.

Non-safety related control power for power circuit breakers and associated protective relays is provided from the 250V DC power systems as shown in Figures 8.2.1-3 and 8.2.1-4 via circuit breakers on panels 6, 7, and 8 of the control room DC distribution board. Physical isolation of control power supplies for control of the two preferred power circuits is achieved by metal barriers between adjacent panels.

Two separate 250V DC buses are provided in these three panels, bus 1 in panels 7 and 8 and bus 2 in panel 6. Each bus can be fed from one of the two 250V battery boards through manual, mechanically interlocked, nonautomatic circuit interrupters. Normally, bus 1 is fed from battery board 1 and bus 2 from battery board 2. The power circuit breaker and associated relay control circuits are allocated to these two DC buses on the basis of switchyard connections. Thus, circuits related to the 161-kV buses 1 and 2, section 2, are fed from the DC bus 2, and those related to 161-kV buses 1 and 2, sections 3 and 4 (with the exception of power circuit breaker No. 924) are connected to DC bus 1. This allocation of control circuits ensures that the control and relay circuits of the three CSSTR's are fed from two independent DC distribution buses and that failure of one DC bus cannot cause the loss of all CSSTR's (A, B, and C). Each circuit is protected by a circuit breaker and supervised by an amber indicating light located on recording and instrument board panel No. 5. These indicating lights are grouped on the panel on the basis of the DC buses they are connected to, and their wiring is physically separated on the panel on the same basis.

A 480V AC distribution system provides the power required for the 161-kV motor-operated disconnect switches (MODs) and air compressors associated with each airblast 161-kV power circuit breaker. ABB 161-kV SF6 breakers have spring charging motors instead of air compressors. These motors are normally powered from the 480V AC distribution system. On loss of the 480V AC normal supply the SF6 breakers automatically transfer to a 250V DC alternate supply. Two separate 6900V feeders from the 6.9-kV common boards supply four 6900V-480V transformers. The 480V distribution systems are ungrounded and provided with a ground indicating light. Each of the four distribution cabinets, located in the 161-kV switchyard, can be supplied from either of two transformers via a normal or an alternate feeder. The selection, at each cabinet, between the two feeders is by means of manually-operated, mechanically-interlocked, nonautomatic circuit interupters. The two 6900V feeders are so arranged and rated that each one can feed all four transformers if required. The allocation of individual loads to the distribution cabinets is based on the arrangement of 161-kV connections. Two cabinets, fed from different 6900V sources, supply loads associated with 161-kV bus 2, section 2, and bus 1, section 4. The two other cabinets supply loads associated with 161-kV bus 1, section 2, and bus 2, section 4.

This corresponds to the allocation of the 250V DC control supplies described above. CSSTR A & B have a further division of load arrangement with respect to the two 161-kV circuit breakers (air blast types) and motor operated disconnect switches. The air compressor for each air-blast breaker is supplied power from a different AC distribution cabinet. The two motor-operated disconnect switches associated with each of the two power circuit breakers are also connected to separate AC supplies.

In addition to the indicating lamps and instruments, the control room operator is provided with an annunciation system which, for the 161-kV and 500-kV switchyard, the unit station service transformers, and the common station service transformers, monitors the following:

Operation of any 161-kV power circuit breaker.

Abnormal air pressure in the LP System for each airblast 161-kV power circuit breaker.

Abnormal air pressure in the HP System for each airblast 161-kV power circuit breaker.

Operation of any 500-kV circuit breaker.

SF6 system or spring energy abnormal

Operation of 161-kV bus breakup relays.

Operation of 161-kV bus differential relays.

Breaker supply voltage failure.

Phase failure at any switchyard 480V distribution cabinet.

Relay operation on each transformer circuit.

High temperature of each transformer.

Low oil level in each transformer.

Cooling System supply transfer for each transformer.

Gas pressure abnormal in each transformer.

Fire Protection Sprinkler System on for each transformer.

Breaker failure relay operation for each transformer.

6900V start bus failure or undervoltage.

6900V start bus fan failure.

6900V start bus transfer.

*250V DC control power failure.

250V DC battery charger failure.

250V DC battery board breaker trip or ground.

*Control power failure alarm is initiated by automatic trip of any 250V DC branch circuit breaker in the distribution panels 6, 7 and 8

8.2.1.5 Switchyard Control and Relaying

The 161-kV switchyard is of the main and transfer bus type with sections arranged in a zigzag pattern. This type bus arrangement has two main buses located on opposite sides and opposite ends of the switchyard and two transfer buses located similarly, thus providing physical separation of the main and transfer buses to reduce the likelihood of a single event causing failure of all buses.

CSSTR C, the intertie transformer bank 5, and the main transformer bank No. 2 are terminated in the bus-tie double breaker bays. In the CSSTR A and B bays, the power circuit breakers connected to the transfer bus also serve as a spare breaker for the lines connected to its corresponding main bus section.

Under normal operating conditions all 161-kV circuit breakers and all bus sectionalizing MOD’s are closed; all bus sections (main and transfer) are energized, and the line MOD's connected to the transfer bus are open.

This switchyard connection scheme operates two of the CSSTR’s in parallel with each other and with the transmission network. CSSTR B is connected to the 161-kV system but does not normally carry load. In the event CSSTR A or C becomes unavailable, the loads supplied by that transformer will be transferred to transformer B. This enhances the reliability of the power supply to the onsite power system from the transmission network in that either circuit is constantly available to perform its design function. At the same time adequate means of electrical isolation of faults are provided to prevent simultaneous loss of both transformers. The means of isolation and protection of the transformers includes:

1. Primary and backup relay protections selected and applied on the basis of long-term operating experience with this type of switchyard arrangement.

2. High-speed power circuit breakers (PCB's) with a tripping time of two cycles having adequate operating and interrupting rating and equipped with redundant trip coils tripped by separate relays.

3. Motor-operated disconnect switches which can be remotely controlled by the operator from the main control room to rapidly isolate sections of the switchyard bus transmission lines and circuit breakers for maintenance or repair.

4. Automatic protection against failure of individual circuit breakers to clear faults.

5. Provision for automatic high and standard speed reclosure of circuit breakers, following certain categories of line faults, to increase the availability of transmission lines from the distribution network.

The design of the offsite power system with its provision of two immediate access circuits from the transmission network, complies with the NRC regulatory position expressed in the Regulatory Guide No. 1.32 Rev. 2 for the preferred design of such a system.

The transmission line relay protection circuits continuously monitor the conditions of the offsite power system and are designed to detect and isolate the faults with maximum speed and minimum of disturbance to the system.

The principal features of these schemes are described below:

The 161-kV lines are protected by three-zone (reversed third zone) step distance phase relays with backup ground relays. The relay potential circuits are fed from a set of potential transformers connected to each main bus section.

The 161-kV transmission line protective relays system is designed to maximize the reliability of the incoming power to the plant. The protective relaying provides for fast detection of faults and should the transmission line protective relays fail to clear the fault, adequate backup protection is available in the form of bus breakup relays. The bus breakup relays consist of impedance and ground relays that initiate a timer. If the fault is not cleared within the time setting of the timer, all breakers connected to the bus section of the faulted line will be tripped and locked out.

Each 161-kV switchyard bus section is protected by a bus differential relay scheme. The bus differential relays continuously monitor the current inflow and outflow from the bus section under their supervision. Whenever the current inflow does not equal the current outflow, the relays operate instantaneously to trip and lock out all breakers in their protected bus section. The bus breakup relays back up the differential relays should they fail to operate. In addition to the line and bus protection schemes, the 161-kV switchyard power transformer breakers are protected by breaker failure relays with current supervision from separate current transformers on the breaker. The breaker failure relays operate through a timing relay and should a breaker fail to trip within the time setting of its timing relay, the associated breaker failure trip relay will trip and lock out both breakers in that particular switchyard bay. The relay will also trip and lock out all breakers connected to the bus associated with the failed breaker. In addition, the breaker failure relays protecting generator 2 power circuit breakers, when operated, will trip turbine steam valves, exciter field breakers, and the associated 6.9-kV breakers on unit station service transformers. Any of the breaker failure relays associated with the intertie transformer bank 5 PCB's will trip and lock out all PCB's connecting it to both the 161-kV and 500-kV switchyards.

The five power transformers (CSSTR’s A, B, and C, main transformer bank No. 2, and intertie transformer bank No. 5) are protected as follows:

Each CSSTR is protected by a percentage differential relay with harmonic restraint, a sudden pressure relay, and a neutral overcurrent relay in the 6.9-kV winding neutral.

The operation of the transformer protection relays will trip and lock out the power circuit breakers connecting it to the switchyard, trip and lock out associated 6.9-kV circuit breakers, and starts a high-pressure sprinkler system to prevent or extinguish any possible fire.

The intertie transformer bank No. 5 is protected by a percentage differential relay with harmonic restraint, nondirectional, torque-controlled overcurrent relays and sudden pressure relays. The sudden pressure relays on this transformer will operate to isolate the transformer from both the 161-kV and 500-kV switchyards and the transformer high-pressure fire protection sprinkler system will be started by thermal devices or a sudden pressure device on the transformer.

The main transformer bank No. 2 is protected by differential and sudden pressure relays whose operation trip and lock out the 161-kV breakers connecting it to the switchyard, and the associated 6.9-kV breakers fed from the unit station service transformers and trip the turbine steam valves and exciter field breaker. In addition, the main bank No. 2 transformer protection relays will also trip and lockout the generator circuit breaker.

The supply to the CSSTR’s possesses a high degree of reliability even under electrical fault conditions. The following discussion describes the sequence of events following postulated faults:

1. Transmission line fault.

   If the instantaneous element of the line protective relays is actuated the line breaker is tripped and a high speed reclosure occurs. If after the high speed reclosure the fault has not cleared, the breaker will trip again and a standard speed (synchronism check-voltage check) reclosure occurs. In the majority of the cases these reclosures will restore the line back to service. However, a trip after this will lock out the breaker isolating the faulted line. There is no appreciable disturbance on the feeders to the CSSTR’s.

2. Transmission line fault and failure of the line circuit breaker to clear the fault.

   The corresponding main bus breakup relay is automatically initiated, starting a timer. If the fault is not cleared within the time setting of the timer, all circuit breakers connected to that bus will be tripped and locked out. With normal position of circuit breakers and MOD's described previously, all CSSTR's (A, B, and C) continue to receive power without interruption.

3. Main bus fault.

   This type of fault is detected by the bus differential protection. When initiated, it trips and locks out the circuit breakers connected to the faulted bus. The effects of this action are similar to those described under 2 above.

4. Transformer or transformer feeder faults.

   These faults cause tripping of all the transformer circuit breakers on the high and low voltage side of the transformer. In addition, the trip relay initiates the transformer fire protection sprinkler and starts the fire pump if the fault is in the transformer.

5. Common transformer or transformer feeder fault and failure of one HV circuit breaker to operate properly.

   These events cause the operation of protection described under 4 above, followed by the operation of the breaker failure relay which trips all breakers connected to the bus at the time of failure. The event results in the loss of one transformer; the other transformers continue to receive power from their main or alternate bus.

The allocation of the 250V DC control power circuits for relays, circuit breaker, and MOD operation (the description of which is included in the preceding section) is coordinated with the switching requirements of the zig zag main and transfer bus arrangement and the requirement for the optimum availability of the CSSTR's.

8.2.1.6 <u>6.9-kV Start Board Control and Relaying</u>

The secondaries of the CSSTRs A, B, and C feed into a 6.9-kV start board containing eight circuit breakers. These breakers are the normal and alternate supply breakers for the four start buses. Start buses 1A and 2A are normally fed from CSSTR A, and start buses 1B and 2B are normally fed from CSSTR C. Transfer to CSSTR B may be automatic or manual but transfer back to the normal source is manual only. There are two automatic transfers to CSSTR B from either CSSTR A or C. Fast transfer is initiated in the event a fault is sensed within the CSSTR, or other transformers supplied from the common source. The other automatic transfer is a slow bus transfer which is initiated by bus undervoltage on the normal feeder (< 70 percent of nominal). The transfer is delayed until the bus residual voltage has decayed to 30 percent of nominal and if the alternate feeder voltage is $\geq$ 90 percent of nominal. Fast transfers are defined as $\leq$ 6 cycle transfers. Both CSSTR A and C can transfer their loads to CSSTR B at the same time automatically for either a fault or undervoltage condition. Manual transfer of the 1A, 1B, 2A, and 2B start bus uses a “make before break” transfer scheme. The undervoltage condition is annunciated in the main control room (MCR).

Each of the four start buses has its own undervoltage detection scheme which will initiate a transfer to its alternate supply (CSSTR B). If an undervoltage transfer of only one start bus occurs then the start board breaker interlock scheme will prevent subsequent start bus transfers except from the same transformer. See Table 8.2.1-1 for complete description of board transfer schemes.

The 250V DC control power for the breakers feeding start bus 1A and 2A is supplied from a battery and battery distribution board separate from that of the breakers feeding start buses 1B and 2B.

The board is protected by overcurrent, ground overcurrent, and differential current protective relays. Manual control of the circuit breakers is provided on the electrical control board in the main control room. The operator has instrumentation showing the voltage on each of the two buses and current flowing in each of the four feeder breakers. The following annunciation is provided:

1. Start Bus Fan Failure
2. Start Bus Transfer
3. Start Bus Failure or Undervoltage

Annunciation of No. 3 above is composed of bus differential relay operation, bus AC voltage failure, and control bus DC voltage failure.

Start bus 1A is the alternate feeder to 6.9-kV unit boards 1A and 1C. Start bus 1B is the alternate feeder to 6.9-kV unit boards 1B and 1D. Start Bus 2A is the normal feeder to 6.9-kV common board A. Start bus 2B is the normal feeder to 6.9-kV common board B. Start bus 2A is the alternate feeder to 6.9-kV unit boards 2A and 2C. Start bus 2B is the alternate feeder to 6.9-kV unit boards 2B and 2D.

8.2.1.7 <u>6.9-kV Unit Board Control and Relaying</u>

The normal feeder to each 6.9-kV unit board is from a USST and the alternate feeder is from one of the start buses.

Each 6.9-kV unit board can be selected for manual transfer between the normal and alternate supply breakers. Manual transfers are high speed (6 cycles or less), and can be made from the normal to the alternate supply or from the alternate to the normal supply. Automatic transfers can only be made from the normal to alternate supply. Automatic transfers initiated by loss of voltage (less than 70 percent of nominal) on the unit board are delayed until the voltage decreases to 30 percent of normal while those initiated by detection of failure of the generator circuit breaker, the power circuit breakers, the main bank or until station service transformers, the isolated phase bus, and the main bank transformer feeder are immediate high speed transfers (6 cycles or less). See Table 8.2.1-1 for complete description of board transfer schemes.

The boards are protected by overcurrent, ground overcurrent, and differential current protective relays. Manual control of the two feeder breakers of each board is provided on the unit control board in the main control room. The operator has instrumentation that gives the voltage and frequency of each board and the current flowing in either of the two feeder breakers. The following annunciation is provided:

1. Unit Board Transfer
2. Unit Board Failure or Undervoltage

Annunciation of No. 2 above is composed of board differential relay operation, board AC voltage failure, and control bus DC voltage failure.

The final link to the onsite (standby) power system (the 6.9-kV shutdown boards) is feeders from the unit boards. Unit boards 1B, 1C, 2B, and 2C are the normal supplies to 6.9-kV shutdown boards 1A-A, 1B-B, 2A-A, and 2B-B, respectively, while unit boards 1A, 1D, 2A, and 2D are the alternate supplies respectively. These feeders are protected by overcurrent and ground overcurrent relays. All of these feeder breakers are normally closed with all transfers between the normal and alternate feeders occurring at the 6.9-kV shutdown board and are manual only.

8.2.1.8 Conformance with Standards

This section discusses provisions included in the design of the offsite power system to achieve a system design in conformance with applicable requirements of GDC 17, Regulatory Guides 1.6 Rev. 0, and 1.32, Rev. 2.

The following requirements of Regulatory Guides 1.6 Rev. 0 and 1.32, Rev. 2, and GDC 17 are applicable:

Regulatory Guide 1.6

Regulatory Guide 1.6, Rev. 0 requires that "Each ac load group should have a connection to the preferred (offsite) power source. A preferred power source may serve redundant load groups."

Regulatory Guide 1.32

Regulatory Guide 1.32, Rev. 2 states that "Criterion 17 delineates the design requirements regarding availability of power from the transmission network. Accordingly, a preferred design would include two immediate access circuits from the transmission network. An acceptable design would substitute a delayed access circuit for one of the immediate access circuits provided that availability of the delayed access circuit conforms to General Design Criterion 17."

Criterion 17

General Design Criterion 17 requires that:

(1) "the offsite power supply be of sufficient capacity and capability to assure, assuming the onsite (standby) power supply is not functioning, that

   (a) specified acceptable fuel design limits and design conditions of the reactor coolant pressure boundary are not exceeded as a result of anticipated operational occurrences.

   and

   (b) the core is cooled and containment integrity and other vital functions are maintained in the event of postulated accidents."

(2) "electric power from the transmission network to the onsite electric distribution system shall be supplied by two physically independent circuits (not necessarily on separate rights of way) designed and located so as to minimize to the extent practical the likelihood of their simultaneous failure under operating and postulated accident and environmental conditions. A switchyard common to both circuits is permitted."

(3) each of the two circuits supplying electric power from the transmission network to the onsite electric distribution system "shall be designed to be available in sufficient time following a loss of all onsite alternating current power supplied and the other offsite electric power circuit, to assure that specified acceptable fuel design limits and design conditions of the reactor coolant pressure boundary are not exceeded."

(4) one of the two circuits supplying electric power from the transmission network to the onsite electric distribution system "shall be designed to be available within a few seconds following a loss-of-coolant accident to assure that core cooling, containment integrity, and other vital safety functions are maintained."

(5) "provisions shall be included to minimize the probability of losing electrical power from any of the remaining sources as a result of, or coincident with, the loss of power from the transmission network, or the loss of power from the onsite electrical power sources."

Each of the above requirements and the provisions included in the design to meet them is addressed in some form in the discussion which follows:

The discussion is arranged in two parts:

(1) Physical measures for achieving independence and physical measures taken to minimize the likelihood of failures of portions of the offsite power system inducing failure of the other power sources.

(2) Functional provisions for achieving adequate capacity, capability, and availability; functional measures taken to achieve independence; and functional measures taken to minimize the likelihood of failure of portions of the offsite power system inducing failure of other power sources.

<u>Physical Measures</u>

The CSSTR's and buses are connected and arranged to provide two physically independent offsite power circuits to the onsite distribution system. Any one of these can be used as the preferred power supply.

For physical description and characteristics of the common station service buses, see Section 8.2.1.3.

The above ground buses run on separate support structures and run approximately 40 feet before entering the start board: The underground cable buses are located in conduit and run approximately 250 feet before entering the start board. The above ground buses are provided with gas resistant seals at the entry to the switchgear. The start board consists of a normal feeder breaker and an alternate feeder breaker for each start bus which obtain their supply from separate buses and separate CSSTR's, thereby giving each start bus two possible and independent sources of power. The normal supply breaker and the alternate supply breaker for each start bus are separated in the start board by two cubicles, therefore, preventing a fault in one breaker from causing damage to the alternate supply breaker.

From the feeder breakers of the 6.9-kV start board the four 6.9-kV unit start buses run as pairs (1A and 1B, 2A and 2B), each pair on a common support structure parallel and adjacent to the south turbine building wall [redacted] Horizontal spacing of the start buses for this run is 4'-6 inches from centerline-to-centerline and 12 inches minimum between adjacent enclosure walls of the separate buses and minimum vertical spacing is 2'-6 inch centerline-to-centerline with 11-5/16 inches between adjacent enclosure walls of the separate buses. The conductors are fully insulated with flame-retardant material, bus supports are flame retardant, and the metal enclosures will prevent any arcing fault in one bus from damaging the other bus.

The start buses are tapped at appropriate places and routed to the appropriate supply breakers in the 6.9-kV unit and 6.9-kV common boards. The normal supply breaker and alternate supply breaker for each board are separated along the length of the board by several feeder breakers, thereby preventing a fault in one breaker from damaging the alternate supply breaker. All buses are provided with gas-resistant seals at entry to the switchgear.

The power from the unit boards is supplied to the shutdown boards by means of cables routed via separate cable trays and conduits to their respective boards. The minimum distance between trays carrying the normal and alternate cables to the redundant shutdown boards is approximately 30 feet, while the trays carrying normal and alternate supplies to the same shutdown board are at a minimum separation of 1 foot. Circuit breakers have been provided at each end of these cables so that even a simultaneous failure of the normal and alternate supply cables to one shutdown board will not effect the offsite power supply to the redundant board.

During the case of failure or fault of a CSSTR, the spare CSSTR is immediately available if not already providing distribution for the other CSSTR. Refer to Table 8.2.1-1 for transfer information.

Functional Measures

Regulatory Guide 1.6, Rev. 0 has been implemented by providing each redundant load group with a connection to each of the preferred source circuits. Figure 8.1.2-1 indicates that when supplied by preferred power circuits, the redundant load groups in each unit are normally fed from different preferred power source circuits. Figure 8.1.2-1 also indicates that alternate feeder alignments at the start buses may result in feeding redundant load groups in each unit from a common preferred power source circuit. The two preferred power source circuits are shared between the two nuclear units.

Regulatory Guide 1.32, Rev. 2 has been implemented by providing an immediate and delayed access circuits to the transmission network. Figures 8.1.2-1 and 8.2.1-1 indicate the functional arrangement of these continuously-energized circuits.

The rest of the discussion deals mainly with the manner in which GDC 17 has been implemented.

Refer to section 8.2.1.1 for the components that comprise the preferred power system. Analysis to show that GDC 17 is satisfied consists of two parts: (1) a qualitative analysis to show that the loss of any one of the components will not cause loss of availability of offsite power to the 6900-volt shutdown boards, and (2) a quantitative analysis to show that the capacity of each of the components is such that it will carry its required load in the event of a simultaneous LOCA of one unit and orderly safe shutdown of the other unit with any of the other components out of service.

Refer to sections 8.2.1.2 and 8.2.1.3 for arrangement details for the components of the preferred power system. Each CSSTR has two 6.9-kV secondary windings. Each secondary of CSSTR's A and C is the normal source for one start bus with CSSTR B providing the alternate source. Each Unit 1 start bus serves as the alternate source to two of the four Unit 1 6.9-kV unit boards; while each Unit 1 USST serves as the normal source to two of the four Unit 1 6.9-kV unit boards. Each Unit 2 start bus serves as the alternate source to two of the four Unit 2 6.9-kV unit boards; while each Unit 2 USST serves as the normal source to two of the four Unit 2 6.9-kV unit boards. Each of the two 6900-volt shutdown boards for each unit has a normal feed from one unit board and the alternate feed from another unit board. The two unit boards feeding each shutdown board have alternate feeds from different start buses which have automatic transfers to CSSTR B. Unit 1 and 2 6.9-kV unit boards have automatic transfers from the normal feed (USST) to alternate feeds (start buses) as specified in Section 8.2.1.7. Refer to Table 8.2.1-1 for board transfer information. For Unit 1 and 2, the loss of any one USST will not cause loss of availability of offsite power to the 6.9-kV shutdown boards.

The four start buses are physically independent in that each bus has its own housing. Thus each bus is protected against migration of a fault from the other start bus by two barriers. This circuit independence extends through the start board on to the common station service transformer terminals.

In the event of a LOCA on one generating unit and a orderly safe shutdown on the other generating unit when unit boards are aligned to CSSTR’s and one CSSTR is out of service, the two remaining CSSTR’s will supply power to the emergency loads on the LOCA unit and to those loads on both units associated with normal operation which are not automatically tripped. These normal operation loads are subsequently reduced by action of the unit operators. However, no operator action is assumed during the first 10 minutes following a LOCA. All loads on both 6900-volt shutdown boards which start automatically are assumed to start simultaneously. All unit normal running loads are assumed to remain without reduction following the accident signals, except those loads automatically tripped.

When each USST automatic load lap changer (LTC) control switch is set to automatic, that USST is capable of carrying its required load in the event of a simultaneous LOCA of one unit and orderly safe shutdown of the other unit with any of the components of the preferred power system out of service. When the 6.9-kV unit boards are aligned to USST's, a failure of a USST will initiate a transfer to a CSSTR, which will supply power as specified above (see unit board transfers in Table 8.2.1-1).

The overcurrent protective relays for the 6900-volt breakers are coordinated to provide a selective system for line faults and for ground faults. Thus a fault on a non-safety load circuit supplied from a 6900-volt unit board, will be isolated so that the continuity of power to that unit board and to the shutdown board fed from that unit board will not be jeopardized by the fault. Each 6900-volt unit board main bus is protected by bus differential relays which will isolate this bus in the event of a unit board bus fault. With the change in manual transfer scheme for start bus supply breakers, the Unit 1 and Unit 2 6.9 kV unit boards, and 6.9 kV turbine building common boards may be subjected to a momentary exposure of fault current that exceeds their rating. This condition only occurs while the start bus is being supplied by both transformers during a manual transfer. Due to the low probability of a close-in three phase fault occurring while this parallel configuration exists, this does not impose a significant risk to the switchgear.

In addition to compliance with the above standards for portions of the offsite power system, the 6.9-kV start board, 6.9-kV unit boards, and the associated 6.9-kV buses were procured in accordance with TVA standards and industry standards. TVA specification 1101 required conformance of this equipment to such standards as the following. The overall construction, rating, tests, service conditions, etc., are required to be in conformance to ANSI C37.20 and NEMA SG-5; the power circuit breakers are referenced to ANSI C37.4 to C37.9 and NEMA SG-4; associated relays are specified to conform to ANSI C37.1, instrument transformers to ANSI C57.13 and NEMA EI-02 and wiring to IPCEA S-61-402 and NEMA WC5.

The design of the equipment arrangement was also implemented to comply with GDC 3 for fire protection and with GDC 18 and Regulatory Guide 1.22 for ease of periodic tests and inspections.

8.2.2 Transmission System Studies (TSS)

The eight 161-kV transmission lines connected to the 161-kV switchyard, the 500-161-kV intertie transformer bank, two 84 MVAR capacitor banks for the 161-kV switchyard, and the five 500-kV transmission lines have sufficient capacity to supply the total required power to the plant's electrical auxiliary power system for all modes of plant operation and shutdown. For the normal internal plant load alignment, the TVA transmission system must be capable of supplying a minimum of 153 kV with a maximum voltage drop of 13 kV during a loss of coolant accident (LOCA) in one unit, followed by an orderly safe shutdown of the other unit. Physical separation of the lines, primary and backup protection systems, and a strong transmission grid minimize the probability of simultaneous transmission failures affecting the offsite power sources.

Steady state analysis shows that the transmission network is a reliable supply to the preferred power system for all modes of plant operation and shutdown.

Steady-state load flow studies have been performed of power flow around the Sequoyah 500- and 161-kV buses for design-basis event scenarios consisting of a shutdown with a LOCA in one unit . This analysis of system adequacy to safely shutdown the SQN units includes scenarios that simulate an outage of the largest generating unit or the loss of the most critical element prior to the DBE. Transient stability studies were also performed for a LOCA shutdown of one unit. Additional stability studies (with no design-basis event) considered transmission contingencies resulting in the loss of one or more components. They show that the resulting disturbance to the offsite power system is acceptable, and the transmission system remains stable. In none of the steady-state or transient stability design-basis event cases was the off-site power sources incapacitated because of thermal over loads, voltage variations or frequency deviations so as to decrease the availability of the transmission system to supply power to the onsite power system.

Due to the large number of diverse generating units and strong interconnections, the likelihood of an outage of a sufficient part of the transmission system to cause the loss of all sources of external power is considered to be extremely remote. In the event such a disturbance occurs, TVA's power dispatchers will isolate the Sequoyah 161-kV switchyard with hydro generation within the proximity of Sequoyah so that critical power needs can be supplied.

TABLE 8.2.1-1 (Sheet 1)

AUXILIARY POWER SUPPLIES AND BUS TRANSFER SCHEMES

General Remarks:

1. Start Bus 1A, 1B, 2A and 2B supply breakers parallel sources when manually transferring.

2. Unit 1 is shown. Unit 2 is similar except for unit designation. Unit 2 is shown for those exceptions.

Item	Board/Bus	Power Supplies Normal	Power Supplies Alternate	Remarks
1	6.9-kV Start Bus 1A	Common Station Service Trans A, X Winding	Common Station Service Trans B, X Winding	The secondaries of the CSSTR's A, B, and C feed into the 6.9-kV start board containing eight circuit breakers. These breakers are the normal and alternate supply breakers for the four start buses. Start buses 1A and 2A are normally fed from CSSTR A, and start buses 1B and 2B are normally fed from CSSTR C. Transfer to CSSTR B may be automatic or manual but transfer back to the normal source is manual only. There are two automatic transfers to CSSTR B from either CSSTR A or C. Fast transfer is accomplished by having the start board breakers control switches in the auto position and is initiated in the event a fault is sensed within the CSSTR, other transformers supplied from the common source, or in the supply sources to the CSSTR. The other automatic transfer is a slow bus transfer which is initiated by bus undervoltage. The slow bus transfer is accomplished by having the start board breaker control switches in the auto position and is initiated by undervoltage on the normal feeder (< 70 percent of nominal) and is delayed until the bus residual voltage has decayed to 30 percent of nominal and if the alternate feeder voltage is ≥ 90 percent of nominal. Fast transfers are defined as ≤ 6 cycle transfers. Manual transfers on Start Bus 1A and 1B are achieved by closing the standby transformer feeder breaker, observing a closed indication as well as load pickup, and opening the original feeder breaker. Start Bus 1A and 1B can transfer load to CSSTR B while CSSTR B is supplying load to the other Unit 1 bus. The undervoltage condition at 70 percent nominal voltage is annunciated in the main control room (MCR).
2	6.9-kv Start Bus 1B	Common Station Service Trans C, Y Winding	Common Station Service Trans B, Y Winding	
2A	6.9-kv Start Bus 2A	CSST A Y Winding	CSST B Y Winding	
2B	6.9-kv Start Bus 2B	CSST C X Winding	CSST B X Winding	
3	6.9-kv Unit Board 1A	USST 1A	START BUS 1A	Manual transfers and automatic transfers (except loss-of-voltage) are fast transfers (≤ 6 cycles). Automatic transfers are initiated upon the following: Loss-of-voltage at unit board: (at board voltage ≤ 70% opens normal breaker, at board voltage ≤30% closes alternate breaker). Generator circuit breaker failure: (detection that current is flowing through GCB after trip) Power circuit breaker failure: (same as GCB failure but for PCB 5034 and 5038) Failure of main bank transformers: (transfers upon detection of current differential, sudden pressure, overcurrent, internal fault) Failure of USST: (transfers upon detection of current differential, sudden pressure, overcurrent, V/Hz limit exceeded) Failure of Isolated phase bus/main bank transformer: (transfers upon impedance protection detection of fault, detection of current differential) Failure of main bank transformer feeder: (transfers upon detection of current differential on feeder from switchyard to main bank transformer)
4	6.9-kV Unit Board 1B	USST 1A	START BUS 1B	
5	6.9-kv Unit Board 1C	USST 1B	START BUS 1A	
6	6.9-kv Unit Board 1D	USST 1B	START BUS 1B	

TABLE 8.2.1-1 (Sheet 2)

AUXILIARY POWER SUPPLIES AND BUS TRANSFER SCHEMES

Item	Board/Bus	Power Supplies Normal	Power Supplies Alternate	Remarks
15	6.9-kV Shutdown Board 1A-A	6.9-kV Unit Board 1B	6.9-kV Unit Board 1A Standby - Diesel Gen 1A-A	Transfer between the normal and alternate sources will be manual fast transfer (≤ 6 cycles). Loss-of-bus voltage (≤ 80 percent) for 1.25 seconds starts the diesel generators, trips incoming feeder breakers and most motor breakers. When diesel generator is up to rated speed and voltage, the emergency breaker will close automatically to connect the diesel to the board, and loads will be applied as required by a sequential timer. Return to normal supply is manual only and is a fast transfer (≤ 6 cycles). Normal or alternate feeder breaker is tripped and annunciated in the MCR after a time delay of 1.25 seconds on loss of voltage condition at 80% nominal. Transfer to the diesel generator for a sustained degraded undervoltage (UV) is initiated at setpoint 9.5 seconds (if a SI has been initiated, or is subsequently initiated) and 5 minutes for non-SI if below setpoint of 93.5% nominal. MCR annunciation occurs for UV of 93.5% nominal and overvoltage of 105% nominal. Transfer to the diesel generator for a sustained unbalanced voltage is initiated upon makeup of the designed permissive 1 out of 2 logic. MCR annunciation occurs when the alarm relay (permissive) actuates ahead of a full logic actuated trip. The shutdown utility bus allows any 6.9-kV shutdown board to be connected to any other or all other 6.9-kV shutdown boards. All circuit breakers connected to this bus are normally open and disconnected. Use of the bus requires manual insertion and closing of two of the breakers.

EQUIPMENT-ELECTRICAL CONTROL
AREA PLAN-EL 732.0
(REVISED BY AMENDMENT 13)

8.3 ONSITE POWER SYSTEM

The Class 1E electric systems provide the electric power used to safely shut down the reactor and limit the release of radioactive material following a design basis event. The electric systems included are comprised of the following interrelated systems:

1. Alternating-current (AC) power systems.
2. Direct-current (DC) power systems.
3. Vital instrumentation and control power systems.

8.3.1 Alternating Current (AC) Power System

The onsite AC power system is a Class 1E System, which consists of: (1) the Standby AC Power System, and (2) the 120V Vital AC System. The safety function of the Standby Power System is to supply power to permit functioning of components and systems required to assure that (1) fuel design limits and reactor coolant pressure boundary design conditions are not exceeded due to anticipated operational occurrences, and (2) the core is cooled and vital functions are maintained in the event of postulated accidents, subject to loss of the Preferred Power System and subject to any single failure in the Standby Power System. The safety function of the 120V Vital AC System is to supply power continuously to reactor protection, instrumentation, and control systems; engineered safety features instrumentation, and control systems; and other safety-related components and systems, subject to loss of all AC power and any single failure within the Vital AC System.

8.3.1.1 Description

Standby AC Power System

The Standby AC Power System is a safety-related system, which supplies power for energizing all AC-powered electrical devices essential to safety. Power continuity to the 6.9-kV Shutdown Boards is maintained by switching among, the normal source (from a unit board), the alternate source (from a different unit board), and the standby (onsite) source. The feeders are also known as the normal, the alternate, and the emergency, respectively. Source selection for a loss of voltage is accomplished by automatically transferring from the normal or alternate source to the standby source. The reverse transfer is manual. The circuits connecting the normal, alternate, and standby sources to the distribution portion of the Standby Power System are shown in Figure 8.1.2-1. The normal and alternate power circuits and the transfer scheme used to effect the source switching of these circuits is further discussed in section 8.2.

System Structure

Figure 8.1.2-1 is the single line representation of the plant AC auxiliary power distribution system. The standby portion of the system is identified as the diesel generators, the 6.9-kV shutdown boards, the 480V shutdown boards, and all motor control centers supplied by the 480V shutdown boards for both units.

The Standby Power System serving each unit is divided into two redundant load groups (power trains). These power trains (train A and train B for each unit) supply power to safety-related equipment. The power train assignment for safety-related electrical boards is indicated by use of a -A, -B, or -S (special) suffix following its designation on drawings and documents. Loads supplied from these boards are safety-related unless designated on the single line drawings with a triangle symbol (▤). Nonsafety-related loads are supplied from the Standby Power System through Class 1E Overcurrent Protection Devices.

The sources and boards comprising each power train are listed in Figure 8.1.2-1.

The ERCW pumping station 480 VAC motor control centers, which have only a 1E power source, are an exception to the normal use of train separation nomenclature. Non-safety related

loads are powered from a portion of the 1E bus that is isolated (shunt tripped) on a loss of offsite power signal. Although these loads are designated with the ▤ symbol, they carry train designated nomenclature to verify they meet all the project separation criteria.

Physical Arrangement of Components

The boards, motor control centers, and transformers comprising the system are arranged to provide physical independence and electrical separations between power trains necessary for eliminating credible common mode failures.

The specific arrangements of these major components are described as follows:

Diesel Generators

Reference: Figure 1.2.3-17

The physical arrangement of the four diesel generators and all support equipment provides physical independence by isolation. Each diesel and its associated support equipment is separated from all other units by missile and fire barrier type walls and physical separation in the DGB corridor.

6900-Volt Shutdown Boards 1A-A, 1B-B, 2A-A, and 2B-B

Reference: Figure 1.2.3-3.

These boards are located in the auxiliary building at elevation 734.0. They are arranged electrically into two power trains with two boards associated with each train and each unit. The boards comprising train A are located in the unit 1 side and those of train B are located in the Unit 2 side. The train A boards are separated from the train B boards by an reinforced concrete block wall extended to the ceiling. The minimum distance between train A and train B boards is 9 feet (including the block wall). The two boards associated with each train are separated from each other by approximately 21 feet. The logic relay panels for both units are located between these panels.

6900-480-Volt Shutdown Board Transformers 1A1-A, 1A-A, 1A2-A, 1B1-B, 1B-B, 1B2-B, 2A1-A, 2A-A, 2A2-A, 2B1-B, 2B-B, and 2B2-B

Reference: Figure 1.2.3-2.

These transformers are located in the auxiliary building at elevation 749.0. Four rooms have been provided so that the transformers associated with train A and B of both nuclear units are in separate rooms. The walls isolating these rooms are made of reinforced concrete blocks and extend to the ceiling. The three transformers associated with one train of each unit are located in one of the four rooms and are separated from each other by an 8 foot tall reinforced concrete block wall.

480-Volt Shutdown Boards 1A1-A, 1A2-A, 1B1-B, 1B2-B, 2A1-A, 2A2-A, 2B1-B, and 2B2-B

Reference: Figure 1.2.3-3.

Each of these boards is located in a separate room in the auxiliary building at elevation 734.0. The isolating walls of these rooms are constructed of reinforced concrete blocks extending to the ceiling. Boards 1A1-A, 1B1-B, 2A1-A, and 2B1-B are in individual rooms. Boards 1A2-A, 1B2-B, 2A2-A, and 2B2-B are in rooms which also contain the control/auxiliary building vent boards. All boards in common rooms have a common unit power train relationship.

480-Volt Reactor MOV Boards 1A1-A, 1A2-A, 1B1-B, 1B2-B, 2A1-A, 2A2-A, 2B1-B, and 2B2-B

Reference: Figure 1.2.3-2.

These boards are located in the auxiliary building at elevation 749.0. They are located in separate rooms on a unit and train basis and are located in the same room as the reactor vent boards associated with the same unit and train. The 480-volt auxiliary building common board is in the room with MOV boards 1A1-A and 1A2-A. The isolating walls of these rooms are constructed of reinforced concrete blocks extended to the ceiling.

480-Volt Reactor Vent Boards 1A-A, 1B-B, 2A-A, and 2B-B

These boards are located in the rooms with the 480-Volt reactor MOV boards described above.

480-Volt Control/Auxiliary Building Vent Boards 1A1-A, 1A2-A, 1B1-B, 1B2-B, 2A1-A, 2A2-A, 2B1-B, and 2B2-B

These boards are located in the rooms with the 480-Volt shutdown boards described above.

480-Volt Diesel Auxiliary Boards 1A1-A, 1A2-A, 1B1-B, 1B2-B, 2A1-A, 2A2-A, 2B1-B, and 2B2-B

Reference: Figure 1.2.3-17.

These boards are located in the diesel generator building at elevation 740.5. They are located in separate rooms on a unit and train basis. The isolating walls of the rooms are reinforced, poured-in-place concrete.

6900-480-Volt Pressurizer Heater Transformers 1A-A, 1B-B, 1C, 1D, 2A-A, 2B-B, 2C, and 2D

Reference: Figure 1.2.3-2.

These transformers are located in the auxiliary building at elevation 759.0. Transformers 1A-A, 2A-A, 2D, and 1D are located in one room in the unit 1 area. Transformers 1B-B, 2B-B, 2C, and 1C are located in one room in the unit 2 area.

480 Volt ERCW Transformers and MCCs 1A-A, 1B-B, 2A-A, and 2B-B

Reference: Figure 1.2.3-14

These components are located in the ERCW Pumping Station at elevation 704. Transformers 1B-B and 2B-B and MCC's 1B-B and 2B-B are in one room. Transformer 1A-A and MCC 1A-A are located in a Unit 1 room. Transformer 2A-A and MCC 2A-A are located in a separate Unit 2 room.

System Operation

The 6.9-kV shutdown boards in each power train derive power from separate 6.9-kV unit boards or from their respective standby power source (diesel generator). The unit board power sources are discussed in section 8.2. During conditions where preferred (offsite) power is not available, each 6.9-kV shutdown board is energized from a separate standby diesel generator.

The alignment of each unit's standby distribution system is determined by plant conditions, the sources selected to energize it, and the status of components within the distribution system.

A loss of voltage ($\leq$ 80%) on the 6.9-kV shutdown board bus is detected by a two-out-of-three logic with a definite time delay, followed by trip of the normal and alternate feeder breaker, start the diesel generator, and trips major 6900V and 480V shutdown board loads (see Table 8.3.1-1). The transfer from normal to alternate and return to normal is initiated manually and is a high-speed transfer, completed in approximately six cycles or less. These transfer schemes are in Table 8.2.1-1.

Table 8.3.1-1 shows the loads that are automatically stripped. Figure 8.3.1-10 shows typical load stripping schematically. The generator will be automatically connected to the 6.9-kV shutdown board bus. This return of voltage to the 6.9-kV shutdown bus initiates logic which connects the required loads in sequence. Table 8.3.1-2 shows the order of applied major loads. The standby (onsite) power system's automatic sequencing logic is designed to automatically connect the required loads in proper sequence should the logic receive an accident signal concurrent with a loss of all offsite power.

To protect the Class 1E buses from a sustained degraded undervoltage, each of the two 6.9-kV Class 1E buses per unit is provided with a set of three instantaneous solid-state undervoltage relays. These relays have a nominal setpoint of 6456V (93.5 percent of nominal). The relays are arranged in a two-out-of-three coincidence logic to initiate three simultaneous time delay sequences.

(1) A time delay of 9.5 seconds is short enough to allow safety-related equipment to be powered within the time required by the safety analysis. At the end of 9.5 seconds if a SI signal has been initiated, or is subsequently initiated, the logic will trip the normal and alternate feeder breaker, start the diesel generator, and trips major 6900V and 480V shutdown board loads (see Table 8.3.1-1).

(2) A time delay of 30 seconds will ride through normal system voltage transients before annunciating the undervoltage in the main control room.

(3) A time delay of five minutes is long enough to allow operator action but not allow damage to connected safety-related equipment. At the end of five minutes, the logic will trip the normal and alternate feeder breaker, start the diesel generator and trips major 6900V and 480V shutdown board loads (see Table 8.3.1-1) if the voltage has not returned to normal.

To protect the Class 1E buses from a sustained overvoltage, each of the two 6.9-kV Class 1E buses per unit will be provided with a set of three instantaneous solid-state overvoltage relays. These relays are arranged in a one-out-of-three coincidence logic which will annunciate in the control room. The relays have a nominal voltage setpoint of 7260 volts (105 percent of nominal). The operator can take the action necessary to reduce the voltage.

To protect the Class 1E buses from a sustained degraded unbalanced voltage, the 1A-A, 1B-B, 2A-A, and 2B-B 6.9-kV Class 1E buses are provided with a set of three solid state phase unbalance relays (negative-sequence overvoltage relays). These relays are arranged in a permissive one-out-of-two coincidence logic where the alarm relay provides the permissive function with either the low or high trip relay providing the trip function. Each relay has a separate voltage setpoint and time delay. Unlike the other undervoltage protection, the setpoint is a comparison of each of the phases rather than a percentage of bus nominal voltage.

(1) The alarm relay alerts the main control room of an abnormal unbalanced voltage level and is needed to protect against equipment “loss-of-life” or long term motor degradation. Alarm nominal voltage setpoint is 1.30V with a time delay of 2.95s to ride through normal system unbalanced voltage transients before annunciating the unbalanced voltage in the main control room.

(2) The low trip relay protects against loss of safety function for the connected Class 1E loads. Low trip nominal voltage setpoint is 2.96V with a time delay of 9.95s, which is short enough to allow safety-related equipment to be powered within the time required by the safety analysis.

(3) The high trip relay protects against loss of safety function for the connected Class 1E loads. This relay provides a faster tripping time for a high level negative sequence/unbalanced voltage. High trip nominal voltage setpoint is 18.13V and a time delay of 3.95s, which is short enough to ensure safety-related equipment protective devices do not actuate for starting and running conditions.

Once the permissive one-out-of-two coincidence logic is satisfied, the existing degraded voltage/loss of voltage logic will trip the normal and alternate feeder breaker, start the diesel generator, and trips major 6900V and 480V shutdown board loads. (See Table 8.3.1-1)

There are no automatic transfers of board supplies between redundant power sources. All 480V shutdown boards and all motor control centers have normal and alternate feeders. Transfers between the normal and alternate feeder are manual. Some manual transfers of loads between power trains are used. These transfers are at the 480V level and involve eight loads which are tabulated in Table 8.3.1-3.

A means of manually interconnecting power sources at the 6.9-kV level is provided. This is provided by the shutdown utility bus, shown on Figure 8.1.2-1, which allows any 6.9-kV shutdown board to be connected to any other or all other 6.9-kV shutdown boards. All circuit breakers connected to this bus are normally open and disconnected (racked out). Use of the bus requires manual insertion and closing of two of the breakers. The purpose of this utility bus is to increase the flexibility of the Standby Power System under levels of degradation beyond consideration of the single failure criteria.

A manual means of supplying power to the 480V auxiliary building common board (which is not normally supplied power from the diesel generators during a condition where offsite power is lost) is provided. Provisions have been made to manually connect this board to the 480V shutdown boards 1B2-B and 2B2-B. This is shown in Figure 8.3.1-11. The purpose is to provide power to operate the ice condenser refrigeration units and glycol pumps during the unlikely condition of a loss of offsite power that exceeds 2-3 days. Also provide power to the Auxiliary Building 125 Ton Crane if needed for Dry Cask Storage operation. The two normal bus feeder breakers must be moved from their normal compartments to the compartments which are connected to the 480V shutdown boards 1B2-B and 2B2-B.

System Instrumentation

Remote instrumentation of the 6.9-kV shutdown boards consist of transducer-driven ammeters for the normal and alternate feeders, diesel generator feeder, and all motor loads. Also included are bus voltmeters and various annunciations which are located in the main control room and auxiliary control station. This is shown on Figure 8.3.1-9. The diesel generator instrumentation is covered in the diesel generator section. This instrumentation is used in testing the diesel generator and in monitoring the 6.9-kV shutdown boards during normal conditions and loss of offsite power conditions.

Remote instrumentation of the 480-volt shutdown boards consists of bus voltmeters and various annunciations all of which are located in the main control room and auxiliary control station. This is shown in Figures 8.3.1-7 and 8.3.1-8. All the boards have locally-mounted ammeters which monitor the normal and alternate feeders.

Remote instrumentation of the 480-volt motor control centers consists of annunciation in the main and auxiliary control rooms upon loss of board voltage.

System Reliability

The redundant power trains shown in Table 8.3.1-4 and Figure 8.1.2-1, have redundant loads connected to corresponding distribution boards in each train such that failure of any one component or the entire train will not prevent the redundant system from performing the required safety function. The equipment requiring ac power during a loss of offsite power and/or accident condition is supplied from the 6.9-kV shutdown board directly or indirectly through transformers at a lower voltage as shown on Figure 8.3.1-6. At the 480-volt level each power train has two 480-volt shutdown boards and one ERCW board. A single spare transformer is provided for the two normal shutdown board transformers and is manually placed in service when one of the normal transformers is taken out of service.

Each 480-volt shutdown board supplies power to a group of motor control centers in addition to the large 480-volt motor loads. A motor control center is normally fed from one of the 480-volt shutdown boards and has an alternate feed from the other shutdown board of the same power train. Manual selection between the normal and alternate feeders is made at the motor control center.

The pressurizer heaters are divided into four groups. Two groups are supplied from each redundant power train 6.9-kV shutdown board through individual transformers. This is shown on Figure 8.3.1-6.

The four diesel generator sets are physically separated, electrically isolated from each other, and protected from the maximum possible flood.

Equipment Identification

Redundant major electrical equipment carries the same name in each power train with the exception that the board designation also has either -A or -B suffix depending upon the power train assignment. For example, 6.9-kV shutdown board 1A-A and 6.9-kV shutdown board 1B-B are redundant to each other. Similar designations are used for safety-related loads being supplied from safety-related (onsite) boards. For example, RHR (Residual Heat Removal) pump 1A-A and RHR pump 1B-B are redundant to each other. Further description of the equipment identification scheme used appears in paragraph 8.3.1.5.

Equipment Capacities

Tables 8.3.1-5 through 8.3.1-8 present the bus rating and the modes for maximum demand for each electrical distribution board in the standby power system. The maximum demand load for each major transformer in the standby power system is given in Table 8.3.1-9. The maximum demand load for the standby power system is within the equipment ratings and capabilities. The continuous rating of each unit is 4400 kw and 5000 kva at $\geq$ 0.8 power factor, 6.9-kv, 3-ph, and 60 Hz. Each diesel generator unit also has a short-time overload rating of 4840 kw for 2 hours in any 24 hour period.

The engine also has a "maximum brake horse power capability" which represents the maximum instantaneous real power that can be delivered, and therefore, determines the maximum amount of electrical load that can be started by the DG set. This capability depends on turbo-charger output and is therefore reduced during the first 3 minutes of operation. The maximum brake horse power capability is 4785 kW for the first 3 minutes and 5073 kW after 3 minutes.

The adequacy of the standby AC Power System is discussed in subparagraph 8.3.1.2.1.

System Controls

Figure 8.1.2-2 shows the vital 125V DC control power sources for each onsite shutdown board. Each board has a normal and emergency control bus, with each bus having access to two 125V batteries (having the same power train separation) by way of a manual transfer switch located in the board. The normal control bus supplies power for main control room operation. The emergency control bus supplies power for auxiliary control station operating modes. This is shown on Figure 8.3.1-6.

The control power for onsite motor control centers is single phase 120V AC supplied either from the center's own bus through a 480-120V transformer or from each individual load feeder through a 480-120V transformer.

System Testing

Located adjacent to each 6.9-kV shutdown board is a test panel equipped with the necessary selector switches, pushbutton switches, and indicating lights for testing the automatic load stripping and load sequencing logic for that particular power train. The tests are to be performed on only one of the two power trains per unit at any one time. Testing of one power train does not prevent the remaining power train from performing its intended safety function.

Testing of the onsite power distribution system is discussed in compliance to Criterion 18 of section 3.1.2.

Figure 8.3.1-10 show a schematic representation of the ability to test groups as described above.

Standby Diesel Generator Operation

The diesel generator system is shown on single line diagram, Figure 8.3.1-9. The schematic of the engine control circuits is shown in Figures 8.3.1-1 through 8.3.1-5. Remote control of the engine from the main control room is accomplished through interposing relays located in the diesel building.

The automatic connection of the diesel generators to the 6.9-kV shutdown boards is initiated by either the loss-of-voltage relays, the degraded voltage relays, or the unbalanced voltage relays on the 6.9 kV bus. For a complete description of the voltage relay logic and settings, see the system description of this section. When the diesel generator set has reached a speed of 850 rpm and design minimum voltage of 96.8 percent of nominal, it is automatically connected to the 6.9-kV shutdown board bus. The return of voltage to the 6.9-kV shutdown board initiates logic which connects the required loads in the proper sequence. Table 8.3.1-2 shows the order in which the loads are applied.

The loss-of-voltage/degraded voltage/unbalanced voltage relays remain in the circuit at all times, regardless of the power feed (normal, alternate, or emergency) to the 6.9-kV Shutdown Board. If the loss-of-voltage/degraded voltage/unbalanced voltage relays' voltage setpoint is reached, the proper operation includes:

1. Annunicate the 6.9-kV SD BD Failure or UV condition.
2. Initiate a DG emergency start signal and enable ERCW valve alignment.
3. To shed loads to be within the diesel generator capacity when the diesel generator automatically connects to the board.*
4. Allow the diesel generator to reach/recover speed and voltage.*

5. Reconnect the loads in the proper sequence.*

*If the board is being supplied from the Emergency Diesel Generator, an installed interlock circuit will prevent actions 3, 4, and 5 if the Diesel Generator output voltage is greater than 70% of nominal. This will prevent unnecessary load shedding during expected voltage transients during diesel loading.

Since the load shedding relays recognize loss of voltage, the design ensures that the starting of the large sequenced loads will not cause actuation of the load shedding feature.

As shown in Table 8.3.1-2, there are two loading sequences. One, which is applied in the absence of a safety injection signal (SIS), "the nonaccident condition," and the other "accident condition," applied when a SIS (and containment spray actuation signal) is received coincident with a sustained loss of voltage on the 6.9-kV shutdown board. A SIS received during the course of a nonaccident shutdown loading sequence is not part of the design basis of the plant (Reference TVA letter to NRC [RIMS L44870312803]). However, the design logic will cause the actions described below:

1. Loads already sequentially connected which are not required for an accident will be disconnected (except fire pumps powered by the DG).

2. Loads already sequentially connected which are required for an accident will remain connected.

3. Loads awaiting sequential loading that are not required for an accident will not be connected.

4. Loads awaiting sequential loading that are required for an accident will have their sequential timers reset to time zero from which they will then be sequentially loaded.

A SIS received in the absence of a sustained loss of voltage on a 6.9-kV shutdown board will start the diesel generators but not connect them to the shutdown boards. There are no automatic transfers of shutdown boards between standby power supplies in compliance with Regulatory Guide 1.6 Rev. 0. The events which initiate a safety injection signal are discussed in Chapter 7.

The diesel can be started by manually operated emergency start switches located in the main control room and auxiliary control room. Automatic starting is from an accident signal or loss of offsite power. All automatic and manual emergency start signals operate to deenergize a normally energized circuit. Emergency start signals operate a lockout relay that removes all manually operated stop signals except emergency stop and all protective relaying on the generator except generator differential, unless the diesel is operating in the exercise mode (generating power parallel to the offsite power grid). The lockout relay must be manually reset at the diesel generator relay panel in the diesel building. A local idle start switch is provided to start and run the engine at idle speed for durations of unloaded operation. During this type operation any emergency start signal will cause the engine to go to full speed and complete the emergency start. The engine also has a local manual start switch as well as remote start from the main control room for test purposes.

In general, after starting, the diesel generators will continue to run until manually shutdown. However, there are protective devices installed to shutdown a diesel generator automatically to prevent heavy damage in the event of a system malfunction. These protective devices are listed below.

Protective devices marked with an asterisk (*) are operative at all times while the others are operative only during the exercise mode of operation. These devices must be manually reset before the engine can be restarted. Protective devices (voltage restrained overcurrent relay, crankcase pressure switch, and overcurrent relay) are for alarm only and do not trip the diesel generator.

The status and operability of the trip bypass circuits can be tested and abnormal values of all bypass parameters are alarmed in the control room.

<u>Generator</u>

Instantaneous overcurrent relay (trip generator breaker only)
phase balance relay
reverse power relay
generator differential relay (*)
loss of field relay

<u>Engine</u>

overspeed switch(*)
low lube oil pressure switch
high water jacket temperature switch

There will never be more than one diesel in the exercise mode (diesel connected parallel to offsite power grid) at a given time. The DG response for a LOOP or an accident signal while in the exercise mode is discussed in DG operational testing. One out of the four diesel-generator sets may be stopped by its protective devices without jeopardizing the safe shutdown of a unit during all postulated design basis events; therefore, the protective devices will prevent excessive damage to a diesel generator set.

The diesel can be stopped by manually operated emergency stop switches located in the main control room, auxiliary control room, and on the diesel control panel in the diesel building. A manual stop switch is provided in the main control room for stopping the engine under normal conditions such as conclusion of a test or upon return to the preferred power source. Under accident or loss of offsite power conditions this stop switch is automatically disconnected from the stop circuit. The normal stopping of the engine will position the electric governor at idle speed (approximately 400 RPM) and allows the engine to run for 10 minutes before bringing the engine to zero speed. Emergency stopping bypasses this 10 minute idle speed time and brings the engine directly to zero speed. Should an emergency start signal be initiated during the 10 minute idle speed time of a normal stop condition, the engine will automatically return to synchronous speed and emergency operation.

Diesel engine speed and generator voltage can be manually controlled remotely from the main control room during exercise operations. An emergency start signal will automatically disconnect these manual controls and returns the unit to automatic control provided the diesel is not in the exercise mode of operation.

A "Local-Remote" manual selector switch, located in the diesel building, must be in the "Remote" position for all manual remote control from the control room to be in effect, with the exception of emergency start. Similarly, for the manual controls located in the diesel building to be in effect the switch must be in the "Local" position with the exception of emergency stop. Switching to the “Local” position requires an electrical permissive interlock signal initiated from the main control room. These operations are shown in Figure 8.3.1-9.

Diesel Generator Description

Each diesel-generator set is furnished by Power Systems Division of Morrison-Knudson Co., and consists of two 16-cylinder engines (model 999-16, type 16-645E4) connected directly to a 6.9-kV, 3-phase, and 60 Hz generator.

The normal operating speed of the set is 900 RPM. The diesel-generator set uses a tandem arrangement; that is, each set consists of two diesel engines with a generator between them, connected together to form a common shaft.

Governor Control of the Diesel-Generator Sets

The governor consists of the following:

(a) Woodward EGB-13P actuator on each engine
(b) 2301A controller (reverse biased)
(c) Magnetic speed pickup

The Woodward EGB-13P actuator used with the 2301A controller is a proportional governor which moves the fuel rack in inverse proportion to the voltage signal from the controller. Based upon the input from the generator, the controller sends an electric signal to the governor actuators on the two engines. This signal goes to the coils of each actuator that are connected in series so that each coil sees the same electric signal. The terminal shaft of each actuator will move the same amount for each change in signal. This means that the fuel control shaft movement on each engine will also be the same.

Attached to the fuel control shaft through an appropriate linkage is an injector rack for each cylinder which by its position meters the fuel injected into its cylinder. This rack is set with a standard factory gauge so that each cylinder will receive the same amount of fuel. Each injector rack is spring loaded to prevent any single injector that may stick from affecting the remaining racks on that engine.

The mechanical governor is set as backup control for unit speed such that at full droop (100% load) there is margin above the 900 rpm of the electrical governor. Since the electrical system is reverse biased, a failure in the electrical system would cause the engine speed to increase until it reached the setpoint of the mechanical governor and at that point the mechanical governor would control the engine.

Diesel Generator Auxiliaries

The diesel generator auxiliaries are supplied power from the diesel 480V Diesel Auxiliary Boards located in the diesel building on EL 740.5 (see Figure 1.2.3-17). These boards and loads are shown on Figures 8.3.1-12 and 8.3.1-13.

Diesel Fuel Oil System

The Diesel Engine Fuel Oil System for each unit consists of a day tank for each engine of the tandem pair holding approximately 550 gallons of fuel and four tanks embedded in the diesel building foundation floor which hold a minimum of a seven day supply. Transfer of fuel between the seven day supply tanks and the engine day tanks is accomplished automatically by a pair of pumps controlled by float-operated switches which sense fuel level in the engine day tanks. Either of the pumps can be selected as the lead pump with the other pump serving as a backup or supplementary pump (see Figure 8.3.1-14). Transfer of fuel from outside the diesel building to the seven day storage tanks is accomplished by manually controlled pumps which can supply fuel from two large storage tanks located near the storage yard or truck tanker piping connection. All of these transfer pump motors are supplied power from 480V diesel auxiliary boards. The fuel storage system that supplies the day tanks is described in Subsection 9.5.4.

Diesel Cooling System

Cooling water for engine heat removal is supplied from the Essential Raw Cooling Water System by way of two motor-operated valves piped in parallel to redundant cooling water heaters. One valve (that supplies ERCW from the train associated with that EDG) opens automatically upon receipt of a speed switch signal indicating that the engine is at 40 rpm or greater. All signals to close these valves must be manually initiated (Figure 8.3.1-15).

The detailed description of the cooling system for a diesel engine is given in Subsection 9.5.5.

Diesel Air Starting System

The actual cranking power to the engine is by compressed air motors which mechanically engage with the flywheel teeth and turn the engine drive shaft.

Four pairs of air motors are provided on each of the generator sets (total of eight air motors per diesel-generator) for cranking power. The air motors are paired (two pairs per engine) with two pairs on either engine or one pair diagonally opposed on each engine as a minimum to provide sufficient cranking power. Under normal conditions, all eight air motors are used to crank the tandem engines. A speed switch is used to shut off the compressed air to the motors when the engines reach a speed of 200 rpm.

The Diesel Generator Air Starting System is further described in Subsection 9.5.6.

Diesel Servicing

A maintenance switch at each diesel-generator set is provided that disables the remote starting equipment while the set is being serviced. A contact of this switch actuates an annunciator in the main control room when the switch is not in the automatic start position. There is no override of the maintenance switch since a start-up could be hazardous to the personnel working on the engines. The switch in no way affects the integrity of the other three diesels, which will still start upon receiving an accident signal.

Diesel Generator Lubrication System

Each diesel engine has a lube oil circulating pump and water heater for use while the engine is not running. The oil is continuously circulated and held at a relatively constant temperature while the engine is stopped in anticipation of a required fast start (see Figure 8.3.1-16). A complete description of the Diesel Generator Lubrication System is given in Subsection 9.5.7.

Diesel Generator Instrumentation

Instrumentation consists of voltmeters, wattmeters, varmeters, ammeters, and annunciation display panels located in the main control room, auxiliary control room, and locally in the diesel building. The instrumentation is not essential for automatic operation of the diesel.

Diesel Generator Control Power (Reference 3)

The control circuit voltage for the diesel generators is 125-V dc (nominal). Indicating lights and contacts for the 125-V dc service show when the diesel generator is: (1) ready for automatic start but not running, (2) cranking, or (3) running. In addition, there is an alarm in the MCR when the 125-V system is unavailable (breaker open). During emergency operation of the diesel generator, the only required source of control power is a battery, which has 58 cells. The battery is operable with 57 cells if one cell is strapped out. During nonemergency operation, power supplies for manual control of the diesel generator are provided by vital power sources 125-V dc and 120-V ac. Per the vendor (see Reference 2), after a discharge, when the float current drops to less than or equal to 1 amp, the battery should be at least 98% recharged. A 98% charged battery maintains at least a 5% design margin.

The DG supplier, MKW Power Systems, Inc., maintains the design basis for the capability of the control power system to start the DG during design basis events. Except for the first few seconds in the duty cycle, the battery, with the charger not operable, is capable of supplying all the loads without dropping below the minimum battery voltage of 105 V, for 30 minutes when the battery is at the lowest expected temperature of 60° F and at the "end-of-life" condition (80% capacity). Further, TVA has performed an independent analysis of the DG battery that supports the conclusions provided by MKW. The DG battery, due to motor transients, will momentarily drop below 105 V during the first 10 seconds of the duty cycle. However, all components will have adequate voltage to support the safety function.

Each battery has an independent dual battery charger which are supplied from the Class 1E 480-V diesel auxiliary boards. The battery charger is of the static rectifier type and is equipped with a contact to annunciate via the diesel generator engine control panel of a low direct current voltage output.

Limiting the frequency of battery discharge tests help maintain the life of the batteries. A minimum float voltage provided by the manufacturer is a battery bank setpoint corresponding to 2.20 volts per cell but an allowable voltage of 2.13 volts per cell is also provided. Since cells below the minimum setpoint but above the allowable are recommended to be equalized, 2.20 volts per cell is recognized as the minimum to support long term performance.

Battery capacity is available at the battery's end of qualified life and with the cell electrolyte at the minimum design temperature of 60° F. The manufacturer's ratings adjusted for minimum design cell temperature and battery end-of-life per guidance in IEEE Standard 485 is the basis for sizing the battery. The batteries are tested per IEEE-450-2002 and the results compared to the vendor capacity ratings.

The batteries have two electrolyte level marks (High and low) on the battery casing. The battery manufacturer's reference point for electrolyte level is the high level line; however, the electrolyte level is considered satisfactory as long as it is at, or above, the low level line and is no more than 1/4 inch above the high level line. Site procedures specify criteria for the minimum electrolyte levels required for battery operability.

Diesel Generator Capacity

DG capacity (quantitative) is given under equipment capability in 8.3.1.1. The present diesel generator loading analysis calculation determines the loading (KW and KVA) on each of the diesels for the following design basis events: (1) loss of offsite power (LOOP), (2) LOOP with simultaneous safety injection signal (SI) and containment isolation Phase A, and (3) LOOP with simultaneous SI and containment isolation Phase B. This analysis confirms that the DGs are capable of supporting two-unit operation while maintaining margin between the maximum transient/steady state loading and the DG manufacturer's ratings and capability. For manual addition of DG loads, administrative control requires the operator to maintain the DG load within the engine rating.

Diesel Generator Operational Testing

The operational testing of the diesel generator is accomplished from the diesel control panel located in the main control room. Full load tests on a DG require that the DG be paralleled with the offsite power in a manual (exercise) mode of operation. Should a loss of offsite power occur under this condition the instantaneous overcurrent relays may trip the diesel generator circuit breaker and reset the governor and voltage regulator for automatic operation. The automatic sequencing logic will then reapply the diesel generator and the required loads to the standby power boards. If an accident signal is received while the diesel is operating in the exercise mode, the diesel may remain in the exercise mode (with all the protective devices operable) and continue to provide power. If the DG does not trip (due to the light loading), it must be manually unloaded and tripped to go to the emergency mode. Diesel Generator tests verify that the critical protective trips that are not automatically bypassed perform their intended function (Reference 3).

Diesel Generator Maintenance

Diesel Generators are inspected in accordance with procedures prepared in conjunction with manufacturer's recommendations for this class of standby service.

Qualification Testing of the Tandem Diesel Configuration

The vendor (Bruce General Motors) performed factory tests designed to demonstrate that the systems would perform the requirements of fast starting, sequential motor starting, load sharing, and continuous load carrying capability. Additional systems tests were also conducted to demonstrate the recovery capability from a sudden application of load, a sudden loss of load, and the sudden loss of a unit.

In addition to the customary test performed to check the operability of the unit, the following tests were conducted on each unit:

Fuel Consumption Tests

The unit was loaded at loads of 1330, 2660, and 4000 kW at 0.8 pf, and the time to consume 100 pounds of fuel was recorded. This series of tests was done three times, and the time to consume 100 pounds of fuel varied from approximately 5 minutes, 52 seconds at 1330 kW, to 2 minutes, 56 seconds at 4000 kW.

Transient Tests

Full load transient tests were made to verify that voltage and frequency transient characteristics of the system. Loads of 1000, 2000, 3000, and 4000 kW at 0.8 pf were picked up and dropped three times. The data in the following table is from the test report on unit D and was considered to be typical.

Load Change	Peak Frequency Change %	Peak Voltage Change %
+1000 kW	- .37	- 7
-1000 kW	+.5	+ 3.5
+2000 kW	- 1	- 7.2
-2000 kW	+1.33	+ 7
+3000 kW	- 1.5	- 13.3
-3000 kW	+1.83	+10.5
+4000 kW	- 2.3	- 15.8
-4000 kW	+2.5	+ 14

In all tests, the systems restored the voltage and frequency to nominal values within 5 seconds. The maximum percent voltage dip due to a 1000-kW step increase in load is shown below for each unit.

Unit A - 9.5 percent
Unit B - 9.2 percent
Unit C - 7.8 percent
Unit D - 7 percent

72 Hour Tests

The units were tested at rated voltage, rated frequency at a load of 4000 kW, 0.8 pf for 72 hours with engine and generator readings being recorded every half hour.

Starting Reliability Tests

To demonstrate their starting reliability each diesel-generator unit was started 100 consecutive times without a failure. Rated speed was obtained within 8 seconds after each start.

During these starting reliability tests, full load was applied within 30 seconds for five minutes on the first start and every tenth start thereafter for a total of ten out of the one hundred.

During the entire testing period for each diesel-generator set, over 200 starts were made with no failure to start and attain rated speed and voltage.

In addition to the above further testing to verify the starting reliability has been done for the Watts Bar generators, which are similar in design to the Sequoyah generators. During this testing 306 successful test cycles were completed on the Watts Bar diesel generators without any failures. During these tests, the diesel generators were started from cold standby conditions, loaded to at least 50 percent of the 30-minute rating within 15 seconds of the start signal, and operated for a period of approximately 15 minutes until the operating temperatures stabilized. Summaries of the results of the start reliability tests are provided in a three volume compilation: 300 Start Reliability Tests Volume 1; Void Report volume 2; and Strip Charts for 306 Starts, Volume 3. These three volumes have been sent to the NRC via letter from J. E. Gilleland to B. C. Rusche dated December 30, 1975.

Onsite Design Verification and Performance Testing

During the late 1980's, the DGs were subjected to a significant on-site testing program in order to resolve many potential issues raised by NRC, TVAN employee concerns, and public concerns. These concerns generally involved allegations that the DGs were overloaded, that load additions were not properly controlled, and that frequency and voltage recovery did not meet the original licensing basis. These issues and their resolution are summarized in the Sequoyah Nuclear Plant Diesel Generator Evaluation Report (DGER)[1] and NRC Revised Safety Evaluation Report[2]. The DGER concludes that TVAN has demonstrated by testing and analysis that the SQN DG system will perform its intended safety function, with acceptable margin. Following issuance and NRC acceptance of the DGER, further improvements were made to the DG transient-voltage response in accordance with the Improvement Plan for SQN SG Transient Voltage Response[3], which successfully improved the voltage performance of the DGs beyond what had been previously analyzed in the DGER[4].

[2]Letter from Stewart D. Ebneter to S. A. White dated March 25, 1988 - Docket Nos. 50-327 and 50-328
[3]SQN Improvement Plan for SQN Diesel Generator Transient Voltage Response (RIMS L44 880708 802)
[4]SQN Diesel Generator Voltage Response Improvement Report (RIMS B25 891127 005)

Station Blackout Diesel-Generator Reliability

The SQN electrical distribution system configuration, SQN site weather data, distribution grid system stability, and other factors were evaluated per NRC Regulatory Guide 1.155 "Station Blackout" and the required overall diesel-generator reliability must be maintained over 0.975 as a target.

VITAL 120V AC CONTROL POWER SYSTEM

The vital 120-volt AC control power system is a Class 1E, safety-related system which provides instrumentation and control power for engineered safety features equipment and other essential AC powered equipment. The system capacity is sufficient to supply these loads during normal operation and to permit safe shutdown and isolation of the reactor in any emergency, including a LOOP condition. Limited shutdown capabilities are maintained for a loss of all AC power condition. Distribution of power is accomplished without automatic transfers between redundant load groups and without automatic load stripping or sequencing. The system is designed to perform its safety function subject to any single failure within the system.

Although there is no automatic load stripping, certain loads are removed from the Vital AC Power Boards within 45 minutes into a Station Blackout event as defined in Regulatory Guide 1.155. The loads that are removed are those that are not required for mitigation of a four hour Station Blackout event. The loads are removed to reduce the battery loading in order to meet the four hour requirement. The station blackout event is assumed to occur during normal plant operation with both units at power, but no accident or other operational transient. The plant is required to be maintained at hot standby during the four hour event with appropriate containment integrity. Sufficient instrumentation is powered during the event to monitor the core conditions and reactor coolant system pressures and temperatures.

System Structure

The configuration of the AC control power system for both nuclear units is shown in Figure 8.1.2-2. Each unit has four identical power Channels, with the equipment of each channel being electrically and physically independent from the equipment of other channels. Each channel consists of an inverter and a distribution panel which facilitates load grouping and provides circuit protection and a spare inverter shared between the units.

Physical Arrangement of Components

The inverters are located in the auxiliary building at elevation 749. The Channels I and II inverters are located in the Unit 1 area and the Channels III and IV inverters are located in the Unit 2 area. The Channels I and II inverters are separated from Channels III and IV inverters by reinforced concrete block wall, extending to the ceiling. The Channel I and the Channel III inverters are separated from the Channel II and the Channel IV inverters respectively, by a distance of about 60 feet. The physical arrangement of the inverters is shown on Figure 1.2.3-2.

System Reliability

The system incorporates features which serve to increase the overall reliability. Each channel has access to three power sources; a 480-volt AC source, a 125-volt DC source, and a 120-volt AC regulated bypass source. Each inverter has an auctioneered solid-state transfer switch between the 480-volt AC and 125-volt DC sources. A static switch is provided for each inverter to automatically transfer between the inverter output and the regulated bypass source in the event of overload or system malfunction without interrupting power to the load. An automatically synchronized manual transfer between the output of the inverter and the spare inverter is provided so that the inverter may be taken out of service for maintenance without interrupting power to the loads. The current limiting feature of the inverter provides self-protection from load faults. The inverter and instrumentation power board are monitored to alert the operator of abnormalities. The distribution bus is sectionalized with coordinated fuses to prevent losing the entire board due to a single branch circuit fault.

Vital 120VAC Loads

Each channel supplies the following types of loads: reactor protection system, reactor systems instrumentation, separations and interlock relay panels, and other panels and equipment associated with reactor instrumentation and control systems. The capability of the inverter to supply its connected load is discussed in Paragraph 8.3.1.2. Nonsafety related loads are supplied from Class 1E breakers located on the Class 1E instrument power board to provide qualified fault isolation.

Loads are assigned to a channel according to its separation division requirement. Those loads requiring four divisions of separation are assigned to the four channels. Those loads requiring two divisions of separation are assigned to Channels I or III and II or IV. Loads which do not require divisional separation are assigned among the four channels of each unit.

In all documents pertaining to Class 1E systems, the method of distinguishing between safety related and nonsafety related loads are clearly defined on the documents.

Inverter

The normal supply of ac power to the distribution panels is from the inverter in each channel. The inverters consist of four major subassemblies: a DC power supply, an auctioneering circuit, an inverter circuit and a static switch. The spare inverters consist of a DC power supply, an auctioneering circuit, and an inverter circuit but do not have a static switch. The DC power supply converts the 480-volt AC normal inverter input to direct current. The auctioneering circuit accepts the DC power supply (normal supply) and battery (emergency supply) inputs and permits a switchless bidirectional transfer between them in the event of 480-volt AC supply failure and restoration. The DC output of the auctioneering circuit is converted to ac by the inverting circuit. The static switch automatically transfers the load between the inverter circuit output and a regulated bypass source upon overload or system malfunction without interrupting of power to the load.

The inverter is a solid-state type which converts three-phase 480-volt AC and 125-volt DC inputs to a nominal 120-volt AC output having a rated capacity of 167 amperes for load power factors from 0.8 to 1.0. Over this output current range, the AC output voltage does not vary more than ± 2.0 percent for normal 480-volt AC supply voltage amplitude variations of +10/-12.5 percent and frequency variations of ± 2.0 percent, and an emergency supply voltage variation from 100 to 140 volts DC. The output frequency regulation is 60 Hz ± 1.0 percent with a harmonic distortion of 5 percent and a maximum rate of change of 1.0 Hz per second. When operating from the emergency supply, the inverter efficiency is proportional to the load.

Some operational features of the inverters are: (1) synchronization to a 120-volt AC bypass source, (2) a current-limit feature which helps prevent commutation failure and limits overload current to a safe value while permitting a 334 ampere short circuit current for a minimum of 1.5 seconds, (3) protective devices which prevent a failed inverter from loading its associated normal and emergency power sources, and (4) metering and alarm circuits to monitor the inverter output.

Vital Instrument Power Board

The eight instrument power boards are located in four separate rooms in the auxiliary building at elevation 734. The two boards and the 125-volt DC Vital Battery Board serving the same channel are located in the same room. Although the two instrument power boards serving the same channel are electrically separated, they are physically constructed side by side.

Mounted on each of these boards are: the distribution bus, maintenance supply transfer switch, subdistribution bus 70-ampere fuses, distribution bus disconnect switch, high speed branch circuit breakers, and various instruments (a panel-mounted voltmeter and an undervoltage relay to warn the operator of a loss of distribution panel power) for monitoring distribution bus AC voltage.

In addition, mounted on boards 1-III and 1-IV is equipment for supplying the CO_2 fire protection system with a source of ungrounded ac power.

Each branch circuit breaker is coordinated to its subdistribution bus fuse. The purpose of this coordination scheme is to prevent a fault on one branch feeder from causing damage to any branch feeder cable or a loss of the entire board due to a single branch feeder fault. All of the branch circuit breakers are 100-ampere frame molded-case breakers. All circuit breakers have alarm contacts to alert the control room operator of an open breaker.

Tests and Inspections

Prior to placing the vital AC system in operation, the system components will be tested to ensure their proper operation. The inverter will be checked for output voltage and frequency, ability to synchronize to the maintenance supply, transfer between normal and emergency sources, and 100 percent output delivery while operating on either the normal or emergency supplies. Panel-mounted instruments monitoring the inverter will be calibrated. For the instrument power board, circuit breakers will be tested for proper trip operation, fuses will be checked to verify the sizes and types specified have been installed, and the board instruments will be calibrated. During plant power operations the vital 120-volt AC control power system will be periodically tested and inspected to ensure its continued capability to perform its operation. The inverters will be tested for their capability to transfer between the 480-volt AC normal power source and the 125-volt DC emergency power source. The inverter and auctioneering equipment may be removed from service for inspection and test by synchronizing and manually transferring to the maintenance power source. The surveillance instrumentation provides continuous monitoring of the system.

Design Bases and Criteria for Safety-Related Motors, Switchgear Interrupting Capacity, Circuit Protection, and Grounding

The design bases for safety related motors are the applicable Onsite Power System design basis listed in Subsection 8.1.4. In particular, bases 1, 3, 4, 5, and 6 apply to safety related motors. The criteria which are applied to motor size, starting torque, and insulation are as follows:

Motor Size and Starting Torque

Each motor has adequate capacity and operating characteristics for all conditions of starting and running which the connected equipment may impose.

The motor nameplate horsepower rating is not normally exceeded when the connected equipment is operating at rated capacity. Motor nameplate horsepower may be exceeded up to 15 percent, only for short-term service (only for motors with a marked service factor of 1.15).

Motor Insulation

For most applications insulation is NEMA class B or better. Motors in areas which are subject to unusual operating conditions either during normal, emergency, or accident operation are designed to be suitable for operation in these environment. These include conditions such as gamma radiation and high humidity, temperature, and pressure.

Electric Circuit Protection

Whether the 6900-volt shutdown boards are being supplied by their normal sources or alternate sources, the entire AC auxiliary power system from the station service transformer to the

emergency load motor control center electrically farthest from the sources is a coordinated selective trip system.

The circuit protective devices, the breaker interrupting ratings, and the 6900-480-volt transformer impedances are properly selected. That is, no motor will have excessive voltage drop on starting or running, each fault interrupter has a rating higher than the maximum available fault current, each motor protector is selected and set to protect the motor and its cable, and each motor feeder protective device is backed up by the next upstream circuit breaker in the event it should fail to open its circuit under fault. Backup protection will isolate the board feeding the faulted circuit but will not necessarily protect the circuit with the failed breaker against damage.

Motors rated 400 horsepower and above are supplied from 6900 volt shutdown boards.

Motors rated 350 horsepower and below are supplied from 480 volt shutdown boards. The smaller motors, in general 50 horsepower and below, are fed from 480-volt motor control centers. Larger motors are usually fed from 480-volt metal-enclosed switchgear (load centers), unless frequency of operation or location of motor relative to a feeder board indicate otherwise.

The 6600-volt motors are protected by induction-type, inverse-current overcurrent relays specially designed for protection of large motors. These relays have three individual contacts which respond to overload and locked rotor for motor protection and to circuit faults. All settings are initially selected according to relay instruction manuals but are subject to later changes if warranted by field tests or vendor information. Generally, the long-time current setting is selected slightly above the full load current at rated service factor (1.15 to 1.4 times normal full load current) and the time lever selection is made to permit locked rotor current to flow for the acceleration period if known or as predicted by experience. The instantaneous current setting is selected as approximately twice the locked rotor current.

The incoming supply breaker on a 480-volt switchgear board has an inverse-time, induction-type overcurrent relay. Each motor feeder breaker has a static-type overcurrent relay with long time and instantaneous settings. The instantaneous current setting is for short-circuit protection and is selected as approximately twice the locked rotor current to avoid nuisance tripping on inrush starting current. The long-time current setting for motor overload protection is as follows:

- 125% of motor full load current if service factor of motor is 1.15 (may be increased to 140 percent if required to start motor and carry load)

- 115% of motor full load current if service factor of motor is 1.0 (may be increased to approximately 130% if required to start motor and carry load).

The long-time delay setting is chosen to permit locked-rotor current for the accelerating time, if known, or according to the switchgear vendor's recommendation.

Each motor control center feeder breaker on the 480-volt switchgear board has a long time setting and a short time setting. These settings are selected such that the complete tripping time-current curve when plotted on coordination paper will be above the curve of the molded-case circuit breaker for the largest motor fed from the motor control center. This molded-case circuit breaker provides short-circuit protection. Motor overload protection is provided by overload heater elements in the motor starter. The incoming breaker in the motor control center is nonautomatic and thus has no trip settings.

Active motor operated valves (MOVs) conform to the intent of Regulatory Guide 1.106, Rev. 1 position C.1(a) (those activated by an accident signal have their TOL's bypassed continuously) or position C.2 except for the auxiliary feedwater turbine (AFWT) trip and throttle MOV (1,2-FCV-01-51) which valves conform to the intent of regulatory position C.1(b).

Active valves are those valves required to perform a mechanical motion to fulfill their safety-related function. Since active valves are the only ones required to change position to shutdown the reactor, or mitigate the effects of a design basis event, they are the only MOVs requiring assurance of position change.

TVA complies with the intent of IE Circular No. 81-13 for active motor-operated valves.

Interrupting Capacity of Distribution Equipment

The criteria for selecting the interrupting capacity of switchgear are as set forth in ANSI Standard C37-010 for 6900-volt circuits and C37.13, section 13-9.3.5 for 480-volt circuits. No circuit interrupter is applied in a circuit where the maximum available fault to be interrupted, as calculated by standard procedures, exceeds the interrupting rating of the device. Circuit impedances were selected to limit fault magnitudes to the circuit breaker ratings without causing voltage to dip below the motor rated starting voltage when starting the largest motor.

The 6900-volt Class 1E switchgear is subjected to a maximum interrupting duty of less than 500 MVA which is within its one time rating of 550 MVA.

Grounding Requirements

The 6900 volt secondary winding of each unit and common station service transformer is wye-connected, with the neutral grounded through a resistor which will limit ground fault current to 1600 amperes maximum. The neutral resistor serves to prevent overvoltage on the winding which could occur in the event of a ground fault if the 6900-volt system were not intentionally grounded. Since there is a deliberate ground current path, each 6600-volt motor and 6900-volt transformer feeder circuit is protected by ground overcurrent relays which will trip that circuit's feeder breaker. The common station service transformer neutral resistor has an over-current relay which will trip the 161-kV breakers which supply that transformer from the 161-kV system. This overcurrent relay is coordinated with the downstream 6900-volt start buses ground overcurrent relays. This coordination is necessary because each start bus automatically transfers to its alternate supply common station service transformer on low voltage. If a start bus ground fault should cause the common station transfer to be deenergized before the fault is isolated by start bus supply breakers, the fault may be transferred to the other common station service transformer and cause it to be tripped also.

The ground overcurrent relays for 6900-volt load feeder circuits are static type used with a ground sensor current transformer which encircles all three conductors of the feeder cable. Thus the sensor is not subject to errors caused by motor starting inrush currents due to differences in saturation. The ground sensor relay then is instantaneous in operation; it can detect ground fault currents as low as 15 amperes. The objective of the sensitivity and speed of this ground protector is to limit the damage to the motor iron in the event of a ground fault. The ground fault current level of 1600 amperes has been successfully used in TVA projects for at least 10 years. This fault level is selected because it is large enough to enable early detection and low enough to prevent excessive damage before fault clearing by the feeder breaker.

The diesel generator is 6900-volt, 3-phase, wye-connected with the neutral grounded through a relatively high ohmic resistance to keep ground fault currents to a low level. The maximum ground fault current available from the diesel generator is approximately 4 amperes. Ground faults are detected by a voltage relay across the neutral grounding resistor. Grounds cause an alarm but do not cause any breaker operation.

The 480-volt system are supplied through 6900-480 volt delta-delta transformers, and 480-volt systems are not grounded. This permits minimum disturbance to service continuity. Ground detectors are provided on each 480-volt switch gear to indicate the presence of a grounded-phase conductor. IPCEA S-61-402 and S-66-524 recommend that cables have insulation levels of 173 percent of nominal for circuits that may be required to operate longer

than one hour continuously with one phase grounded. TVA meets the intent of the IPCEA recommendation by specifying that cable used in 480-volt circuits be rated at 600 volts with 133 percent insulation level. This application is equivalent to specifying 480-volt cable with 173 percent insulation level (within 4 percent). The nominal voltage between any line and a earth ground is 277V, but the maximum line to ground voltage with a single line to ground fault is 480V. No ground fault relaying was required since there would be only a very small current flowing to a single-line-to-ground fault. A ground fault on more than one phase is a line-to-line fault and will trip the feeder breakers of the faulted circuits.

8.3.1.2 Analysis

8.3.1.2.1 Standby AC Power System

The Standby AC Power System is designed to comply with the requirements set forth in GDC 17 and 18. The design also conforms with Regulatory Guides 1.6, Rev. 0 and IEEE Std 308-1971, and the intent of, but not the numerical values of, Regulatory Guide 1.9, Rev. 0. The following paragraphs discuss each of the requirements.

Capacity, Capability, and Margin

General Design Criteria 17

The standby AC power system is designed to provide sufficient capacity and capability to assure that (1) specified acceptable fuel design limits and design conditions of the reactor coolant pressure boundary are not exceeded as a result of anticipated operational occurrences (2) the core is cooled and containment integrity and other vital functions are maintained in the event of postulated accidents.

Regulatory Guide 1.9, Rev. 0[1]

Each diesel generator set is capable of starting and accelerating to rated speed, in the required sequence, all the needed engineered safety feature and emergency shutdown loads. At no time during the loading sequence does the frequency and voltage decrease to less than 95 percent of nominal and 75 percent of nominal, respectively.[2] During recovery from transients caused by step load increases or resulting from disconnection of the largest single load, the speed of the diesel generator set does not exceed 75 percent of the difference between nominal speed and the overspeed trip setpoint or 115 percent of nominal, whichever is lower. Frequency is restored to within 2 percent of nominal, and voltage is restored to within 10 percent of nominal within 60 percent of each load sequence time interval. A greater percentage of the time interval may be used if it can be justified by analysis.[1]

IEEE Std 308-1971

Each distribution circuit is capable of transmitting sufficient energy to start and operate all required loads in that circuit.

A failure of any unit of the standby power source (diesel) does not electrically jeopardize the capability of the redundant standby power sources (diesels) to start and run the required shutdown systems, emergency systems, and engineered safety feature loads.

Fuel at the site has the capacity to operate the standby power source (diesels) while supplying post-accident power requirements for seven days.

The total standby power source (diesel) capacity for the plant is sufficient to operate the engineered safety features for a LOCA in one unit and those systems required for concurrent

---

[1]Voltage and Frequency recovery requirements are taken from Regulatory Guide 1.9, Revision 1.
[2]Exception is taken for frequency immediately following DG breaker closure. The DG breaker is designed to automatically close at about 94 percent of nominal frequency. This exception was accepted in Safety Evaluation Report NUREG-1232 Vol. 2 dated May 1988.

safe shutdown on the remaining unit. No single failure of a standby power source unit (diesel) will jeopardize this capability.

Redundancy

General Design Criteria 17

The onsite AC electrical power sources (diesels) and the onsite electrical distribution system have sufficient independence, redundancy, and testability to perform their safety function assuming a single failure.

Regulatory Guide 1.6, Rev. 0

The electrically powered AC safety loads are separated into redundant load groups such that loss of any one group will not prevent the minimum safety functions from being performed.

IEEE Std 308-1971

Sufficient physical separation, electrical isolation, and redundance is provided to prevent the occurrence of common failure mode in Class 1E systems. The Class 1E system design includes:

(1) Electric loads separated into two redundant load groups.

(2) The safety actions performed by each group of loads are redundant and independent of the safety actions provided by its redundant counterpart.

(3) Each of the redundant load groups has access to both a preferred and a standby power supply. Each power supply consists of one or more sources.

Independence

Regulatory Guide 1.6, Rev. 0

The design of the standby ac power system conforms with the independence requirements placed on redundant systems by Regulatory Guide 1.6, Rev. 0.

These include:

(a) The standby source of one load group cannot be automatically paralleled with the standby source of another load group or with the offsite system.

(b) No provisions exist for automatically connecting one load group to another load group.

(c) No provisions exist for automatically transferring loads between redundant power sources.

(d) Where means exist for manually connecting redundant load groups together, at least one interlock is provided to prevent an operator error that would parallel their standby power sources.

IEEE Std 308-1971

Class 1E electric equipment is physically separated from its redundant counterpart or mechanically protected as required to prevent the occurrence of common failure mode.

Each type of Class 1E electric equipment is qualified either by analysis, successful use under conditions, or by actual test to demonstrate its ability to perform its function under normal and design basis events.

Distribution circuits to redundant equipment are physically and electrically independent of each other.

Auxiliary devices that are required to operate dependent equipment are supplied from a related bus section to prevent the loss of electric power in one load group from causing the loss of equipment in another load group.

Protective devices are provided to isolate failed equipment automatically. Sufficient indication is provided to identify the equipment that is made unavailable.

By means of breakers located in Class 1 structures it is possible to disconnect completely Class 1E systems from those portions located in other than Class 1 structures.

Surveillance and Testability

General Design Criteria 18

Electric power systems important to safety are designed to permit appropriate periodic inspection and testing of important areas and features. In particular, the systems are designed with capability for periodic testing of the operability and functional performance of the components of the systems, such as onsite power sources, relays, switches, and buses, and also, the operability of the systems as a whole. In addition, under conditions as close to design as practical, the full operational sequence that brings the systems into operation will be tested periodically including applicable portions of the protection system, and the transfer of power among the nuclear power unit, the offsite power system, and the onsite power system.

The distribution system is monitored to the extent that it is shown to be ready to perform its intended function.

Status indicators are provided to monitor the standby power supply continuously. Annunciators are provided in the control room to monitor and alarm the status of the standby power supply.

Availability

IEEE Std 308-1971

The standby power supply is available following the loss of the preferred power supply within a time consistent with the requirements of the engineered safety features and the shutdown systems under normal and accident conditions.

8.3.1.2.2 Analysis of Vital 120-Volt AC Control Power Systems, AC Distribution Boards, and Inverters

General

The 120-volt AC Class 1E electrical systems were designed, components fabricated, and have been installed meeting the requirements of the NRC 10 CFR 50 General Design Criteria, IEEE Std 308-1971, NRC Regulatory Guides 1.6, Rev. 0 and 1.9 Rev. 0, IEEE Std 336-1971, and other applicable criteria as referenced herein.

Refer to section 8.3.1.1 for equipment locations and system description. Refer to Subparagraph 8.3.1.4.2 for separation conformance.

Since this equipment is outside the primary containment area, it will not be exposed to hostile environments or significant radiation due to a LOCA. The system design, equipment location, separation, and redundancy assure ability to meet the requirements for the applicable accident in Chapter 15 and are in full compliance with NRC General Design Criteria 17 and Regulatory Guide 1.6 Rev. 0.

120-Volt AC Vital Instrument Power Distribution Boards

All load output circuit breakers used on the boards are high-speed hydraulic-magnetic type having the unique characteristic of high-speed tripping at low-fault currents. This type breaker is capable of providing low-fault current selective tripping when the board power source is from the inverter which has a low-fault current capability. The breakers are fed in groups from a stub bus with a current-limiting fuse. The fuses and breakers have current-time tripping characteristics which are coordinated with the load cable and/or load thermal characteristics to provide selective clearing of all faults.

The bus work within the board is sized electrically to supply the maximum load required and is capable of withstanding the electrical and mechanical forces resulting from the maximum short-circuit current available.

The input power is delivered to the main bus via a manually operated transfer switch. The switch has make-before-break contacts that permit transferring the bus feeder from either source while maintaining circuit continuity.

Uninterruptible Power Supply (120 Volt AC Vital Inverter)

The UPS delivers the required AC power via a 2-wire, 120-volt circuit. The electrical characteristics of the UPS units are sized and coordinated to maintain the required inverter output for the worst maximum or minimum operable input conditions. Each UPS system is capable of delivering 167 amperes continuously which is adequate to meet the maximum design load requirement of 125 amperes. Also each UPS systems is capable of delivering without damage a short-circuit current of 334 amperes for a period of at least 1.5 seconds to assure selective tripping of the AC distribution board feeder breakers.

The normal AC input power is derived from the 480-volt shutdown boards. The 480V normal AC input is rectified to DC power. The DC alternate input power source is derived directly from the DC distribution board. The DC alternate input is biased against the normal rectified AC input by means of an "auctioneered" diode circuit to permit use of the battery source only in the event the rectified DC input voltage falls below that of the battery. Input protective devices for both sources are coordinated and sized in accordance with circuit requirements.

Surveillance and Monitoring

Each distribution board and UPS system is equipped with the proper instruments to provide visual indication of the necessary electrical quantities. All circuit breakers and fuses are equipped with an alarm contact that closes for a blown fuse or automatic operation of a circuit breaker. Undervoltage alarm relays provide annunciation for loss of power on the buses or power input to the UPS. Closure of any alarm contact provides annunciation in the main control room.

Seismic Qualification

One complete board assembly and one complete UPS system assembly have been subjected to the SSE as described in Section 3.10. The tests were performed in conformance to IEEE Std 344-1971, Guide for Seismic Qualification of Class 1E Electric Equipment. Equipment surveillance and alarm components were energized and monitored during the test. The seismic test assures that

the complete assembly will continue to function properly and continue to deliver the required power during and after any expected SSE condition.

Design Test

All inverters were electrically tested to assure that each unit is capable of performing all requirements as specified.

All boards were subjected to and satisfactorily passed the following tests as specified under the indicated paragraphs of section 20-5 of ANSI C37.20-1969:

20-5.2.1.1 - Power Frequency Withstand
20-5.2.2 - Rated Continuous Current
20-5.2.3 - Momentary Current
20-5.2.8 - Flame Resistance for Barrier, Bus, and Wire Insulation
20-5.3.2 - Mechanical Operation
20-5.3.4.1 - Control Wiring Continuity
20-5.3.4.2 - Control Wiring Insulation

All molded-case circuit breakers comply with NEMA Publication NO. AB-1-1964 requirements. All control circuit wiring has insulation rated 600 volts in accordance with paragraph 6.1.3.1 of ANSI C37.20-1969. All equipment is certified to operate within the environmental requirements called for in the design criteria. (Refer to Section 3.11) The arrangement of circuit interrupters and switches permits easy isolation of the installed assemblies for future test and maintenance purposes.

Quality Assurance

A QA program implemented from the beginning of the specification for this equipment and continued throughout installation and final checkout assures that the equipment meets all applicable design and operational criteria. The specifications require that suppliers of this equipment maintain a QA program throughout the duration of the contract and that the program conform to the essential elements as defined in NRC Appendix B of 10 CFR, Part 50. An inplant examination of each contractor's QA program assures compliance with these requirements. The design, specification, and any design changes are reviewed by designated staff engineers to assure compliance with QA procedures and design criteria. All records, drawings, test reports, etc., depicting quality assurance review are maintained in appropriate files in accordance with established procedures.

8.3.1.2.3 Safety-Related Equipment in Potentially Hostile Environment

The safety related electrical equipment that must operate in a hostile environment during and/or subsequent to an accident is identified below. Safety-related electrical equipment located in a harsh environment (both inside and outside containment) has been evaluated against the environmental conditions as described in section 3.11.

Electrical equipment located inside containment has been designed to maintain equipment safety functions and to prevent unacceptable spurious actuations. All power cables feeding equipment inside containment are provided with individual circuit breakers to protect the cable and penetration (both 1E and non-1E) from the effects of electrical shorts.

Additionally, each power cable except cables for 6.9kV circuits is provided with a cable limiter fuse which, in the event of a breaker failure, is designed to protect the containment penetration. These breakers and fuses ensure that, should an electrical short occur inside containment, the mechanical integrity of the electrical penetration will be maintained.

A listing of major nonsafety-related electrical components located inside containment that may be inundated following a LOCA appears in Table 8.3.1-11 along with an explanation of the

safety-significance of the failure of the equipment due to flooding. In addition to the electrical equipment listed in the table, the water level inside containment may also flood nonsafety related local control stations, electrical sensors, electric motors for motor operated valves, and electric solenoids for air-operated valves. The following paragraphs illustrate how the flooding of this equipment does not affect the plant safety.

All local control stations located inside the containment are either provided with manual throw switches outside the containment at the motor control center or have their power disconnected permanently. These manual switches, when provided, are used to remove control power from the local control switches during normal operation. In order to utilize the local control stations during operating condition where containment access is permitted, the manual switch must be closed to provide power to the local stations. Indications are provided in the main control room for the manual throw switch positions; this indication is accomplished either electrically or administratively. In the cases where local control stations are installed inside the containment but analysis indicates their use is no longer required, the control power is removed for all modes of operation. Thus, spurious operation of equipment due to post-LOCA submergence of the local control station is prevented.

There are no electric motor-operated valves located inside containment below the maximum LOCA water level that are required to function for other than containment isolation. Valves used for containment isolation will close prior to submergence. The submergence of a motor-operated valve will not cause the valve to change from its safe position.

The control air supply is automatically isolated outside containment in the event of a LOCA (Phase B). The air operated valves are fail closed as are the inline solenoid valves. Therefore, the submergence of electric solenoids serving air-operated valves cannot affect the safe positioning of these valves.

The plant operators rely on the qualified post accident monitors following a LOCA so that any spurious indications from nonqualified electrical sensors that could become submerged would not jeopardize appropriate operator actions.

There is no Class 1E equipment required to operate during or after a LOCA or main steam line break that will be submerged. Some Class 1E cable is located below flood level. This cable is protected by being enclosed in a sealed raceway. Such equipment is designed to meet the average worst possible containment environmental conditions, as given in FSAR Section 3.11.

<u>Inside Primary Containment</u>

Cable materials for use inside containment meet IEEE 383-1974 flame test or equal. Additional flame tests that are determined to be equal or better than IEEE 383 are documented in Reference 1. The use of polyvinylchloride (PVC) jacketed cable inside containment at Sequoyah Nuclear Plant has been minimized to the extent possible. The reactor coolant pump power cable is PVC jacketed but is also almost completely enclosed by conduit.

Cable insulation and jacket materials are identified and specified in Reference 1. The materials are selected based on temperature rating, ampacity, and environmental considerations as described in UFSAR Section 3.11.

<u>Electrical Penetration Cables</u>

The cables are derated and sized according to their ampacities for the penetration ambient temperatures. The cables have passed all tests conforming to IEEE Standards for Electrical Penetration Assemblies in Containment Structures for Nuclear Fueled Power Generating Stations, IEEE 317-1971 or IEEE 317-1976 or IEEE 317-1983.

Overcurrent Protection for Containment Electrical Penetration Assemblies

Refer to section 7.1.3 for a description of the various types of penetrations. As shown in Figures 8.3.1-17 through 8.3.1-20, the time/current damage curve for the penetration is above that shown for the protective devices and the maximum available circuit current. This along with the seismically designed cable supports in Category I structures provide assurance of containment penetration integrity.

1. 6900 Volt Circuit

   The power circuits for the reactor coolant pump are the only 6900 volt circuits which penetrate the containment. Figure 8.3.1-17 shows the circuit, maximum available short circuit current, and the associated time/current curves for the protective devices and the penetration. The branch circuit breaker which controls the pump and the supply feeder breaker are controlled from separate DC supplies and provide the required redundancy to ensure penetration integrity.

2. 480 Volt Circuit

   An example of a typical 480-volt circuit electric penetration is shown in Figure 8.3.1-18. The circuit and curves shown are for a circuit fed from the 480-volt low voltage switchgear and contain a low voltage power circuit breaker with a solid-state overcurrent trip device and a current limiting fuse. The circuit breaker time/ current characteristics are bounded by two curves as determined from manufacturer's data.

3. 120 Volt AC Circuit

   Figure 8.3.1-19 shows the circuit and associated curves for a typical 120 volt AC circuit. This circuit utilizes a circuit breaker and a dual element fuse to provide the required redundancy. The circuit breaker is bounded by two curves as determined from manufacturing tests.

4. 125 Volt DC Circuit

   Figure 8.3.1-20 shows the circuit and associated curves for a typical 125 volt DC circuit through penetration. This circuit utilizes a fuse in addition to a circuit breaker to ensure containment penetration integrity. The circuit breaker is bounded by two curves as determined from manufacturing test.

Outside Primary Containment

Initial plant design required cables which run on cable trays and switchboard (which includes instrument panels) wiring that were capable of passing the vertical flame test according to section 6.19.6 of Insulated Power Cable Engineers Association (IPCEA) Standard S-19-8l (fifth edition). Current design requirements for cables require them to meet IEEE 383-1974 flame test or equal. Current design requirements for switchboard wiring (14AWG and larger) require them to meet VW-1 flame test of UL44. Switchboard wiring 16AWG and smaller meet the flame test of IEEE 383-1974 paragraph 2.5.6. Additional flame tests that are determined to be equal or better than IEEE 383 are documented in Reference 1. The fire protection system (and the cable requirements) is described in The Fire Protection Report (see Section 9.5.1). The cable tray fill is limited and conservative cable temperature ratings are used to assure that cable fires will not occur as a result of overheating. Cable insulation and jacket material are selected based on temperature rating, ampacity, and environmental considerations as described in UFSAR Section 3.11.

The features provided to ensure Main Control Room habitability during and after a postulated hazardous chemical release meet the guidelines given in Regulatory Guide 1.78, Rev. 0, Regulatory Position 14, even though the design was completed well before issuance of the Regulatory Guide. Refer to paragraph 6.4.1.3 and section 9.4.1 for further discussion of the features provided for the Main Control room Habitability System.

Qualification Tests and Analyses

Description of Qualification Tests Performed on Class 1E Electrical Equipment Cables Inside Primary Containment.

For qualification testing, a cable type includes those cables having the same materials, dielectric level, similar construction, and manufacturing process by a given manufacturer. The specifications required a selected cable type sample of low-voltage power or control, and signal cable be subjected to tests to confirm its capability to function in the postulated environment during and subsequent to a loss-of-coolant accident (LOCA).

Electrical Penetration Assemblies

The electrical penetration assemblies have been qualification type tested by the vendors, Westinghouse Electric Corporation and Conax Corporation and approved by TVA. Tests were performed to verify that the penetration assemblies were capable of continuous operation under normal and emergency environmental conditions, and were capable of maintaining the following containment integrity. These tests envelope plant parameters listed below.

Normal Environmental Conditions

Parameters	Inside Containment	Outside Containment (Annulus)
Temperature	60˚F to 135˚F	50˚F to 105˚F
Pressure	14.3 psia to 14.7 psia	Atm (-)
Relative humidity	30% - 80%	10% - 90%
Accumulated radiation dose	1 x 10^8 rad	

Emergency Environmental Conditions

First 20 Minutes

Parameter	
Temperature	259˚F
Pressure	-0.1 to +12 psig
Relative humidity	30% - 100%

Next 10 days

Parameter	
Temperature	150˚F
Pressure	-0.1 to +12 psig
Relative Humidity	30% - 100%

Penetration assemblies were also subjected to a borated water spray that is more severe than Sequoyah's chemical spray composition of 0.184 molar H_3BO_3 (2000 PPM boron), 0.033 molar NaOH resulting in a ph of 8.3 at 25°C.

Qualification Test Results

Cables Inside Containment

The documentation of successful completion of test included certified test reports of all tests required and listed in the specifications and its quality assurance appendix, and applicable TVA inspector's reports. Some test results were obtained from tests performed during the manufacturing process, on samples selected in accordance with the specification. Other test results, comparable to the requirements specified, were obtained from previous type tests performed on cables having known or proprietary materials in their construction. The manufacturer has certified that the cable furnished, duplicates the production and materials composition of the tested cable.

Electrical Penetration Assemblies

The Westinghouse canister type electrical penetration assemblies have been tested to TVA specification requirements which conform to IEEE-317, 1971, "IEEE Standard for Electric

Penetration Assemblies in Containment Structures for Nuclear Power Generating Stations." The Conax and Westinghouse modular electrical penetration assemblies meet the 1976 or 1983 version of IEEE-317. Each penetration complies with the standard that was applicable at the time of procurement.

The documentation of successful completion included certified test reports of all tests required and listed in the specifications and quality assurance appendix, and applicable TVA inspector's reports.

Each electrical penetration assembly furnished has been shop inspected by a commissioned representative of the National Board of Boiler and Pressure Vessel Inspectors. Each assembly has been Code stamped, in accordance with the 1971 or 1986 Edition ASME Boiler and Pressure Vessel Code, Section III.

The dose rate at which TVA has conducted 100 hour tests on materials and equipment is 10^6 Rad/hr dose rate that may occur during the first hour of a LOCA. It is the TVA position that a factor of 5 in dose rate is not significant in this region. There is no mechanism that TVA is aware of that would tend to produce significant increases in degradation in the region between 10^6 and 10^7 Rad/hr. However, radiation-induced oxidation of materials can become an important damage mechanism at lower exposure rates and consequent longer exposure times. Therefore, IEEE 278, "Guide For Classifying Electrical Insulating Materials Exposed to Neutron and Gamma Radiation," recommend using exposure rates above 10^7 Rad/hr. It is the TVA position that 10^6 Rad/hr for 100 hours represents a reasonable and conservative combination of dose rate and exposure time for radiation testing.

Cable terminations to low voltage power, control, and indication penetration assemblies are generally made in all metal splice boxes. However, in a number of instances on the outboard side of containment electrical penetrations, field cables were spliced to the penetration pigtails in cable trays. In these cases, a special enclosure was used to act as a qualified fire stop. These particular splices are located within the last 5-foot section of the cable tray. The trays in the annulus area of containment containing these splices are fitted with solid top and bottom covers in the immediate area of these splices. A qualified fire barrier made of silicone foam and ceraform/kaowool fiberboard was installed on the side of the splice opposite to the penetration. On the other side of the splice in the tray (end of tray runs toward the electrical penetration), kaowool materials were inserted in the voids between conductors, and all the exposed conductors to the electrical penetration were covered with Flamemastic material. Replacement penetrations manufactured to IEEE 317-1983 with pigtails in accordance with IEEE 383-1974 will not have their conductors coated with flamemastic between the splice enclosures and the penetration because the cables are flame retardant without the coating. This configuration constitutes a qualified fire barrier which in the unlikely event of a fire in the splice area, will contain and isolate the fire from adjacent trays of electrical equipment. Splices were made in accordance with vendor-recommended splicing procedures, and fully meet the environmental qualifications required for this location. The fire barrier and the electrical penetration splice box designs are based upon tests performed by Factory Mutual and TVA on full scale mockups. The TVA test results have been reviewed and approved by the NRC.

8.3.1.3 Conformance with Appropriate Quality Assurance Standards

Conformance with appropriate quality assurance is described in Chapter 17 and the Nuclear Quality Assurance Plan.

8.3.1.4 Independence of Redundant AC Power Systems

The criteria and their bases which have been used to establish the minimum requirements for preserving the independence of redundant Class 1E electric systems are stated in IEEE-308 and Regulatory Guide 1.6, Rev. 0. The TVA Nuclear Quality Assurance Plan describes the administrative responsibility and control that has been provided to assure compliance with these criteria during the design and installation.

The nuclear power generating station protection system (GSPS) includes the reactor protection system (RPS), engineered safety features (ESF), essential supporting auxiliary systems (ESAS),

and Class 1E electric systems. These systems are required for the safe shutdown of the reactor. Redundant systems are provided so that single failures, including failure of a redundant subsystem, will not result in failure to safely shutdown the reactor.

The reactor protection system (RPS) is the overall complex of instrument channels, power supplies, logic channels, and actuators together with their interconnecting wiring, involved in producing a reactor trip and is further described in section 7.2.

The engineered safety features (ESF) and essential supporting auxiliary systems (ESAS), as elements of the nuclear power generating station protection system, are the systems which take automatic action to isolate and to provide the cooling necessary to remove the thermal energy and thus enable the containment of fission products within the reactor vessel and primary containment in the event of a serious reactor accident. Certain ESAS systems may also be on continuous duty to prevent as well as to mitigate reactor accidents. Examples of ESAS systems are component cooling, emergency raw cooling water, together with their supporting electrical power and control systems.

These ESF systems consist of sensor instrument channels, power supplies, actuation channels, and actuators together with their interconnecting wiring involved in the operation of engineered safety features are actuated by the separate actuation channels. Each coincidence network energizes an engineered safety features actuation device that operates the associated safety features equipment (e.g., motor starter, valve operator, etc.) and are further described in section 7.3.

8.3.1.4.1 Cable Derating and Cable Tray Fill

Limitations imposed by cable tray fill and EQ cable derating have been considered in cable applications.

Selection of conductor sizes are based on IPCEA P-46-424 Power Cable Ampacities, except for safety related cable in tray, which are based on IPCEA P-54-440. Circuit breakers are used for high-speed clearing of faults to prevent damage to the 3-phase power cables. For power cables rated above 600 volts between conductors, the minimum size is 2/0 AWG. Ampacity of cables feeding motor circuits is based on not less than 125 percent of full-load current.

Conduit (for three cables or more) is sized for a maximum of 40 percent cable fill of the inside area of the conduit. Conduit for two cables is sized for a maximum of 31 percent cable fill of the inside area of the conduit. Conduit for single cables are sized for a maximum of 53 percent cable fill. Medium-voltage (6900-volt) power cables are routed on trays with other cables of the same voltage. All 6900-volt cables larger than 2/0 AWG are grouped triangularly and are separated from other circuits by a minimum distance overall of one fourth the effective diameter of the grouped 3-phase circuit. The 6900-volt cables which are 2/0 AWG may be laid at random on cable trays and are separated (as described above) from grouped 3-phase circuits. The nominal spacing may be less where cables enter or exit a tray and at tray fittings where it is necessary to prevent exceeding the minimum cable bend radius. However, nominal spacing is restored as soon as practical. Low-voltage power cable tray fill shall be limited to a maximum of 30 percent of the cross-sectional area of the tray, except when a single layer of cable is used. Cable tray fill for control and instrumentation cables shall be limited to a maximum fill of 60 percent of the cross-sectional area of the tray (if all cable are limited to 10A and less). Any exceptions to the above are evaluated and documented in design criteria SQN-DC-V-12.2 and/or SQN-DC-V-11.3.

8.3.1.4.2 Cable Routing and Separation Criteria

Electrical wiring for the GSPS, which includes the RPS, ESF, ESAS, and Class 1E electric systems, are segregated into separate divisions of separation (channels or trains) such that no single event, such as a short circuit, cable fire, pipe rupture, missile, etc., is capable of disabling

sufficient equipment to prevent safe shutdown of the reactor, removal of decay heat from the core, or to prevent isolation of the primary containment. The degree of separation required for GSPS electrical cables varies with the potential hazards in a particular zone or area of the power plant. These criteria do not attempt to classify every area of the nuclear plant, but specifies minimum requirements and guidelines that have been applied with good engineering judgment as an aid to prudent and conservative layout of electrical cable trays, wireways, conduits, etc., throughout the plant (both inside and outside the containment). Any exceptions to the requirements in this section are evaluated and documented in design criteria SQN-DC-V-12.2.

Mechanical Damage (Missile) Zone

Zones of potential missile damage exist in the vicinity of heavy rotating machinery or near other sources of mechanical energy, such as pipe whip, steam release, or pipes carrying liquids under high pressure. Layout and arrangement of cable trays, conduit, wireways, etc., are such that no locally generated force or missile can destroy both GSPS. In rooms or compartments having heavy rotating machinery, such as the reactor coolant pumps, or in rooms containing high-pressure feedwater piping or high-pressure steam lines, a minimum separation of 20 feet, or a minimum 6-inch thick reinforced concrete wall is provided between trays containing cables of different divisions. In an area containing an operating crane, such as the upper compartment of the reactor building, there is a minimum horizontal separation of 20 feet or a minimum 6-inch thick reinforced concrete wall between trays containing cables of the different divisions of separation.

Fire Hazard Zone

The electrical cabling has been arranged so as to eliminate, insofar as is practical, all potential for fire damage to cables and to separate the redundant divisions of GSPS cabling. Such arrangement ensures that fire in one division will not cause damage to cables in another division. Routing of power or control cable for GSPS through rooms or spaces where there is potential for accumulating large quantities (gallons) of oil or other combustible fluids through leakage or rupture of lube oil or cooling systems is avoided where possible. In cases where it is impossible to provide other routing, only one division of GSPS cables are allowed in any such space, and the cables are protected from dripping oil by the use of conduits or flanged covered cable trays designed to prevent oil from reaching the cables. No GSPS cables are routed through rooms containing oil storage tanks. In any room (except the auxiliary instrument room and the annulus) or space in which the only source of fire is of an electrical nature, cable trays carrying redundant divisions of GSPS cables have a minimum horizontal separation of 3 feet if no physical barrier exists between the trays. If a horizontal separation of at least 3 feet is not attainable, a fire-resistant barrier is provided. This barrier is either a 1/2-inch minimum thickness of Marinite-36 (or its equivalent), or a fire-resistant barrier of two sheets of minimum 14-gauge steel with a minimum 1-inch air space separating the two sheets of steel, extending at least 1 foot above (or to the ceiling) and 1 foot below (or to the floor) the line-of-sight communication between the two trays. Vertical stacking of trays carrying cables of different divisions of GSPS cables is avoided whenever possible. However, whenever it becomes necessary to stack open-top trays vertically, one above the other, there is a minimum vertical separation of 5 feet between trays carrying cables of different divisions. The lower tray has a solid steel cover and the upper tray has a solid steel bottom. If 5 feet is not attainable, then a fire-resistant barrier is provided. This barrier is either a 1/2-inch minimum thickness of Marinite-36 (or its equivalent), or two sheets of minimum 14-gauge steel with a minimum 1-inch air space separating the two sheets of steel. This barrier extends a minimum of 3 feet (or to nearest wall) on each side of the tray edge. In cases where trays carrying cables of different divisions of separation cross, there is a minimum vertical separation of 12 inches (tray top of lower tray to tray bottom of upper tray) with the bottom tray covered with a solid steel cover and the top tray provided with a solid steel bottom for a minimum distance of 3 feet on each side of the tray crossing.

Cable Spreading Room

The cable spreading room is the area provided under the main control room where cables leaving the various control board panels are dispersed into cable trays or conduits for routing to all parts

of the plant. Since the cable spreading room is protected from missiles by its seismic Category I walls and there are no internal sources of missiles, such as high-pressure piping or heavy rotating machinery, the only potential source of damage to redundant cables is from fire. Fire protection features provided for the cable spreading room are described in the Fire Protection Report (see 9.5.1). Where GSPS cables of different divisions of separation approach the same or adjacent unit control panel (see the Main Control Room discussion) with spacing less than 3 feet, these cables are run in metal (rigid or flexible) conduit or enclosed wireway to a point where 3 feet of separation exists. A minimum horizontal separation of 3 feet separates trays carrying cables of different divisions (channels or trains) if no physical barrier exists between the trays. Where a horizontal separation of 3 feet does not exist, a fire-resistant barrier of either a 1/2-inch minimum thickness of Marinite-36 (or its equivalent), or two sheets of steel (minimum 14 gauge) with a minimum 1-inch air space separating the two sheets of steel, extending at least one foot above (or to the ceiling) and one foot below (or to the floor) the line-of-sight communication between the two trays. Vertical stacking of cable trays carrying cables of different divisions of separation has been avoided whenever possible. However, whenever it becomes necessary to stack open trays vertically, one above the other, there is a minimum vertical separation of five feet between trays carrying cables of different divisions of separation. The lower tray has a solid steel cover and the upper tray has a solid steel bottom. If five feet is not attainable, then a fire-resistant barrier is provided. This barrier is either a 1/2-inch minimum thickness of Marinite-36 (or its equivalent), or two sheets of steel (minimum 14 gauge) with a minimum 1-inch air space separating the two sheets of steel. This barrier extends a minimum of 1 foot (or to the nearest wall) on each side of the tray edge.

In cases where trays carrying cables of different divisions of GSPS cables cross horizontally, there shall be a minimum vertical separation of 1 foot (tray top of lower tray to tray bottom of upper tray). The bottom tray shall be covered with a solid steel cover, and the top tray provided with a solid steel bottom for a minimum distance of 3 feet on each side of the tray crossing or to the wall(s).

Auxiliary Instrument Room and Reactor Building Annulus

The auxiliary instrument room is the area under the cable spreading room. The auxiliary instrument room contains the process instrument racks, the solid-state protection racks, and associated instrument and relay racks. Since the auxiliary instrument room is protected from missiles by its seismic Category I walls and there are no internal sources of missiles, such as high-pressure piping or heavy rotating equipment, the only potential source of damage to redundant cables is from fire. Fire protection features provided for the auxiliary instrument room are described in the Fire Protection Report (see 9.5.1). No power cables that have a protective device rated greater than 30 ampere are routed in this room unless they are in separate conduits.

Solid-bottom type cable trays with solid steel flanged covers have been used where a minimum horizontal separation of 1 foot and a minimum vertical separation of 3 feet cannot be maintained. A minimum horizontal separation of 1 foot is provided between trays carrying cables of different divisions (channels or trains) if no physical barrier exists between them. If required the same barriers as in the cable spreading room are provided. Whenever it becomes necessary to stack different division trays vertically, one above the other, there is a minimum separation of 3 feet between these trays carrying cables of different divisions. If 3 feet is not attainable, then a fire-resistant barrier is provided. Whenever it becomes necessary to stack channel I, II, III, or IV trays vertically, one above the other, there is a minimum separation of 1 foot between the tray top of lower tray and the tray bottom of upper tray. If 1 foot is not attainable, then a fire-resistant barrier is provided. These barriers for trays (trains or channels) stacked vertically are equivalent to either a 1/2-inch minimum thickness of Marinite-36 (or its equivalent), or two sheets of steel. This barrier extends a minimum of 1 foot (or to nearest wall) on each side of the tray edge. In cases where redundant trays cross, there is a minimum vertical separation of 1 foot (tray top of lower tray to tray bottom of upper tray) with covers and

bottoms 3 feet on each side of crossing. As the cable trays or enclosed wireways leave the solid-state protection system racks, they are spread as soon as possible to attain these separations.

The Annulus

The annulus is the area in the reactor building between the steel containment vessel and the concrete shield building. Cables leaving the various electrical penetrations in the annulus are dispersed into cable trays or conduit for routing through the shield building wall to other areas of the plant. Since the annulus is missile protected by its seismic Category I wall and there are no internal sources of missiles such as rotating heavy machinery, the only potential source of damage to redundant cables would be from fire. Fire protection features provided for the annulus are described in the Fire Protection Report (see 9.5.1). Separation requirements for raceways containing redundant divisions of GSPS cables are the same as the Auxiliary Instrument Room.

Main Control Room and Auxiliary Control Room

Redundant GSPS cables enter the main control room through separate floor openings. Each unit control panel, which has redundant components, has a minimum of three separate vertical and/or horizontal risers (enclosed wireways) from each of the respective terminal block groups to the control room floor (or bottom of walk space). Metal conduit penetrations may also be used to provide separation. Non-safety related cables are routed through one or more riser(s), preferably near the center of the control panel. The redundant GSPS cables (train A or train B separation) are routed separately in each of the other two or more risers, preferably one near each end of the control panel. Risers of like trains of separation have been arranged such that the adjacent panel has a corresponding like train riser (i.e., train A in one panel has train A nearest it in the adjacent panel).

The minimum separation distance between redundant Class 1E circuits internal to Control Boards, Panels, Relay Racks, etc., is 6 inches of free air space. Wherever this separation distance is not maintained, barriers are provided between redundant Class 1E wiring. Within the Westinghouse supplied main and auxiliary control room panels, braided sheath material, such as Belden Braid, is an acceptable barrier for reducing the redundant Class 1E separation to less than 6 inches. The braid is used only over wire with teflon or other approved insulation. Braid covered wiring for redundant Class 1E circuits are restrained such that their braids do not touch nor are they able to migrate with time to touch.

Within an enclosure containing multiple divisions of wiring the redundant divisions of Class 1E wiring are separated from non-divisional wiring by a 6-inch air space or barrier, except as described below. If non-divisional wiring must be terminated on a Class 1E (divisional) component (switch, relay, terminal block, etc.), the component must be rated for the maximum voltage and current which could be applied to the non-divisional component and the non-divisional circuit is run with the divisional wiring, terminated on the divisional riser, and treated as a non-divisional cable routed with divisional (GSPS) cables per cable tray and conduit systems separation requirements. The non-divisional wiring is in close proximity to the Train "A" wiring and must not be routed with Train "B" cables or routed to Train "B" equipment.

Most Class 1E panels and enclosures contain wiring for only one division of redundant Class 1E circuits and wiring for non-divisional circuits. For these enclosures the non-divisional circuit wiring is assumed to be in close proximity to the wiring for the single division of Class 1E circuits in the enclosure. Therefore, the entire non-divisional circuit (including external cabling) is separated from all wiring and cabling of the opposite redundant division of Class 1E circuits. All non-divisional cables routed to the enclosure are treated as "non-divisional cables routed with divisional (GSPS) cables" per cable tray and conduit systems separation requirements. Also see section 7.7.1.10 for electrical separation in the panels.

Wiring for utility power outlets and lighting circuits installed in control boards, panels, or enclosures are in dedicated conduits to provide separation from Class 1E and Non-Class 1E wiring.

Non-safety related functions that are derived from Class 1E circuits must employ adequate isolation. Isolation is adequate if no credible failure on the non-Class 1E circuit prevents the Class 1E circuit from performing its design basis function. Credible failures include short circuits, open circuits, grounds, and the application of the maximum credible AC or DC potential.

Separation of Class 1E Electric Equipment

All Class 1E electric equipment has physical separation, redundancy, and a controlled environment to prevent the occurrence of an external event that would threaten the safe shutdown of the reactor. No internally generated fault can propagate from Class 1E electric equipment to its redundant equipment during any design basis event. All Class 1E electric equipment that has to operate during a flood has been located above maximum possible flood level unless it is designed to operate submerged in water.

Separation for fire protection is provided as described in the Fire Protection Report (see FSAR Section 9.5.1).

The Class 1E electrical loads are separated into two or more redundant load divisions (channels or trains) of separations. The number of divisions has been determined by the number of independent sources of power required for a given function. The electric equipment that accommodates these redundant divisions is separated by sufficient physical distance or protective barriers. The separation distance has been determined by the severity and location of hazards. The environment in the vicinity of the equipment is controlled or protection provided such that no environmental change or accident will adversely affect the operation of the equipment.

The physical identification of safety-related electrical equipment is in accordance with Paragraph 8.3.1.5.

6900-Volt Equipment

The diesel generators and 6900-volt shutdown boards are designed for a two-division (train A and train B) separation. Refer to section 8.3.1.1 for location and arrangement information. The 6900-volt equipment is located in seismic Category I structures. The diesel generators are shown in Figure 1.2.3-17. The 6900-volt shutdown boards are shown in Figure 1.2.3-3.

480-Volt Equipment

The 480-volt shutdown boards, 480-volt reactor MOV boards, 480-volt reactor vent boards, and control and auxiliary building vent boards locations and arrangements are described in section 8.3.1.1 and shown in Figures 1.2.3-2 and 1.2.3-3.

125-Volt DC Equipment

The separation of the 125 Volt DC equipment is addressed in section 8.3.2.1.1.

120-Volt AC Equipment

The vital inverters location and arrangement is described in 8.3.1.1 and shown in Figure 1.2.3-2.

Auxiliary Control Board

Shutdown from remote locations outside the main control room due to the main control room, cable spreading room, or the auxiliary instrument room becoming uninhabitable or inoperable is

performed at auxiliary control stations. This remote shutdown auxiliary control is fully described in section 7.4 and the Fire Protection Report (see 9.5.1).

Electrical Penetrations of Primary Containment

Redundant GSPS cables enter the containment via separate electrical penetrations. Where possible, redundant GSPS cables utilize electrical penetrations spaced horizontally instead of vertically. Where redundant GSPS cables are installed in electrical penetrations spaced vertically, power cables carrying high energy are located above low energy circuits, or barriers are provided between the high energy and low energy circuits where the vertical spacing is less than 3 feet. Two or more areas have been provided for electrical penetrations so that redundant GSPS cables can be installed in separate penetration areas. Cables through penetrations of the primary containment are grouped in such an arrangement that failure of all cables in a single penetration cannot prevent a RPS or engineered safety features action. The penetrations are tabulated in Figures 8.3.1-21 and 8.3.1-22.

8.3.1.4.3 Sharing of Cable Trays and Routing of Nonsafety-Related Cables

There are five different cable tray systems, namely: 6900-volt, 480- volt, control, medium-level signal, and low-level signal trays. The 6900-volt trays carry only 6900-volt cables and are located in the highest level position of stacked trays. All 480-volt power cables and power and control cable, lighting cabinet feeders, and DC power cables that have a protective device rated greater than 10 amperes are run in 480-volt trays. Old installations were limited to cables rated above 30 amperes. Medium-level signal trays carry the following cables: signal cables for inputs to and outputs from the computer other than thermocouples; instrument transmitter, recorders, RTD's greater than 100 millivolts, tachometers, and indicators; rotor eccentricity and vibration detectors; and shielded annunciator cables used with solid-state equipment. Signal cables for thermocouples, strain gauges, thermal converters, and RTD's that are 100 millivolts or less are run in low level signal trays which occupy the lowest level in a stack of trays. All other cables are run in control trays. Any exceptions to the requirements of this section are evaluated and documented in design criteria SQN-DC-V-12.2 or SQN-DC-V-11.3.

Within a division the minimum standard spacing between trays stacked vertically is 9 inches, tray bottom to tray bottom. Within a division, the minimum standard spacing between trays installed side by side is 6 inches. The trays are constructed of galvanized steel, 6 to 18 inches wide and approximately 4 inches deep. Cable tray systems are supported as described in Subsection 3.10.2.

Divisional RPS cables, inside and outside containment, are routed in cable trays and/or conduits that are designated for their respective division of separation.

ESF and ESAS cables (trains A and B) are routed in 6900-volt, 480-volt, or control trays and/or conduits that are designated for their respective division of separation.

Vital cables for the GSPS which includes the RPS and ESF may be routed in the same conduits, wireways, or cable trays provided the circuits have the same characteristics such as power supply and channel identity (I, II, III, or IV).

Automatic actuation and power circuits for the GSPS which includes the RPS, ESAS, reactor scram logic, and ESF may be routed in the same conduits, wireways, or cable trays provided the circuits have the same characteristics such as power supply and division identity.

Unit 1 and Unit 2 circuits may be routed in the same conduits, cable trays, or wireways provided the circuits have the same characteristics such as power supply and channel identity (I, II, III, or IV).

Cables for non-safety related functions shall not be run in conduit used for GSPS circuits except at terminal equipment where only one conduit entrance is available. The non-safety related

cable shall be separated from the GSPS cable as near to the terminal equipment as practical. Cables for non-safety related circuits may be run in cable trays with those for GSPS circuits with the following restrictions. When a non-safety related cable is installed in a tray with GSPS cables, it is not permissible to subsequently route that cable or any cable in the same circuit onto another tray containing a different division of separation of GSPS cables. All conduit systems (for safety related cables) located in seismic Category I structures have seismic Category I supports, and are described in Subsection 3.10.2. Under no circumstances shall GSPS cable(s) be installed in any non-safety related cable tray or conduit located in a Seismic Category I structure.

There are certain safety-related components which are located in a nonseismic structure. The circuits for these components or devices have the following separations. While in a Category I structure, these circuits are routed with train or channel circuits depending on their application. When they leave the Category I structure, these circuits have been separated physically and electrically to reduce the possibility of damage to more than one redundant circuit.

There are certain safety-related components which are powered from two redundant divisions (channels or trains) through manual transfer devices. These components include, but not limited to, the component cooling water pump C-S, and the steam turbine driven auxiliary feedwater pumps 1A-S and 2A-S. The output feeder cables from the transfer device to the component require special separation and are routed in separate conduit(s) with no other circuits with the following exception. Cables with a suffix S may be routed together provided the following two conditions are satisfied: (1) voltage levels are compatible and (2) circuits are designed such that under any design basis event, all cables in the raceway will always be of the same division (channel or train) when energized. These circuits are identified by a suffix S added to their respective conduit and cable numbers. The redundant feeder supply cables to the transfer devices are routed in separate conduit, or are separated by 6 inches of free air space or barrier provided within panels housing transfer devices, and the cables shall have divisional separation depending on the source of supply and physical location.

The GSPS receives its power supply from preferred (off-site) and the standby (onsite) sources. The normal power and control circuits from the preferred source are routed in conduits or cable trays separate from the alternate power and control circuits. These circuits are identified by a suffix S1 or S2 added to their respective cable numbers, except for the circuits involved with the primary of common station service transformer (CSST) which are identified by suffix S3.

The feeder circuits from the 125-volt vital battery boards to the control buses in the shutdown boards are separated into four divisions (Channels I, II, III, and IV). Feeder cables to the control buses in the train A shutdown boards are supplied from battery boards I and III and the feeder cables to the control buses in the train B shutdown boards are supplied from battery boards II and IV. The Channels I, II, III, and IV vital instrument power systems are supplied from vital battery boards I, II, III, and IV, respectively, and have been physically separated and routed independently from each other.

8.3.1.4.4 Fire Detection and Protection in Areas Where Cables Are Installed

Fire protection features provided in areas where cables are installed are described in the Fire Protection Report (See 9.5.1)

8.3.1.4.5 Cable and Cable Tray Markings

Field wiring (with associated conduits and cable trays) of the GSPS, which includes RPS, ESF, and Class 1E electric systems, is identified so that two facts are physically apparent to plant operating and maintenance personnel:

1. That wiring is properly identified as being associated with the GSPS and

2. That wiring is properly identified as part of a particular division (or grouping) of enforced segregation within the GSPS.

Each cable has been assigned a number consisting of a combination of letters and numbers. In addition, cables of the GSPS have been assigned special separation suffixes (A or B for train A or train B; or S for special; or I, II, III, IV for channels I, II, III, or IV, respectively).

A computerized cable routing program has been used to route and check all cables.

The main functions of this program are as follows:

1. To route and measure cables through the shortest route in a tray system

2. To maintain a predetermined maximum tray loading

3. To ensure proper separation of divisional cables is maintained on its respective tray assignment

4. To separate circuit types (high-voltage power, low-voltage power, control, signal, and thermocouple)

5. To provide installation information

6. To maintain cable inventory

7. To provide printouts of all cables routed on any tray

8. To provide printouts of all cables for a system.

Initial inputs into the computer include the cable list and the cable tray systems. The cable list includes all cable types that will be used for the project. These cable types are identified by code-mark letters. The corresponding cross-section area (based on nominal outside diameter of the cables) for each cable is also entered since the maximum tray loading is based on cross-sectional area except when a single layer of cable (or grouping of 3-phase circuits) is used. The tray system lists each section of tray, its from and to nodes, length between nodes, maximum allowable tray fill and a node voltage level code letter which identifies it for a particular circuit type. The node voltage levels for the respective cable tray system are as follows:

NV-1 - Nonsafety related low level signal cables

NV-2 - Engineered safety feature train A and B and nonsafety-related medium level signal cables

NV-3 - Nonsafety related control cables

NV-4 - Nonsafety related low-voltage power cables (480V or lower voltage with a current of 10 amperes and above)

NV-5 - Nonsafety related 6.9-kV power cables

NV-6 - Reactor protection system channel I cables

NV-7 - Reactor protection system channel II cables

NV-8 - Reactor protection system channel III cables
(The reactor protection system identification for channel III has been translated to C3 for computer programming purposes.)

NV-9 - Reactor protection system channel IV cables

NV-10 - Engineered safety features train A control cables

NV-11 - Engineered safety features train B control cables

NV-12 - Engineered safety features train A low-voltage power cables (similar to NV-4)

NV-13 - Engineered safety features train B low-voltage power cables (similar to NV-4)

NV-14 - Engineered safety features train A 6.9kV power cables

NV-15 - Engineered safety features train B 6.9kV power cables

NV-16 - Engineered safety features special control cable

NV-17 - Engineered safety features special low voltage power cable

The field wiring for the GSPS equipment and components have distinct color coded tags at terminations for each division of separation (channels or trains). The conduits, conduit boxes, and cable trays for field wiring of the GSPS equipment are color coded (by tags, nameplates, or markings on exterior surfaces) at conspicuous intervals showing their respective division of separation. The color coding scheme used to identify divisions of separation follows:

System	Division of Separation	Basic Color or Background	Letters or Engraving
Engineered Safety Features (ESF), Essential Supporting Auxiliary Systems (ESAS), and the Class 1E Diesel Generator Power Systems	Train A	Orange	White
	Train B	Brown	White
	Special*	Gold	Black
Reactor Protection System (RPS) and the Class 1E Vital AC and DC Battery Systems	Channel I	Red	White
	Channel II	Black	White
	Channel III	Blue	White
	Channel IV	Yellow	Black
Post Accident Monitoring (PAM)	PAM 1 (J cables)	Purple	White
	PAM 2 (K cables)	Green	Black

*The circuits requiring special separations are identified by a suffix S and described in Subparagraph 8.3.1.4.3.

Cable tray markings are identified by a 2- or 3-letter system. First letter designations for the different voltage levels are assigned as follows:

A through D are for 6900-volt trays
E through I are for 480-volt trays

J through S are for control trays, except Q
T and U are for low level signal trays
V and X are for medium level signal trays

The cable trays which carry cables of the generating station protection system are further physically identified by adding a suffix -A, -B, -I, -II, -III, or -IV for its respective division of separation. The markings are color coded as indicated above.

8.3.1.4.6 Spacing of Power and Control Wiring and Components Associated with Class 1E Electrical Systems in Control Boards, Panels, and Relay Racks

Redundant power and control wiring and components associated with Class 1E electrical systems in control boards, panels, and relay racks are separated by either a minimum of six inches of air space or metal barrier (braided sheath material). See paragraph 7.1.2.2 for more detail of spacing of wiring and components in control boards, panels, and relay racks. Any exceptions to the above are evaluated and documented in design criteria SQN-DC-V-12.2.

8.3.1.4.7 Separation Between Redundant Trays

The criteria for separation between redundant trays for various zones or areas of the plant is described in Subparagraph 8.3.1.4.2. Where the physical separation between redundant trays could not be attained, fire resistant barriers have been provided. This is not to be confused with the specific fire protection principles applied to equipment required for FSSD (i.e., Appendix R). General fire protection principles have been applied in protecting safety-related systems from unacceptable fire hazards. Fire barriers for safe shutdown requirements of 10 CFR 50, Appendix R and Appendix A to BTP 9.5.1 are described in the Fire Protection Report (see 9.5.1).

Cable fire stops for redundant cable tray runs through openings in floors and openings in walls between buildings have been provided. Also, fire barriers have been installed in floor openings for redundant cables entering the main control room. These barriers are described in the Fire Protection Report (see 9.5.1).

8.3.1.5 Physical Identification of Safety-Related Equipment in AC Power Systems

The onsite power system equipment is identified similar to that described in section 8.3.1.4.5. The scheme used to physically identify major safety-related electrical equipment employs a suffix label. The suffix label added to the equipment name is -A or -B, which represents train A or train B diesel-generator power source. For example, 6900-volt shutdown board 1A-A is safety-related equipment, where the 1 indicates Unit 1, the A represents board A, and the -A is assigned to train A.

The 125-volt DC vital system is shared between both units and divided into four channels. The 125-volt vital charger, 125-volt vital battery board, and 125-volt vital battery of each channel is physically identified in its label by I, II, III, or IV, respectively.

The 120-volt AC vital instrumentation and control power system is divided into four channels. Four each of the 120-volt AC vital inverters and vital instrument power boards are identified by Unit 1 or 2 prefix and a -I, -II, -III, or -IV suffix, respectively. For example, 120-volt AC vital instrument power 1-I is safety-related equipment, where the 1 indicates Unit 1, and the -I is assigned to channel I.

Nameplates, tags, or markings on exterior surfaces of this equipment are color coded respective to its division of separation as described in Subparagraph 8.3.1.4.5, except in the unit control and auxiliary (backup) control rooms. The mimic buses or modules on these boards are color coded by systems. The component nameplates on exterior surfaces of the panels or boards in these rooms are white background with black letters except for the Post-Accident Monitoring System components in the Unit Control Room (UCR). The component nameplates on exterior surfaces of the panels associated with the Post-Accident Monitoring System in the Unit Control

Room shall be as described in Section 7.5.2.3. To indicate to the operator that a component in these rooms is safety related, an appropriate symbol is added to those applicable nameplates. The symbol is

 for train A,  for train B.

The component nameplates on exterior surfaces of the boards in the unit control and auxiliary (backup) control rooms have the same color scheme for compatibility. The face plates on control switch modules and the mimic buses are color coded distinctly for each mechanical or electrical system for TVA standard operational convenience. To further divide operational systems into divisional colors would require twice as many colors, would be confusing, and would offer very little operational information to the operator. The reason for adding the unique symbol on an exterior nameplate is to readily identify to the operator which division of separation that component is assigned. However, termination of field wiring inside these boards is color coded by its respective division of separation as defined in Subparagraph 8.3.1.4.5. In addition, the enclosed wireways for board wiring and wire bundle groupings of board wiring are similarly marked.

The physical identification of the field wiring (with associated conduits and cable trays) for the onsite power system equipment is described in Subparagraph 8.3.1.4.5, cable and cable tray markings.

8.3.2 Direct Current (DC) Power System

8.3.2.1 Description

8.3.2.1.1 Vital 125V DC Control Power System

The vital 125-volt DC control power system is a Class 1E system whose safety function is to provide control power for engineered safety features equipment, emergency lighting, vital inverters, and other safety related DC powered equipment for the entire plant. The system capacity is sufficient to supply these loads during normal operation and to permit safe shutdown and isolation of the reactor for the loss of all AC power condition. The system is designed to perform its safety function subject to a single failure.

System Design Requirements

The requirements described below were implemented in the design of the Vital DC Power system.

Redundancy

The system is composed of four redundant channels (I, II, III, and IV). These four channels are used to provide emergency power to the four vital 120V AC inverters per unit which supply control power to the reactor protection system. Other loads are either two divisional or nondivisional loads. No automatic connections are used between the four redundant channels.

Separations

The four channels are electrically independent and physically separated so that a single failure in one channel will not cause a failure in another channel. Each channel has a charger, a battery, and a load distribution board.

Each 125-volt vital battery is separated from all other 125-volt vital batteries by providing individual rooms for each battery with 8 inch reinforced concrete block walls extending to the ceiling. The ventilation system is designed to remove and dissipate the hydrogen given off by the batteries (see Section 9.4). The 125-volt battery chargers (6-one per battery and two

spares) are physically separated from each other. Each 125-volt vital battery board is separated from all other 125-volt vital battery boards by 8 inch reinforced concrete block wall extending to the ceiling. The location of these batteries, chargers, and boards is shown in Figures 1.2.3-2 and 1.2.3-3.

The fifth vital battery is similarly separated from the other vital batteries. The fifth vital battery system has manual transfer switches that allow it to replace any of the other four batteries.

Capacity

Each battery charger has the capacity to continuously supply the normal, or the SBO (DB accident) loads and maintain the battery in a fully charged condition. With the batteries in the fully charged condition each battery has the capacity to supply the connected loads for 45 minutes and to supply a load reduced for Station Blackout (loss of all ac power) for an additional 195 minutes. The total connected loads are analyzed with a diversity factor. This capacity is available at the battery's end of qualified life and with the cell electrolyte at the minimum design temperature of 60° F. The primary vital batteries and vital battery V are designed to an end voltage of 1.75 volts per cell with 60 cell and 62 cell configurations, respectively. The primary vital battery is composed of 60 cells and Vital Battery V is composed of 62 cells. The additional two cells in Vital battery V makes up for the additional voltage drop involved in connecting it to a primary vital battery board. The manufacturer's ratings adjusted for minimum design cell temperature and battery end-of-life per guidance in IEEE Standard 485 is the basis for sizing the battery. The vital batteries are tested periodically to verify that the battery can supply the currents required to meet the loading requirements. The battery is tested per IEEE-450 and the results compared to the vendor capacity ratings. This rating was confirmed by TVA acceptance tests.

Charging

The normal and spare chargers have the capacity to continuously supply the normal loads and maintain the batteries in the design maximum charged state or to recharge the batteries from the design discharge state within an acceptable time interval, while supplying the normal loads. Each charger may be replaced by a spare charger. One spare charger is provided for each two normal chargers.

Vital battery V charger (non 1E) is sized exclusively to maintain vital battery V at float voltage when this battery is not in service.

Ventilation

Each battery room has redundant ventilation systems to prevent the accumulation of explosive gases. In addition to the ventilation systems provided to prevent accumulation of the hydrogen produced by the battery, there are voltmeters, high voltage alarms, and administrative procedures for control of equalizing charges that will provide additional protection. Also as an added precaution all cells are of the sealed type and have an explosion-proof vent that is designed to prevent the ignition of gases within the cell from a spark or flame outside the cell.

Vital Battery Loading

Loads are assigned according to their divisional requirements. Loads requiring four divisions of separation are assigned to the four channels. Loads requiring two divisions of separation are assigned to Channels I or III and II or IV. Two divisional loads primarily associated with Unit 1 are assigned to Channels I and II, while those primarily associated with Unit 2 are assigned to channels III and IV. The nondivisional load assignments are distributed among the four channels.

Each channel supplies the following types of loads: control circuits for the shutdown boards, relay panels, solenoid valve fuse panels, emergency lighting cabinets, inverters, annunciators, and panels associated with reactor instrumentation and control systems. Loads are assigned

according to the divisional requirements. The divisional loads primarily associated with Unit 1 are assigned to Channels I and II while loads primarily associated with Unit 2 are assigned to Channels III and IV. Nondivisional loads primarily associated with Unit 1 are assigned to Channels I or II. Similarly nondivisional loads associated with Unit 2 are assigned to Channels III or IV. Nondivisional loads that are primarily associated with plant common services are distributed among the four channels. Some loads have a normal and alternate feeder. The normal feeder is from one channel while the alternate feeder is from another channel. The transfer of the loads between the two feeders is manual and is interlocked to prevent paralleling the redundant power sources.

Due to the requirements of 10 CFR 50.63, the SQN safety related DC power system is required to mitigate a SBO event for four hours. The four hour duty cycle necessitates the stripping of loads. Loads are stripped from the vital battery before 45 minutes into a station blackout event. Forty five minutes is sufficient for the operators to recognize that a SBO is in progress and to dispatch operators to the vital battery board rooms to switch off designated circuit breakers. Certain loads in the station battery rooms are removed prior to 45 minutes into the SBO event. The SQN power system has been analyzed for the SBO event and those circuits that are necessary to mitigate the event and to restore off-site power when it becomes available are maintained. SQN also retains sufficient instrumentation to monitor the condition of the reactor core so that in the event that core damage becomes likely, the containment can be isolated.

Nonsafety related loads are supplied from the Class 1E distribution board. The feeders for these loads have circuit breakers located in the distribution board to automatically isolate a faulted feeder from the system.

Most of the DC loads (during battery recharge following an AC outage the inverters and lighting loads are supplied from AC power) for each channel are supplied from a battery charger when it has either normal or standby AC power available from the 480-volt shutdown boards. If the normal charger is unavailable, the loads are supplied from either the associated battery or a spare charger which can be manually connected to the battery board.

Tests and Inspections

The 125-V DC control power system is periodically tested and inspected to assure the continued adequacy of the system to perform its intended function throughout the life of the plant. The system is equipped with ground detection and instrumentation to continuously monitor the system.

Periodic surveillances are performed on the batteries pilot cells to verify the electrolyte temperature is greater than 60 degrees F, and on each connected cell that the electrolyte level is greater than the minimum level indication mark and less than or equal to 1/4 inch above the maximum level indication mark to ensure compliance with Technical Specifications (Reference 3).

Identification

Equipment identification for DC is identical to AC equipment as discussed in Paragraph 8.3.1.5.

Load Time of Application

The vital battery system capacity and load time is addressed in the Capacity and Vital Battery Loading parts of this section. Manual load stripping is utilized to cope with a SBO.

System Structure

The configuration of the DC control power system is shown on Figure 8.1.2-2. Each channel is ungrounded and incorporates ground detection devices, with alarm in the main control room.

Physical Arrangement of Components

The battery boards, vital chargers, vital batteries, and diesel generator batteries comprising the DC power system are arranged to provide adequate physical isolation and electrical separations to prevent common mode failures. The analysis verifying the adequacy of independence appears in Paragraph 8.3.2.2. The specific arrangement of components is discussed below.

125-VOLT VITAL BATTERIES I, II, III, AND IV Reference: Figure 1.2.3-2

These batteries are located in individual rooms on elevation 749 of the auxiliary building. The heating and ventilating systems are described in section 9.4.

VITAL BATTERY V Reference Figure 1.2.3-2.

The fifth vital battery is located on elevation 749 of the Auxiliary Building. The fifth vital battery system meets the technical specification requirements when a normal battery is out of service. The fifth vital battery with 62 cells responds identically to the normal batteries with 60 cells. With one cell removed, the fifth vital battery has slightly, but not significantly, more capacity than the normal batteries.

The fifth vital battery is a subsystem of the 125 V Vital DC Power System and comprises a battery, non-safety related charger, a battery board and two distribution panels, cabling and conduits. The vital battery system is shown in key diagram format in figure 8.1.2-2.

Electrical separation between the fifth vital battery and the normal batteries is provided by circuit breakers located in each normal battery board and a transfer switch at the fifth vital battery board. Refer to the section on the Vital Battery Board V for more information on breaker operation. These panels contain additional transfer switches which are normally maintained open. System operation is completely manual and the conduits and cables are designated -S (special) division of separation. The interconnecting cables are routed independently of all other trains and divisions of separation.

125-VOLT VITAL BATTERY BOARDS I, II, III, IV, AND V Reference Figures 1.2.3-2 and 1.2.3-3

Battery boards I, II, III, & IV are located in individual rooms on elevation 734.0 of the auxiliary building. Board V is also located in the Auxiliary Building in a room on elevation 749. The heating and ventilating system is described in section 9.4.

125-VOLT DIESEL GENERATOR BATTERIES 1A-A, 1B-B, 2A-A AND 2B-B Reference: Figure 1.2.3-17

These batteries are located in individual rooms on elevation 722.0 of the diesel generator building. They are located in the room with the diesel generator with which each is associated. Each battery is equipped with its own exhaust hood located directly over it. The heating and ventilating system for the diesel generator rooms is described in section 9.4.

Normal DC Supply (Reference 3)

The normal supply of DC current to the battery boards is from the battery charger in each channel. Each charger maintains a floating voltage of approximately 135 volts on the associated battery board bus (the battery is continuously connected to this bus also) and is capable of maintaining 140 volts during an equalizing charge period (all the loads have been specified and designed to operate at the 140 volt equalizing voltage). The charger supplies normal load demand on the battery board and maintains the battery in a charged state. Optimal long term performance is obtained by maintaining a minimum float voltage of 129 V DC. This voltage is greater than the 2.13 V per connected cell in the 60 connected cell battery. This provides adequate over-potential, which limits the formation of lead sulfate and self

discharge. Normal recharging of the battery from the design discharged condition can be accomplished in 12 hours (with accident loads being supplied) following a 30-minute AC power outage and in approximately 36 hours (with normal loads being supplied) following a 4-hour AC power outage. Per the vendor (see reference 2), after a discharge, when the float current drops to less than or equal to 2 amps, the battery should be at least 98% charged. A 98% charged battery maintains at least a 5% design margin. Two spare chargers are available for the four channels (one each for two channels). It can substitute for or operate in parallel with the normal charger in that channel.

Each charger is provided with manual transfer facilities to connect either a normal or an alternate AC input source. The normal and alternate sources are so arranged such that a loss of a single emergency

AC onsite power supply does not leave a charger without an AC input source. Each charger is equipped with a DC voltmeter, DC ammeter, and charger failure alarm. Malfunction of a charger is annunciated in the main control room. Each charger is powered from the 480V shutdown boards (normal and alternate) which upon loss of normal power are energized from the standby power system.

The charger is a solid-state type which converts a three-phase 480-volt AC input to a nominal 125-volt DC output having a rated capacity of at least 150 amperes. Over this output current range the DC output voltage will vary no more than ± 1.0 percent for a supply voltage amplitude variation of ± 7.5 percent and frequency variation of ± 2.0 percent.

Some operational features of the chargers are: (1) an output voltage adjustable over the range of at least 129 to 140 volts, (2) equalize and float modes of operation (the charger normally operates in the float mode, but can be switched to the equalize mode), (3) a current-limit feature which limits continuous overload operation to 125 percent of rated output, (4) protective devices which prevent a failed charger from discharging its associated battery and protect the charger from external overloads, (5) metering and alarm circuits to monitor the charger output, (6) parallel-operation capability.

The fifth vital battery charger is never used as the normal supply to battery boards I, II, III, or IV. It only maintains fifth vital battery when it is not in service.

Emergency DC Supply

The emergency supply of DC current to each distribution board is from its associated vital battery or Vital Battery V. There are four vital batteries for the plant--one associated with each channel. The vital batteries supply the entire plant safety-related DC load in the event the normal power source is unavailable. With normal power unavailable and one battery out of service, the three remaining vital batteries are capable of supplying continuously for 30 minutes all loads required for safe shutdown of both units. The batteries also have the capability to supply the essential loads required to maintain the plant in a safe shutdown condition for four hours following a loss of all normal and standby AC power, but no accident. Each battery is normally required to supply loads only during the time interval between loss of normal feed to its charger and the receipt of emergency power to the charger from the standby diesel generator.

Vital Battery V may be the emergency DC supply (See discussion in section on Vital Battery Board V).

Vital Battery Boards I, II, III, and IV

Battery board I to IV consists of four metal-enclosed panels. Mounted on these panels are: the main distribution bus, battery and charger input buses, load group fuses, load group buses, subdistribution circuit breakers, and various instruments for monitoring board loading.

Each subdistribution circuit breaker is coordinated to its load group fuse. Each load group fuse is coordinated to the 1600-ampere battery supply fuse. The charger input fuses are coordinated to the battery supply protective devices. The purpose of this coordination scheme is to prevent a fault on one subdistribution or charging feeder causing a loss of the emergency supply.

The variation in fuses is based on the individual circuit breaker trip settings, or ratings for all devices, which are shown in Figure 8.3.2-1.

All circuit breakers have trip alarm contacts to alert the control room operator of a tripped breaker. The ground indicator has an alarm contact to warn the operator of a distribution system ground. Metering on the distribution board includes: battery current, bus voltage, main and spare charger voltage, board charging current, and ground current. Metering for battery current and bus voltage are also located on the main control board. Battery discharge alarm is provided in the MCR.

Vital Battery Board V

This board consist of two metal enclosed panels. Mounted on these panels are: the main distribution bus, battery and charger input circuit breakers, battery board main breaker and fuse, one transfer switch and various instruments for monitoring the board.

The fifth vital battery board is used to connect the vital battery V to a normal vital battery board when the corresponding normal battery is out of service for any reason. For this purpose there is a transfer switch composed of two inter-connected non-automatic circuit breakers separated by a metallic barrier. One breaker is connected to a distribution panel which is associated with vital battery boards I and III and the other breaker is connected to a distribution panel which is associated with vital battery boards II and IV. These breakers are normally open and provide isolation between the two panels. Refer to Figure 8.1.2-2 for a functional key diagram of the system and the normal vital battery interfaces. During periods when the fifth vital battery is in service, the circuit breaker connecting the fifth vital battery charger is maintained in the open position.

Tests and Inspections

Prior to placing the vital DC system in operation, the system components were tested to ensure their proper operation.

The batteries are tested during preoperational testing by discharging them with a load which simulates their loading during an AC power outage. The test is performed in accordance with IEEE-450, Recommended Practice for Maintenance, Testing and Replacement of Large Stationary Type Power Plant and Substation Lead Storage Batteries. The actual discharge current for the test is determined using the worst case load data. The basis for each actual individual load current value is either the measured value from actual test or a value calculated from manufacturer's data.

The charger will be checked for normal and equalizing voltage adjustability, 100 percent output capability, specified regulation with and without the battery connected, and panel instruments calibration. For the distribution board, circuit breakers are tested for proper trip operation, fuses are checked to verify that the sizes and types specified have been installed, and the board instruments are calibrated.

8.3.2.1.2 Nonsafety Related DC Power Systems

There are three nonsafety related DC power systems: (1) the 24-volt DC Power Distribution System, (2) the 48-volt DC Power Distribution System containing a 48-volt Telephone Battery and a 48-volt Plant Battery, and (3) the 250-volt DC Power Distribution System. These systems supply power primarily for balance-of-plant systems.

24-Volt DC Power Distribution System

This system consists of: a 12-cell lead-acid battery, two 24-volt battery chargers, a 200 amp power board, and 24-volt DC distribution panels.

48-Volt DC Power Distribution System

This system consists of: a 24-cell lead-acid battery, a 24-cell lead-acid telephone battery, a 48-volt plant battery charger, a 48-volt telephone battery charger, a 48-volt spare battery charger that can be substituted for either a plant or telephone battery charger, a 48-volt plant battery board, a 200 amp power board for the telephone battery, and separate 48-volt DC distribution panels for the telephone and plant battery loads. The telephone battery provides power to telephone and other communication equipment. The plant battery provides power for 161-kv and 500-kv line carrier equipment and for data logger and data acquisition equipment. Loads supplied by this system are not safety related.

250-Volt DC Power Distribution System

This system consists of: a 120-cell lead-acid battery and connected battery board primarily associated with Unit 1, a 120-cell lead-acid battery and connected battery board primarily associated with Unit 2, a 250-volt battery charger for the battery primarily associated with Unit 1, a 250-volt battery charger for the battery primarily associated with Unit 2, a spare 250-volt battery charger that can be substituted for either of the other two chargers, and distribution panels for system loads. The batteries provide power for loads such as the preferred and TSC inverters, turbo-generator auxiliaries, controls for 6.9-kv and 480-volt non safety related boards, and switchyard control and relaying equipment. Circuits supplying switchyard control power are discussed in Paragraph 8.2.1.4.

The mission of the 250 V DC Power System during a SBO event is to provide control power to re-connect off-site power to the safety related shutdown busses when it becomes available in the switchyard. The battery with manual load stripping has the capacity to operate the required controls at the end of a four hour SBO event. This capability is verified by analysis.

Testing

The 250 V Station Battery is covered by an augmented QA program to ensure that the battery will function during a SBO event. The battery will be tested per guidance in IEEE-450 and industry standards to assure the capability of meeting the Station Blackout requirements.

8.3.2.2 Analysis of Vital 125-Volt DC Control Power Supply System

The 125-volt DC Class 1E electrical systems were designed, components fabricated, and installed meeting the requirements of the NRC 10 CFR 50 General Design Criteria, IEEE Standard 308-1971, NRC Regulatory Guides 1.6, Rev. 0, 1.9, Rev. 0, and 1.32, Rev. 0, IEEE Standard 336-1971, and other applicable criteria as enumerated herein.

The system consists of five lead-acid-calcium batteries, six 150-ampere (minimum) battery chargers, five battery boards, two distribution panels, cable and hardware. Each battery board is supplied normally from its battery charger and from its corresponding battery (or vital battery V) during an emergency. However, there are two spare chargers for supplemental and/or backup capacity. Each spare charger is connected so as to be available for use on either of two of the distribution boards for supplying load or charging the batteries. A manually operated switch transfers the spare charger from one board to another, and it is interlocked to prevent accidental parallel connection of the vital power systems. Whenever the vital battery V is substituting one of the normal batteries, the spare charger associated with the normal battery will be used as the system charger as long as the normal battery is out of service.

Battery boards I, II, III, and IV are each located in separate rooms in a seismic Category I structure, and they are protected from potential missile hazards. The batteries are located in separate rooms, and the chargers are physically separated in two separate rooms of this same building. Vital battery V, vital battery board V and the vital charger V are located in the

Auxiliary Building at El. 749. Fifth Vital Battery Distribution boards are located in the Auxiliary Building at El. 734. The fifth vital battery and its distribution equipment are located in a mild environment. Therefore, this equipment will not be exposed to hostile environments and since it is outside the primary containment area, it will not be exposed to significant radiation due to a LOCA. Battery board V is separated from all the normal vital batteries so that no single occurrence can affect more than a single battery. Thus the system design, equipment location, separation, and redundancy assure ability to meet the requirements for the applicable accident events described and evaluated in Chapter 15 and is in full compliance with NRC General Design Criteria 17 and Regulatory Guide 1.6, Rev. 0.

The normal power source to each distribution board is from the battery charger which is supplied from either one of two 480-volt AC shutdown distribution boards. The battery serves as an emergency source in the event the battery charger source is lost or is inadequate for the load required. The total design load for each board with 480-volt AC available is less than the battery charger rating. Therefore, the primary charger supplying each board is of more than ample capacity to supply load currents and maintain full charge on the battery. Since each battery has an emergency two hour rating of 643 amperes minimum at 60°F with a minimum of 105 volts DC at the battery terminals and since the vital battery V has an emergency two hour rating of 663 amperes at 60°F with a minimum of 108.5 DC volts at the battery terminals, and the startup time on the diesels is 10 seconds or less, the battery capacity far exceeds the maximum design load requirements for each board. Also, based on the rating of vital battery V, whenever a normal vital battery is out of service and vital battery V and the spare vital charger are the emergency and normal power supplies respectively, the system capacity and capability are not degraded.

The overall design of the system (including batteries, chargers, distribution boards, and cabling) incorporates sufficient capacity and capability to deliver the maximum design load currents required at each remote point and also to clear any possible short-circuit fault currents.

The load demand from each of the four battery boards can be grouped into essentially three categories for analysis purposes. These are (1) the vital inverters, (2) 6900- and 480-volt shutdown board control power, and (3) miscellaneous control and instrumentation load. The output fuse and breaker trip ratings and trip times are coordinated to provide protection and isolation for the cable leaving the board as well as providing protection for the end load service.

Referring to Figure 8.1.2-2, it can be seen that each of the three groups of loads are supplied from the main bus through a fuse to a "stub" bus from which the power is delivered to each load circuit via a molded-case automatic circuit breaker. Each stub bus may supply one or more breakers (Figure 8.3.2-1). Each breaker and fuse has a current capability of the battery and charger combined. Each breaker and fuse is sized in accordance with circuit requirements. The interposing fuse between the main and stub buses not only provides high-speed clearing for a very severe close-in feeder fault, but it also provides redundant protection of the feeder in the event an associated breaker fails to operate, thus preventing a single feeder fault resulting in the loss of the entire bus. The fuse is likewise coordinated with the main bus supply protective devices. The one panel of the distribution board that is devoted entirely to fused load circuits is powered from the main bus through a molded-case breaker which provides redundant protection and serves as an isolating disconnect switch.

The vital chargers are rated for a load duty as dictated by the battery board distribution and battery charging requirements. The output load of the charger is delivered through a 2-pole molded-case breaker that is capable of interrupting the battery backfeed into the charger if necessary. The trip setting of the breaker is chosen to permit the charger to operate at its maximum output capability without experiencing a false trip. The electrical characteristics of the charger provide the necessary output power regulated and filtered as required by the load for the worst maximum and minimum input power conditions. The charging capacity exceeds that required to restore the battery from the design minimum charge state to the fully-charged state under worst case load conditions in compliance with Regulatory Guide 1.32, Rev. 0. The input circuit of the charger is protected from the source power by a

molded-case breaker that also serves as an isolating or disconnect switch. The manually-operated transfer switch through which the power is delivered is interlocked in such a manner so as not to parallel the two shutdown boards in compliance with Regulatory Guide 1.6, Rev. 0. NOTE: The fifth vital battery charger is used only to maintain battery V and is not subject to the above discussion.

Surveillance and Monitoring

Each distribution board and charger is equipped with the proper instruments to provide visual indication of the necessary electrical quantities. An alarm contact is provided on all circuit breakers on the distribution board that close for automatic opening of the breaker. Circuits important to safety which do not have alternate means for blown fuse detection will have indicating fuses for alarm annunciation. Other circuits, both safety-related and non-safety related which are fed from the DC distribution panel may use non-indicating fuses. These circuits are monitored either by status lights in the control room, system responses (i.e., changes in level, temperature, flow, pressure, etc.), or other indicators for blown fuse detection. Additionally, non-indicating fuses may be used on circuits that go to the fail-safe condition, or circuits that are used on demand and the time to replace the fuse is not critical, or circuits which have routine existing surveillance instructions which would detect a blown fuse. Also, non-safety related circuits may contain non-indicating fuses depending on the importance of the circuit to plant operation. The indicating means for blown fuse detection, other than indicating fuses meet the requirements of IEEE 308-1971. Undervoltage alarm relays provide annunciation for loss of power on the buses or power input to the chargers. Relays which detect a no-charge condition are provided on the chargers to detect a charger failure. Closure of any contact provides annunciation in the main control room.

The overall system design (including function requirements, redundancy, capability, availability, surveillance, and energy storage capacity) is in full conformance with IEEE 308-1971, Criteria for Class 1E Systems.

Seismic Qualification

One complete board assembly and one complete battery charger assembly have been subjected to the SSE conditions as described in Section 3.10. The tests were performed in conformance to IEEE Standard 344-1971, Guide for Seismic Qualification of Class 1 Electric Equipment. One breaker of each type used on the equipment was operated under simulated fault conditions at the same time the assembly was experiencing the seismic forces. The seismic test results assure that the complete assembly will continue to function properly and continue to deliver the required power during and after any expected SSE condition.

Design Test

All battery chargers were electrically tested to assure that each unit is capable of performing all requirements as specified. All boards were subjected to and satisfactorily passed the following tests as specified under the indicated paragraphs of section 20-5 of ANSI C37.20-1969:

20-5.2.1.1 - Power Frequency Withstand
20-5.2.2 - Rated Continuous Current
20-5.2.3 - Momentary Current
20-5.2.8 - Flame Resistance for Barrier, Bus, and Wire Insulation
20-5.3.2 - Mechanical Operation
20-5.3.4.1 - Control Wiring Continuity
20-5.3.4.2 - Control Wiring Insulation

All molded-case circuit breakers comply with NEMA Publication No. AB-1-1964 requirements, and all drawout low-voltage circuit breakers comply with NEMA Publication No. SG3-1965.

All control circuit wiring has self-extinguishing insulation rated 600 volts. All equipment is certified to operate within the environmental requirement called for in the Design Criteria. (Refer to Section 3.11).

Quality Assurance

A Quality Assurance program implemented from the beginning of the specification for this equipment and continued throughout installation and final checkout assures that the equipment meets all applicable design and operable criteria. The specifications require that suppliers of this equipment maintain a Quality Assurance Program throughout the duration of the contract and that the program conform to the essential elements as defined in NRC Appendix B of 10 CFR, Part 50. An inplant examination of each contractor's Quality Assurance Program assures compliance with these requirements. The design, specification, and any design changes are reviewed by designated staff engineers to assure compliance with Quality Assurance procedures and design criteria. All records, drawings, test reports, etc., depicting quality assurance review are maintained in appropriate files in accordance with established procedures.

8.3.2.3 Conformance with Appropriate Quality Assurance Standards

Conformance with appropriate quality assurance is described in Chapter 17 and the TVA Nuclear Quality Assurance Plan.

8.3.2.4 Independence of Redundant DC Power Systems

The treatment of the redundant onsite DC power systems is included in paragraph 8.3.1.4 with the onsite AC power systems.

8.3.2.5 Physical Identification of Safety-Related Equipment in DC Power Systems

The physical identification of the onsite DC power systems is combined with the onsite AC power systems and is described in paragraph 8.3.1.5.

8.3.2.6 Sharing of Batteries Between Units

The safety loads are assigned to the vital 125-volt batteries so that such sharing will not significantly impair their ability to perform their safety functions, including in the event of an accident in one unit, an orderly shutdown and cooldown of the remaining unit.

The 125-volt DC power required for engineered safety features is arranged as follows:

Unit 1 "A" Train - Vital Battery I
Unit 1 "B" Train - Vital Battery II
Unit 2 "A" Train - Vital Battery III
Unit 2 "B" Train - Vital Battery IV

Four channel 120-volt AC vital instrument power is supplied from eight (four per unit) uninterruptible power supply units. The normal input to these units is supplied from the 480-volt shutdown system with backup supply coming from the vital batteries. The 480-volt AC input is rectified and biased against the dc by means of an auctioneered diode circuit to permit use of the battery source only if the AC input voltage is lost.

The safety loads supplied from these units have been grouped as follows:

Unit 1, Channel I - Unit 1 RPS Channel I input relays, ESF "A" Train output relays.

Unit 1, Channel II - Unit 1 RPS Channel II input relays, ESF "B" Train output relays.

Unit 1, Channel III - Unit 1 RPS Channel III input relays.

Unit 1, Channel IV - Unit 1 RPS Channel IV input relays.

Unit 2, Channel I - Unit 2 RPS Channel I input relays.

Unit 2, Channel II - Unit 2 RPS Channel II input relays.

Unit 2, Channel III - Unit 2 RPS Channel III input relays, ESF "A" Train output relays.

Unit 2, Channel IV - Unit 2 RPS Channel IV input relays, ESF "B" Train output relays.

Devices that require power to actuate are normally assigned to Channels I and II for Unit 1 and Channels III and IV for Unit 2. RPS inputs are assigned to all channels.

The loss of major safety loads due to vital 125V DC battery loss concurrent with loss of offsite power is shown in Table 8.3.2-1.

Conformance with General Design Criteria, Regulatory Guides, and Branch Technical Position.

GDC 5	The failure of a vital battery does not significantly impair the ability of systems and components important to safety to perform their safety functions, including in the event of an accident in one unit, an orderly shutdown and cooldown of the remaining units.
RG 1.6	There are no provisions for automatically connecting one load group to another load group. There are no provisions for automatically transferring loads between redundant load groups.
RG 1.81 and BTP EICSB 7	The design of the Sequoyah 125-volt vital DC system meets all the requirements for multi-unit generating stations for which construction permit application were made before May 1, 1973, as described in RG 1.81 and BTP EICSB 7.

2 - Full rejection
3 - Safety Injection - A
4 - Safety Injection - B

Note - The demand load is the total of all loads that are energized at the same time under worse case conditions as indicated in the mode of maximum demand column. Transformer losses are included in maximum demand.

* For the calculated maximum load demand, see the Auiliary Power System calculations.

TABLE 8.3.1-11

Major Non-Safety-Related Electrical Equipment That Could Become Submerged Following a LOCA

Equipment	Evaluation
Motors for the fans of the control rod drive mechanism coolers	These coolers are used to maintain the ambient temperature in the area of the control rod drives within an acceptable range during normal operation. Their function is not required for LOCA mitigation. (Ref Section 9.4.8*).
Reactor coolant drain tank pumps	These pumps remove from inside containment the normal leakage of the reactor coolant system that has been colected in the reactor coolant drain tank. This is not a safety function. The discharge path of the pumps is automatically isolated in a LOCA. (Ref Section 9.3.3.3*).
Floor and equipment drain sump pumps	These pumps remove from inside containment any leakage inside containment that is not collected in the reactor coolant drain tank. This is not a safety function. The discharge path of the pumps is automatically isolated in a LOCA. (Ref Section 9.3.3.38*).
Pressurizer heaters	Automatically deenergized in the event of a LOCA.

*If energized when flooded, the motors will short to ground and cause opening of the power supply breakers.

(LS) SOLID STATE OVERCURRENT TRIP DEVICE WITH LONG DELAY AND SHORT DELAY TRIP RANGES.

NOTES

1. 480V SDB 1A1-A SHOWN AND 2A1-A AS NOTED. 1B1-B AND 2B1-B ARE SIMILAR.
2. NSR INDICATES NON-SAFETY RELATED EQUIPMENT.
3. SEQUENTIAL TIMER APPLIES LOAD TO DIESEL GENERATOR.
4. THE NORMAL & ALTERNATE DC CONTROL SUPPLIES AS SHOWN ON THIS DRAWING FOR THE NORMAL & BACKUP BUSSES ARE THE EXACT REVERSE FOR BOARD 2A1-A.
5. RECEPTACLE FOR 480V POWER DURING OUTAGES.
6. ALL CIRCUITS BEING SUPPLIED BY THIS RECEPTACLE SHALL HAVE THEIR OWN PROPERLY SIZED ELECTRICAL CIRCUIT PROTECTION.

480V SD BOARD 1A1-A, 2A1-A AS NOTED

SOLID STATE OVERCURRENT TRIP DEVICE WITH LONG DELAY AND SHORT DELAY TRIP RANGES.

NOTES:

1. 480V SDB 1A2-A SHOWN 2A2-A AS NOTED. 480V SDB 1B2-B & 2B2-B SIMILAR.
2. ALL EQUIPMENT SHOWN ON THIS DRAWING IS SUPPLIED FROM POWER TRAIN A. ALL EQUIPMENT IS SAFETY RELATED UNLESS NOTED BY THE SYMBOL NSR EQUIPMENT WITH TRAIN SUFFIX "S" MAY BE POWERED FROM EITHER TRAIN.
3. THESE CONTACTS ARE ON SEQUENTIAL TIMER (LOCATED ON 6.9KV SD BD LOGIC RELAY PANEL) THAT APPLIES LOAD SEQUENTIALLY TO THE DIESEL GENERATOR.
4. LOAD SHEDDING IS ACCOMPLISHED BY RELAYS LOCATED ON 6.9KV SD BD LOGIC RELAY PANEL
5. EQUIPMENT DESIGNATIONS SHOWN FOR UNIT 1. DESIGNATIONS FOR UNIT 2 SIMILAR EXCEPT FOR UNIT PREFIX AND EXCEPT AS NOTED.
6. THE NORMAL & ALTERNATE DC CONTROL SUPPLIES AS SHOWN ON THIS DRAWING FOR THE NORMAL & BACKUP BUSSES ARE THE EXACT REVERSE FOR BOARD 2A2-A.
7. RECEPTACLE FOR 480V POWER DURING OUTAGES.
8. ALL CIRCUITS BEING SUPPLIED BY THIS RECEPTACLE SHALL HAVE THEIR OWN PROPERLY SIZED ELECTRICAL CIRCUIT PROTECTION.

NOTES:

1. THE INCOMING LINE SUPPLY BREAKERS, A & B, & BUS TIE BREAKER C ARE INTERLOCKED IN SUCH A MANNER THAT THE COMMON BOARD TRANSFORMERS CANNOT BE PARALLELED. NORMALLY EACH BUS IS FED FROM ITS OWN TRANSFORMER WITH THE BUS TIE BREAKER OPEN. THE AUTO-MANUAL TRANSFER SELECTOR SWITCH IS TO BE PLACED IN THE "MANUAL" POSITION.
2. TO USE THE TWO EMERGENCY SUPPLIES THE BREAKERS 52A AND 52B MUST BE MOVED TO THE EMERGENCY SUPPLY COMPARTMENTS. THE EMERGENCY SUPPLIES CANNOT BE PARALLELED WITH EACH OTHER OR A NORMAL POWER SUPPLY, THROUGH THE BUS TIE BREAKER.
3. NO EQUIPMENT ON THIS BOARD IS SAFETY RELATED.

SYMBOLS:

LI — SOLID STATE OVERCURRENT TRIP DEVICE WITH LONG DELAY AND INSTANTANEOUS TRIP RANGE.

LS — SOLID STATE OVERCURRENT TRIP DEVICE WITH LONG DELAY AND SHORT DELAY TRIP RANGES.

NOTES:

1. BATTERY BD BREAKERS ARE PROVIDED WITH ALARM CONTACTS WHICH CLOSE WHEN BREAKER TRIPS DUE TO OVERLOAD OR SHORT CIRCUIT. CONTACTS ARE WIRED OUT TO TERMINAL BLOCKS IN REAR OF EACH PANEL AND ARE TO BE CONNECTED IN PARALLEL FOR COMMON ANNUNCIATION.
2. PANEL 4 FUSES ARE PROVIDED WITH ALARM CONTACTS WHICH CLOSE WHEN FUSE OPENS DUE TO OVERLOAD OR SHORT CIRCUIT. THE CONTACT OF EACH FUSE IS WIRED TO A COMMON COLUMN ALARM BUSS FOR ANNUNCIATION.
3. BATTERY RELAY-AMMETER TO BE SET TO ALARM FOR A DISCHARGE OCCURRING FOR GREATER THAN 15 SECONDS.
4. BATTERY BOARDS ARE CLASS 1 AS DEFINED IN IEEE 308 AND TVA PROCUREMENT SPECIFICATION 1337.
5. CIRCUIT SAFETY CLASSIFICATION WILL BE IDENTIFIED AS FOLLOWS:
   S-SAFETY RELATED, NS-NONSAFETY RELATED.
6. THE BATTERY BOARD MAIN FEEDER BREAKER 003 HAS HAD ITS AUTOMATIC TRIP FUNCTION DISABLED BY REMOVING TRIP PADDLE.
7. JUMPER FROM BREAKER 227 TO BREAKER 226.

NOTES: (CONTINUED)

8. DELETED
9. DELETED
10. DELETED
11. DELETED
12. THE BATTERY IS OPERABLE WITH EITHER 59 OR 60 CELLS. UNDER THE 59 CELL CONFIGURATION THE UNUSED CELL WILL BE STRAPPED OUT USING THE NORMAL VENDOR SUPPLIED INTER-TIER CABLES AND PLATES.
13. CIRCUIT DESIGNATED "SBO" IS NOT REQUIRED FOR STATION BLACK OUT AND SHALL BE MANUALLY TRIPPED WITHIN 45 MINUTES AFTER SBO INITIATION.
14. BREAKERS 225, 226, 227, 325, 326, 327 AND 328 MAY BE EITHER WESTINGHOUSE HKA BREAKERS OR CUTLER HAMMER, 400 AMP FRAME, MOLDED CASE SWITCHES WHICH DO NOT HAVE A THERMAL TRIP ELEMENT.
15. THE MANUAL TRANSFER SWITCH IS A 3-POSITION SWITCH (NORM-OFF-EMER), THAT IS SHOWN IN IT'S NORMAL CONFIGURATION.
16. THE DUTY CYCLE FOR VITAL BATTERIES I, II, III, AND IV ARE TESTED TO 751 AMPS FOR 0-1 MIN, 560 ±1 AMPS FOR 1 TO 45 MIN, AND 398 AMPS FOR 45 - 240 MINUTES. HIGHER CURRENT LEVELS MAY BE USED IN THE IEEE 450 SERVICE TEST NOT TO EXCEED THE MFR RATING FOR THE PERIOD.

9.0 AUXILIARY SYSTEMS

9.1 FUEL STORAGE AND HANDLING

9.1.1 New Fuel Storage

9.1.1.1 Design Bases

1. Storage space will be provided for a total of approximately 146 fuel assemblies.

2. New fuel, up to 5.0% by weight U-235, will be stored dry in the new fuel storage facility but in an array such that K_{eff} will be less than 0.95 if flooded with unborated water or less than 0.98 if optimally moderated.

3. The new fuel storage facility shall be capable of withstanding loads imposed by the dead load of the fuel assemblies, loads resulting from the impact and handling of fuel assemblies and loads from 1/2 Safe Shutdown Earthquake (SSE) and SSE's. Any resulting damage shall not be such as to increase K_{eff} above 0.95 if flooded with unborated water or above 0.98 if optimally moderated. The facility shall not be required to withstand loads that would be imposed by dropping heavy objects onto it, but the movement of such object over it shall be administratively prohibited.

4. Consideration of criticality safety analyses is discussed in Subsection 4.3.2.

9.1.1.2 Description

The location of the new fuel storage vault is shown in Figure 9.1.1-1 and in Figures 1.2.3-4 and 1.2.3-8. Figure 9.1.1-2 shows the design of the new fuel storage racks.

9.1.1.3 Safety Evaluation

The racks are individual vertical cells fastened together in a 4 x 5 array forming modules that are firmly bolted to embedded plates in the floor of the new fuel vault. The new fuel racks, including supports, are made of austenitic stainless steel and are constructed so that it is impossible to insert fuel assemblies except in prescribed locations having a minimum center-to-center spacing of 21 inches in both directions. However, to preclude criticality during optimum moderation conditions, 34 of the 180 cells are physically blocked to prevent use (configuration shown in Technical Specification Figure 4.3.1.2-1). The spacing is sufficient to assure $K_{eff} < 0.95$ even if immersed in unborated water or $K_{eff} \leq$ 0.98 if optimally moderated by being enveloped by an aqueous foam or mist. The new fuel storage racks are designed in accordance with AISC, Sixth Edition, 1963. The new fuel storage vault is designed in accordance with ACI 318-1963.

The racks and the anchor bolts which hold them in place, have been designed to withstand SSE, 1/2 SSE, and shipping and handling loads as well as the dead load of the fuel assemblies. They can withstand impacts imposed by bumping them with objects normally handled in the new fuel pit including fuel assemblies and tools.

With new fuel in storage vaults, movement of heavy objects over the facility is administratively prohibited so that the fuel will not be damaged from heavy falling objects. The facility is shared between the two units; however, this does not increase the potential for damage to the new fuel. Sharing of the new fuel storage between two operating reactors has no effect on the safety or operation of the plant.

The details of the seismic design and testing procedures are presented in Section 3.7.

9.1.2 Spent Fuel Storage

9.1.2.1 Design Bases

1. Spent fuel storage space will be provided for a total of 10 cores (193 per core) plus 161 extra storage positions. However, only 159 of the 161 extra storage spaces may be utilized due to physical obstructions. Therefore, 2089 total spaces are available for fuel assembly storage. Storage space for full core offload capability is an operating strategy, maintaining full core offload capability in the spent fuel pool is not a licensing requirement.

2. Spent fuel storage racks are designed for new fuel enriched to a maximum of 5.0% by weight U-235 with K_{eff} less than 1.0 when flooded with unborated water and considering uncertainties. With partial credit for dissolved boron in the pool, K_{eff} is less than or equal to 0.95 with 300 ppm boron for normal conditions.

   The racks are regionalized into three arrangements as to what limitations exist on fuel assemblies stored in each region.

3. Administrative controls over fuel loading, discussed in Section 4.3.2.7, assures that the fuel will be stored in an array such that K_{eff} will be less than 1.0 even if the water in the storage pit contains no boron. However, for some accident conditions, the presence of dissolved boron in the pool water is taken into account as a realistic initial condition. This assumption can be made by applying the double contingency principle of ANSI N16.1-1975 which requires two unlikely, independent, concurrent events to produce a criticality accident. Maintaining 700 ppm dissolved boron in the pool shall meet the criteria for K_{eff} to be less than 0.95 with consideration of uncertainties.

4. The depth of shielding water over the spent fuel will be sufficient to limit the radiation dose to acceptable levels.

5. The spent fuel storage facility will be capable of withstanding loads imposed by the dead load of the fuel assemblies, loads resulting from the impact and handling of fuel assemblies, the maximum uplift force from the spent fuel bridge hoist and loads from 1/2 SSE and SSE's. Damage to spent fuel pit and storage racks will neither be sufficient to cause a loss of water below the top of the racks nor increase K_{eff} to 1.0.

6. Electrical and mechanical interlocks are provided to prevent the movement of loads over stored spent fuel.

7. The spent fuel shipping cask loading area will not be separated from the spent fuel storage area. A cask drop is not a credible event provided that heavy loads and safe load paths are in place in accordance with NUREG-0612 (SRP-9.1.2, NUREG-0800).

8. Adequate cooling water will be available for cooling the pool water (Section 9.1.3).

9. Consideration of criticality safety analysis is discussed in Section 4.3.2.

9.1.2.2 Description

The location of the spent fuel pit is shown in Figure 9.1.1-1 and in Figures 1.2.3-5 and 1.2.3-8. Figure 9.1.2-1 shows the design of the spent fuel storage racks. Figure 9.1.2-2 shows the spent fuel storage rack layout in the spent fuel pool and cask pit.

9.1.2.2.1 Storage Rack Structure

The high density Spent Fuel Storage Racks consists of 12 modular racks containing a total of 2091 storage cells with a 8.972" nominal pitch. All rack modules are of the so-called "free-standing" type in as much as the modules are not attached to the pool floor and they do not require any lateral braces or restraints. These rack modules rest on the pool floor on an adjustable support leg and bearing pad arrangement. All modules are of "non-flux trap" construction. The base plates on all rack modules extend out beyond the rack module wall such that the contiguous edges of the plates act to set a geometric separation between the facing cells in the modules.

The principal construction materials for the Spent Fuel Racks are SA240-Type 304L stainless steel sheet and plate stock, and SA564-630 (precipitation hardened stainless steel) for the adjustable support spindles. The only non-stainless material utilized in the rack is the neutron absorber material which is a boron carbide and aluminum-composite sandwich available under the patented product name "Boral". Boral is a thermal neutron absorbing material consisting of finely divided particles of boron carbide (B_4C) uniformly distributed in type 1100 aluminum and pressed and sintered in a hot rolling process. Boron carbide is a compound having a high boron content in a physically stable and chemically inert form. The 1100 alloy aluminum is a light-weight metal with high tensile strength which is protected from corrosion by a highly resistant oxide film. The two materials, boron carbide and aluminum, are chemically compatible and ideally suited for long-term use in the radiation, thermal and chemical environment of a spent fuel pool. Boral has garnered an excellent record of application in light water reactor fuel pools. The Boral sheets are axially centered with respect to the active fuel region and are sandwiched between cells.

All material used in the construction of the Sequoyah racks have an established history of in-pool usage. Their physical, chemical and radiological compatibility with the pool environment is well established. Consistent with recent practice, the fuel pool rack construction allows full venting of the Boral space. Representative Boral coupon samples are available on a mounting called a "tree" for monitoring the integrity of the neutron absorber material without disrupting the integrity of the storage system. The coupon tree is placed in a designated cell and surrounded by spent fuel. Specimens may be removed from the coupon tree array and certain physical and chemical properties measured from which the stability and integrity of Boral in the spent fuel storage cells may be inferred.

9.1.2.2.2 Storage Rack Interface With Spent Fuel Pool

Each independent and free-standing rack module is supported by four legs which are remotely adjustable. Each of the four legs rests on a pedestal bearing pad, which rests on the pool floor. The racks are not physically connected to the pool liner in any way, except for the pedestal bearing pad resting on the pool floor. The rack module support legs were engineered to accommodate variations in the flatness of the pool floor. Readily accessible sockets are provided in each support to enable remote leveling of the rack after its placement in the pool. The support legs also provide an under rack plenum for natural circulation of water through the storage cells. The placement of the rack pedestals in the spent fuel pool has been designed to preclude any support legs from being located over existing obstructions on the pool floor.

An adjustable support pedestal is utilized in the cask pit area to accommodate the 13th rack should the rack be installed in the future. The adjustable pedestal provided installation support during the new rack installation project, and was readjusted after use to the required dimensions of the 13th rack. The adjustable support pedestal provides vertical height increase for the rack placed in the cask pit as the cask pit floor is lower than the spent fuel pit floor and also to insure consistent fuel handling between racks located in the spent fuel pit and the cask pit storage rack.

Separate pedestal bearing pads are not used in the cask pit area, in that the adjustable pedestal has weight distribution pads integrated into the pedestal design to account for this weight bearing function.

9.1.2.3 Safety Evaluation

The spent fuel pit is a reinforced concrete structure which rests on the rock formation which underlies the Sequoyah site. The pit is designed to withstand 1/2 SSE and SSE forces and the maximum uplift force of the spent fuel bridge hoist without deformation, as is the Auxiliary Building in which the pit is located. The pit is lined with stainless steel plates to ensure water tightness. Radiological aspects of the facility are discussed in Chapter 12.

The spent fuel pit structure includes a fuel storage area, a spent fuel cask loading area, and a transfer canal which communicates with the refueling canal in the containment building. The following discussion shows how the facilities comply with the design bases given in Section 9.1.2.1:

1. The fuel storage area contains six 13 X 14 spent fuel storage rack arrays, two 12 X 14 spent fuel storage rack arrays, three 13 X 13 spent fuel storage rack arrays, and one 12 X 13 spent fuel storage rack array, for a total of 2091 storage locations. This provides storage space for 10 cores plus 161 additional storage spaces. Some storage spaces are "shadowed" by overhead obstructions. All but two of the "shadowed" spaces were pre-loaded prior to final rack positioning, therefore only 2089 cells can be utilized. The two inaccessible cells are located beneath the gate opening between the spent fuel pool and the transfer canal and are shadowed by a support plate for the transfer canal gate.

2. The spent fuel storage racks provide a nominal spacing of 8.972 inches between fuel assemblies. The nominal gap between rack arrays is 2 1/8 inch north-south and 1.5 inch east-west. The spacing is such that K_{eff} is below 1.0 if the racks are filled with fuel assemblies having the highest anticipated enrichment even when flooded with 2000 ppm borated water and including all mechanical tolerances. The design of the racks precludes criticality even with a misplaced fuel assembly on top of to the rack. The design of the racks precludes placement of a fuel assembly adjacent to the rack.

   Partial credit for dissolved boron in the pool water ensures the k_{eff} shall remain less than 0.95 with consideration of uncertainties and fuel mis-placement. The spent fuel pool boron concentration is nominally above 2000 ppm though only 700 ppm is required.

   The spent fuel racks are regionalized into three arrangements as to what limitations exist on fuel assemblies stored in each region.

3. The normal depth of water in the spent fuel storage area is about 39 feet 10 inches. The SFPCS maintains adequate water depth for shielding in the spent fuel pit, for spent fuel storage and for handling spent fuel over the storage racks. A low level alarm is annunciated in the control room when the water level drops to approximately two inches below normal pool level. The hoist on the spent fuel pit bridge is physically prevented from lifting the active fuel region of a spent fuel assembly higher than a level which is approximately 10 feet below the low level alarm setpoint due to the length of the long handle tool. Thus, the requirement of a water shield of 10 feet above the fuel assembly active fuel region is met.

4. The spent fuel storage racks shown in Figure 9.1.2-1 are designed to comply with the stress limits of ASME boiler and pressure vessel code, Section III, Subsection NF (1986).

   The racks have been shown by dynamic analysis to withstand SSE and 1/2 SSE loads as well as the dead load of the fuel assemblies. The racks are also capable of withstanding accidental drops of a fuel assembly or the gates which cover the slots between the pool and transfer canal and cask loading pit.

5. Electrical interlocks and mechanical stops are provided on the Auxiliary Building crane which prevent movement of loads over the area in which spent fuel is stored. The electrical interlocks are redundant and conform to IEEE standards. In addition, mechanical stops are provided which limit travel of the crane trolley when the spent fuel cask or other heavy loads are being moved to, from, or past the spent fuel pit. Figure 9.1.1-1 shows the region within which the interlocks prohibit movement of the main hook of the Auxiliary Building crane. The figure also shows the limit of hook travel imposed by the mechanical stops.

   Most operations, which must be carried out with the auxiliary building crane, can be performed without bypassing the interlocks and physical stops. The interlocks and physical stops are designed to prevent loads in excess of 2100 pounds from travel over the fuel assemblies in the spent fuel storage pool. These interlocks and physical stops will be verified operable within seven days prior to crane use and at least seven days thereafter during crane operation, except for those times when they are in the bypass condition under administrative control. The interlocks and physical stops will be returned and verified operable after operation in the bypassed condition. Only two loads greater than 2100 pounds are permitted to travel over fuel assemblies in the spent fuel pool. These are the spent fuel pool transfer canal gate and the spent fuel pool divider gate. Note that the movement of the gate at the cask loading area can be performed without bypassing interlocks because the auxiliary hook (10-ton capacity) which is used for this function is located 4 feet and 6 inches south of the main hook.

   The mechanical stops limit travel of the crane trolley when the spent fuel cask or other heavy loads are being moved past the spent fuel pool and when a spent fuel cask is moved to and from the cask loading area. The stops are engaged by the electrical interlocks.

   Engagement of stops is indicated by a red light located beneath the operator's cab. The light is visible from virtually any point on the operating floor. Three main line power disconnect pushbutton stations are located along the north wall of the Auxiliary Building and allow a supervisor on the operating floor to stop the crane at any time.

6. As shown in Figure 9.1.1-1, a wall separates the cask loading area from the fuel storage area. The gate is not to be installed.

7. Adequate cooling water is provided by a seismic Category I cooling system (Section 9.1.3).

8. All structures below the water line in the spent fuel pit, including the pit liner, spent fuel storage racks, tools, and gates, are of austenitic stainless steel. Other materials in the pit are the zirconium alloy of the fuel assemblies, the Boral neutron poison in the storage racks, and the Boral coupon tree. Additional radioactive material and associated shielding may be temporarily stored in the spent fuel pool or cask loading area. These materials are fully compatible in the spent fuel pit environment. Boral compatibility is described in Section 9.1.2.2.1.

   The spent fuel pit is a shared facility; however, this does not increase the potential for damage to the spent fuel. Aside from the fact that there is more spent fuel in one pit, sharing of the spent fuel storage facilities has no significant effect on the safety or operation of the plant. Ordinarily, only one reactor will be refueled at a time. If both reactors were refueled at one time, it would be necessary to coordinate use of the spent fuel pit bridge.

   As discussed above, the design of the facility satisfies the applicable sections of "Fuel Storage Facility Design Basis," Regulatory Guide 1.13.

9.1.3 <u>Spent Fuel Pit Cooling System</u>

The Spent Fuel Pit Cooling System is designed to remove from the spent fuel pit water the decay heat generated by stored spent fuel assemblies. Additional functions of the Spent Fuel Pit Cooling System (SFPCS) are to clarify and purify the water in the spent fuel pit, transfer canal, and refueling water storage tanks. If a warning of flood above plant grade is received when one or both reactor vessels are open or vented to the containment atmosphere, then the SFPCS will be modified as indicated in Paragraph 2.4A.4.2 to accomplish cooling the reactor core(s).

9.1.3.1 <u>Design Bases</u>

The Spent Fuel Pit Cooling System design parameters are given in Table 9.1.3-1.

9.1.3.1.1 <u>Spent Fuel Pit Cooling</u>

The Spent Fuel Pit Cooling System is designed to remove the decay heat from the spent fuel assemblies stored in the pit following back-to-back refueling of the two units. Analysis results for bounding discharge scenarios are described in Table 9.1.3-1. When the spent fuel pit contains the spent fuel resulting from back-to-back refueling of both units, the system can maintain the spent fuel pit water temperature at or below 150°F when two spent fuel pit pumps and two heat exchangers are in operation. If it is necessary to remove a complete core from one unit subsequent to the refueling of both units (assuming a 60 day period between the shutdown and the end of the previous refueling and the heat load from the spent fuel assemblies discharged during the 27 previous normal refuelings in the spent fuel pit and cask pit area) the time to beginning of core unloading will be adjusted so that 12 days have elapsed from time of shutdown to initiation of core unloading. For this scenario, the spent fuel pit cooling system can maintain the spent fuel pit water at or below 150°F using two trains of spent fuel cooling.

For all core off loading operations, actual pool heat load can also be used to establish an alternative shutdown to fuel movement interval. This requires the calculation of decay heat rates for the actual fuel assemblies stored in the pool as well as the fuel assemblies to be off loaded. When the total decay heat generation rate of fuel assemblies (SFP and core off load) is less than the maximum allowable heat load of the SFP cooling system, core unloading is acceptable.

For core off-load activities during a refueling outage, the heat load in the spent fuel pool is normally limited to 45 E+06 Btu/Hr. Alternatively, up to 55 E+06 Btu/Hr can be placed in the spent fuel pool within specific limitations on spent fuel pool cooling heat exchanger fouling and component cooling system supply temperatures less than the design temperature of 95°F.

Specific guidance in the form of allowable SFP decay heat curves for less than design conditions for SFP heat exchanger fouling and shell side cooling temperatures has been developed. The decay heat curves, provided in applicable design output documentation, allow outage specific variation in maximum SFP decay heat based on known values of SFP heat exchanger fouling factors and CCS temperatures. Operation of the SFPCCS within the constraints of heat load, SFP heat exchanger fouling and less than design values for CCS coolant temperatures ensures the maximum design temperatures of the SFP are not exceeded, should a loss of one SFP cooling train occur. Information in Table 9.1.3-4 provides a summary of maximum allowable decay heat loads and resultant SFP thermal parameters.

Localized boiling within the spent fuel storage racks has been evaluated for the highest allowable spent fuel decay heat load (55 MBtu/Hr). The conclusions of the evaluation indicated approximately 3.5°F margin to localized boiling exists between the maximum local water temperature and the local saturation temperature even at the higher allowable heat load. Additionally, the analysis has shown that, even though the maximum fuel clad temperature is greater than the local water saturation temperature, departure from nuclear boiling (DNB) will not occur; therefore, the fuel cladding integrity is maintained.

The system design incorporates two trains of equipment (plus a spare pump capable of operation in either train), either train being capable of removing more than 50 percent of the design heat load at design conditions. The flow through the pit provides sufficient mixing to assure uniform water conditions throughout the pit.

9.1.3.1.2 Spent Fuel Pit Dewatering Protection

System piping is arranged so that failure of any pipeline cannot drain the spent fuel pit below the water level required for radiation shielding.

9.1.3.1.3 Water Purification

The system's demineralizer and filter are designed to provide adequate purification to permit unrestricted access to the spent fuel storage area for plant personnel and maintain optical clarity of the spent fuel pit water. The optical clarity of the spent fuel pit water surface is maintained by use of the system's skimmers, strainer, and skimmer filter.

9.1.3.1.4 Flood Mode Cooling

Paragraph 2.4A.2.2 presents the design basis operation of the SFPCS when it may be used for reactor core cooling during flooded plant conditions.

9.1.3.2 System Description

The Spent Fuel Pit Cooling System flow diagram, shown in Figure 9.1.3-1, consists of two cooling trains (plus a backup pump capable of operation in either train), a purification loop, and a surface skimmer loop. The Spent Fuel Pit Cooling Pump logic is shown in Figure 9.1.3-2.

The Spent Fuel Pit Cooling System removes decay heat from fuel stored in the spent fuel pit. Spent Fuel is placed in the pit during the refueling sequence and stored there until it is shipped offsite or the spent fuel assemblies may be placed in interim storage at SQN Independent Spent Fuel Storage Installation (ISFSI) (Section 9.1.5). During a normal refueling, the system normally handles the heat loading from a complete core freshly discharged from each reactor, plus previous discharges which have decayed for more than a year. Heat is transferred from the Spent Fuel Pit Cooling System, through the heat exchangers to the Component Cooling System.

When the Spent Fuel Pit Cooling System is in operation, water flows from the spent fuel pit to one or both spent fuel pit pump suctions, is pumped through the tube side of the heat exchanger, and is returned to the pit. Each suction line, which is provided with a strainer, is located at an elevation four feet below the normal spent fuel pit water level, while the return line contains an anti-siphon hole near the surface of the water to prevent gravity drainage of the pit.

While the heat removal operation is in process, a portion of the spent fuel pit water may be diverted through a demineralizer and a filter to maintain spent fuel pit water clarity and purity. This purification loop is sufficient for removing fission products and other contaminants which may be introduced if a fuel assembly with defective cladding is transferred to the spent fuel pit.

The spent fuel pit demineralizer may be isolated, by manual valves, from the heat removal portion of the Spent Fuel Pit Cooling System. By so doing, the isolated demineralizer may be used in conjunction with a refueling water purification pump and filter to clean and purify the refueling water while spent fuel pit heat removal operations proceed. Connections are provided such that the refueling water may be pumped from either the refueling water storage tank or the refueling cavity of either unit, through the demineralizer and filter, and discharged to the refueling cavity or refueling water storage tank of either unit. Connections are also provided to allow clean-up of the water in the common transfer canal. Water can be drawn from the canal and is pumped by a refueling water purification pump through the spent fuel pit demineralizer and a refueling water purification filter before being returned to the transfer canal.

To further assist in maintaining spent fuel pit water clarity, the water surface is cleaned by a skimmer loop. Water is removed from the surface by the skimmers, pumped through a strainer and filter, and returned to the pit surface at three locations remote from the skimmers.

The spent fuel pit is initially filled with water that is approximately the same boron concentration as that in the refueling water storage tank. Borated water may be supplied from the refueling water storage tank via the refueling water purification pump connection, or by running a temporary line from the boric acid blender, located in the Chemical and Volume Control System directly into the pit. Demineralized water can also be added for makeup purposes (i.e., to replace evaporative losses).

The spent fuel pit water may be separated from the water in the transfer canal by a gate. The gate is installed so that the transfer canal may be drained to allow maintenance of the fuel transfer equipment.

A description of the operation of the SFPCS during flood mode operation is given in Section 2.4A.

9.1.3.2.1 Component Description

Spent Fuel Pit Cooling System Codes and Classifications are given in Section 3.2. Equipment design parameters are given in Table 9.1.3-2.

Spent Fuel Pit Pumps

The pumps are horizontal, centrifugal units. They can circulate spent fuel pit water through the heat exchangers, demineralizer, and filter. The pumps are controlled manually from a local station. A third pump is available to serve as a backup to either of the two pumps normally used for cooling the spent fuel pit water.

Spent Fuel Pit Skimmer Pump

This horizontal, centrifugal pump circulates surface water through a strainer and a filter and returns it to the pit.

Refueling Water Purification Pumps

These horizontal, centrifugal pumps can be used to circulate water from the transfer canal, the refueling cavity and the refueling water storage tank through the spent fuel pit demineralizer and a refueling water purification filter. The pumps are operated manually from a local station.

Spent Fuel Pit Heat Exchangers

The spent fuel pit heat exchangers are of the shell and U-tube type with the tubes welded to the tube sheet. Component cooling water circulates through the shell, and spent fuel pit water circulates through the tubes.

Spent Fuel Pit Demineralizer

This flushable, mixed-bed demineralizer is designed to improve pit water clarity and provide for unrestricted access by plant personnel to the pit working area.

Spent Fuel Pit Filter

The spent fuel pit filter is designed to improve the pit water clarity by removing submicron particles and provide for unrestricted access by plant personnel to the pit working area.

Spent Fuel Pit Skimmer Filter

The spent fuel pit skimmer filter is used to remove particles which are not removed by the strainer.

Refueling Water Purification Filters

The refueling water purification filters are designed to improve the clarity and purity of the refueling water in the refueling canal or in the refueling water storage tank by removing submicron particles.

Spent Fuel Pit Strainer

A strainer is located in each of the two spent fuel pit pump suction lines for removal of relatively large particles which might otherwise clog the spent fuel pit demineralizer or damage the spent fuel pit pumps.

Spent Fuel Pit Skimmer Strainer

The spent fuel pit skimmer strainer is designed to remove debris from the skimmer process flow.

Spent Fuel Pit Skimmers

Two spent fuel pit skimmers are provided to remove water from the spent fuel pit water surface in order to remove floating debris.

Valves

Manual stop valves are used to isolate equipment and manual throttle valves provide flow control. Valves in contact with spent fuel pit water are austenitic stainless steel or equivalent corrosion resistant material.

Piping

All piping in contact with spent fuel pit water is austenitic stainless steel. The piping is welded except where flanged connections are used to facilitate maintenance.

9.1.3.3 Safety Evaluation

9.1.3.3.1 Availability and Reliability

The Spent Fuel Pit Cooling System has no short term emergency function during an accident. This manually controlled system may be shutdown for limited periods of time for maintenance or replacement of malfunctioning components. The pit is sufficiently large that an extended period of time would be required for the water to heat up if cooling were interrupted (see Table 9.1.3-1). In the event of a failure of one spent fuel pit pump, the backup pump would be aligned and operated. In the event of loss of cooling to one spent fuel pit heat exchanger, cooling of spent fuel pit water could be maintained by the remaining equipment; however, the reduced heat removal capacity would result in elevation of the equilibrium spent fuel pit water temperature to a higher but acceptable temperature.

In the event that cooling capability was lost for an extended period, the pool water temperature would approach boiling. If the cooling systems are lost at a time coincident with the peak bulk temperature, the water loss by evaporation could reach a maximum of about 118 gpm for the Case 3 scenario described in Table 9.1.3-1. For this situation, it would take approximately 26 hours from the instant of loss of cooling to evaporate water to a level within 10 feet of the top of the active fuel. A seismically qualified line is available from the common discharge of the refueling water purification pumps to the spent fuel pool cooling loop. All piping, valves, and pumps from the RWST to the common discharge of the refueling water purification pumps are seismically qualified. Other sources for makeup are the demineralized water system and the fire protection system. Fire hoses located near the spent fuel pit are capable of supplying more than 103 gpm.

9.1.3.3.2 Spent Fuel Pit Dewatering

The most serious failure of the spent fuel pool storage and cooling system would be a complete loss of water in the storage pit. Several design provisions are in place to protect against the possibility of the pool draining to unacceptable levels. A gate between the transfer canal and the spent fuel pit is normally kept in place. The spent fuel pit cooling system suction connections enter near normal water level so that the pit cannot be siphoned. The 10" cooling water return line is truncated approximately 2.5 feet below normal water level. In addition, all cooling water return lines contain an anti-siphon hole to prevent any significant loss of water from the pit. These design features assure that the pit cannot be drained below two feet below normal water level. Minimum normal water level in the spent fuel pit is over 26 feet above the top of the active fuel region of the stored spent fuel.

The transfer canal has a drain connection in the bottom of the canal. The partially embedded line connects to a siphon breaker line. A valve in the anti-siphon line, located in a short run of un-embedded pipe, is locked open at all times except when the canal is to be drained. With this arrangement, if any un-embedded portion of the transfer canal drain line ruptures, the canal (and spent fuel pool during periods when the gate is removed) cannot be drained to a level below 713'6". At this level over 13 feet of water still remain over the active fuel region of the stored spent fuel, thus ensuring that the regulatory requirement [NUREG 0800 Section 9.1.3, Subsection III.e] of 10 feet of water over fuel is maintained at all times, including abnormal conditions.

9.1.3.3.3 Water Quality

Except for operation of this system in the flood mode of reactor cooling, only a very small amount of water is interchanged between the refueling canal and the spent fuel pit as fuel assemblies are transferred in the refueling process. Whenever a fuel assembly with defective cladding is transferred to the spent fuel pit, a small quantity of fission products may enter the spent fuel cooling water. The purification loop provided removes fission products and other contaminants from the water. By maintaining radioactivity concentrations in the spent fuel pit water at 0.01 mCi/cc or less, the exposure rate 3 feet above the surface of the pool is 2.5 mR/hr or less. The demineralizer and filtration equipment in the SFPCS will maintain the long term steady state concentration of radioactivity in the spent fuel pit water below 0.01 mCi/cc regardless of the number of spent fuel assemblies that are stored in the spent fuel pit. As the number of stored assemblies increases, the interval between required changing of the filter and of demineralizer resins may decrease slightly; however, changes are normally expected to occur no more often than once per refueling.

9.1.3.4 Test and Inspections

Active components of the Spent Fuel Pit Cooling System are either in continuous or intermittent use during normal plant operation. Periodic visual inspection and preventive maintenance are conducted in accordance with approved procedures.

9.1.3.5 Instrument Application

The instrumentation for the Spent Fuel Pit Cooling System is discussed below. Alarms and indicators are provided as noted.

9.1.3.5.1 Temperature

Instrumentation is provided to measure the temperature of the water in the spent fuel pit and give local indication as well as annunciation in the control room when normal temperatures are exceeded.

Instrumentation is also provided to give local indication of the temperature of the spent fuel pit water as it leaves the heat exchangers.

9.1.3.5.2 Pressure

Instrumentation is provided to give local indication of the pressure at points upstream and downstream of each pump and filter.

9.1.3.5.3 Flow

Instrumentation is provided to give local indication of the flow leaving the spent fuel pit filter and local indication of flow to the SFPCS pumps.

9.1.3.5.4 Level

Instrumentation is provided which gives an alarm in the control room when the water level in the spent fuel pit reaches either the high or low level condition.

9.1.4 Fuel Handling System

9.1.4.1 Design Bases

The Fuel Handling System consists of equipment and structures utilized for handling new and spent fuel assemblies in a safe manner.

The following design bases apply to the Fuel Handling System:

1. Fuel handling devices have provisions to avoid dropping or jamming of fuel assemblies during transfer operation.

2. Fuel lifting and handling devices are capable of supporting maximum loads under safe shutdown earthquake conditions.

3. The fuel transfer system, where it penetrates the containment, has provisions to preserve the integrity of the containment pressure boundary.

4. Cranes and hoists used to lift spent fuel employ lifting tools to limit maximum lift height so that the minimum required depth of water shielding is maintained.

9.1.4.2 System Description

The Fuel Handling Equipment consists of the equipment needed for refueling the reactor. Basically this equipment is comprised of:

1. Hoisting equipment, including:
   - auxiliary building crane
   - spent fuel pit crane
   - new fuel elevator
   - manipulator crane

2. Handling equipment, including:
   - spent fuel long handling tool, used with the spent fuel pit crane
   - new fuel short handling tool, used with the auxiliary building crane
   - rod cluster control (RCC) changing fixture located on the refueling canal wall
   - RCC changing fixture, portable, located in the spent fuel pit
   - burnable poison handling tool, used with the spent fuel pit crane
   - thimble plug handling tool, used with the spent fuel pit crane, or manipulator crane auxiliary hoist

3. A separate fuel transfer system for Unit 1 and Unit 2, which runs from the refueling RB canal, through the fuel transfer tube, and into the fuel transfer canal. This system includes:
   - fuel transfer tube with upenders at each end
   - fuel container used on the transfer car and upenders
   - fuel transfer car (fuel conveyor car, fuel transfer container)

The following structures, starting on the containment side, are associated with the Fuel Handling Equipment:

1. Refueling canal
2. Refueling cavity including the fuel transfer tube
3. Fuel transfer canal
4. Spent fuel pit including the cask loading area and the spent fuel racks
5. New fuel storage vault including the new fuel racks
6. Auxiliary building, including truck/rail unloading/loading area

New fuel is received in approved containers. The new fuel assemblies are removed from the containers within the ABSCE using the auxiliary building crane. The assemblies are inspected. The auxiliary building crane, in conjunction with a short handling tool can be used to unload the fuel to the new fuel storage vault or the new fuel elevator where it can be lowered and stored in the spent fuel pit.

New fuel can be delivered to the reactor by removing individual assemblies from the storage vault and placing them in the new fuel elevator. The assemblies are lowered into the transfer canal and are taken through the transfer system.

The fuel transfer system layout is shown on Figure 9.1.4-1.

The reactor is refueled with fuel handling equipment designed to handle spent fuel under water from the time it leaves the reactor vessel until it is placed in a cask for shipment from the site or the spent fuel assemblies may be placed in interim storage at SQN Independent Spent Fuel Storage Installation (ISFSI) (Section 9.1.5). Underwater transfer of spent fuel provides an effective, economic, and transparent radiation shield, as well as a reliable cooling medium for removal of decay heat. Boric acid is added to the water to insure subcritical conditions.

The fuel handling structures may be generally divided into the reactor cavity and refueling canal which are flooded only during plant shutdown for refueling, the transfer canal and the spent fuel pit which is kept full of water and the new fuel storage area which is separated and protected for dry storage. The refueling canal and spent fuel pit are connected by the fuel transfer tube and transfer canal. Fuel is carried through the tube on the underwater conveyor car. This tube is fitted with a blind flange on the reactor containment end and a gate valve on the transfer canal end. The blind flange is in place and the gate valve is normally closed when containment integrity and annulus secondary containment is required.

An upender at either end of the fuel transfer tube is used to pivot a fuel assembly. Before entering the fuel transfer tube the upender pivots the fuel container containing a fuel assembly to the horizontal position for passage through the transfer tube. After the transfer car transports the fuel assembly through the transfer tube, the upender at that end of the tube pivots the assembly to a vertical position so that it can be lifted out of the fuel container.

Fuel is normally moved between the reactor vessel and the refueling canal by the manipulator crane. A rod cluster control changing fixture located on the refueling canal wall can be used for transferring control elements from one fuel assembly to another. A portable rod cluster control changing tool is located in the spent fuel area and is normally used to transfer control rods.

In the reactor cavity, fuel is removed from the reactor vessel, transferred through the water and placed in the fuel container in a vertical position by a manipulator crane. The fuel assembly is moved to the horizontal position by an upending fixture and is moved through the transfer tube on the conveyor car. In the transfer canal another upending frame moves the fuel assembly to a vertical position. The fuel assembly is removed from the fuel container and placed into the spent fuel storage racks by a long-handled manual tool suspended from the spent fuel pit bridge hoist. In the spent fuel pit, decay heat is removed by the spent fuel pit cooling system. After a sufficient decay period, the fuel may be removed from the racks and loaded into a shipping cask for removal from the site or the spent fuel assemblies may be placed in interim storage at SQN Independent Spent Fuel Storage Installation (ISFSI) (Section 9.1.5).

9.1.4.2.1 Refueling Description

The refueling operation follows a detailed procedure which provides a safe, efficient refueling operation. The following significant points are assured by the refueling operation:

1. The refueling water and the reactor coolant are maintained at least at a boron concentration which is the more restrictive of 2000 ppm or the concentration calculated to maintain the core subcritical by at least 5 percent $\Delta k/k$ during refueling operations.

2. The water level in the refueling cavity is high enough to keep the radiation levels within acceptable limits when the fuel assemblies are being removed from the core. This water also provides adequate cooling for the fuel assemblies during transfer operations.

The refueling operation is divided into five major phases: (1) preparation, (2) reactor disassembly, (3) fuel handling, (4) reactor assembly, and (5) dry cask storage operation as discussed in FSAR Section 9.1.5.3. A general description of a typical refueling operation through the five phases is given below:

1. Phase I - Preparation

   The reactor is shutdown and cooled to cold shutdown conditions with a final $k_{eff} \leq 0.95$ (all rods in). Following a radiation survey, the containment vessel is entered.

2. Phase II - Reactor Disassembly

   All missile shields, cables, air ducts, insulation, piping, and studs are removed or disconnected as required to allow removal of the reactor head assembly. The refueling canal is prepared for flooding by closing the refueling canal drain holes; removing the blind flange from the fuel transfer tube; checking the underwater lights, tools, and fuel transfer system; and sealing off the reactor cavity. With the refueling canal prepared for flooding, the vessel head is unseated and taken to its storage pedestal. Water from the refueling water storage tank is pumped into the reactor coolant system by the residual heat removal pumps, filling the vessel and eventually the refueling cavity to a safe shielding depth. Additional water from the CVCS Holdup Tanks (HUT) can be processed and pumped to the refueling canal by the Gas Stripper Feed Pumps or the HUT Recirculation Pumps. The control rod drive shafts are disconnected and the upper internals are removed from the vessel. The fuel assemblies and rod cluster control assemblies are now free from obstructions and the core is ready for refueling. Final checkout of the fuel transfer system and manipulator crane is completed. The gate valve in the fuel transfer tube is opened when needed to connect the refuel cavity and fuel transfer canal.

3. Phase III - Fuel Handling

   A complete core offload is normally performed with core component shuffle in the spent fuel pit. In-core fuel shuffles may also be performed.

   The general fuel handling sequence is:

   a. The manipulator crane removes a spent or partially spent fuel assembly from the core and places it in the fuel assembly container of the transfer car.

   b. The upender pivots the fuel assembly container to the horizontal position.

   c. The transfer car moves the fuel assembly to the transfer canal in the auxiliary building.

   d. The upender pivots the fuel assembly container to the vertical position.

   e. The spent fuel pit bridge hoist removes the fuel assembly from the fuel assembly container and places it in the spent fuel rack.

f. Spent or partially spent fuel assemblies are transferred as above until all necessary assemblies have been moved from the reactor core to the spent fuel racks.

g. Core components (RCCAs, thimble plugs, etc.) are transferred as necessary to ready the partially spent and new fuel assemblies for core reload.

h. Reload of partially spent and new fuel assemblies back into the reactor is essentially the reverse of (a) through (f) above.

i. Partially spent fuel assemblies may also be moved directly to new core positions as required for the next operating cycle.

j. Spent, partially spent, and new fuel assemblies may also be placed in the RCC changing fixture for transfer of core components (RCCAs and thimble plugs) or the transfer may occur in the upender or spent fuel pool using portable component handling tools.

k. New fuel assemblies are transferred directly from the new fuel elevator to the upender fuel assembly container or go into the spent fuel pool using the spent fuel bridge.

l. Fuel assemblies or components may also undergo inspections in the spent fuel area to determine integrity.

4. Phase IV - Reactor Assembly

Reactor assembly, following refueling, is essentially achieved by reversing the operations given in Phase II - Reactor Disassembly.

5. Phase V - Dry Cask Storage Operations

Dry cask storage operations are provided in SQN Independent Spent Fuel Storage Installation (ISFSI) (Section 9.1.5.3).

9.1.4.2.2 Component Description

Manipulator Crane

The manipulator crane (Figure 9.1.4-3) is a rectilinear bridge and trolley crane with a vertical mast extending down into the refueling water. The bridge spans the refueling cavity and runs on rails set into the edge of the refueling cavity. The bridge and trolley motions are used to position the vertical mast over a fuel assembly in the core. A long tube with a pneumatic gripper on the end is lowered down out of the mast to grip the fuel assembly. The gripper tube is long enough so that the upper end is still contained in the mast when the gripper end contacts the fuel. A winch mounted on the trolley raises the gripper tube and fuel assembly up into the mast tube. The fuel is transported while inside the mast tube to its new position.

All controls for the manipulator crane are mounted on a console on the trolley. The bridge and trolley position indication is provided to the operator. The drives for the bridge, trolley, and winch are variable speed and include a separate inching control on the winch. Electrical interlocks and limit switches on the bridge and trolley drives limit the movement to prevent damage to the fuel assemblies. The winch is also provided with limit switches plus a mechanical stop to prevent a fuel assembly from being raised above a safe shielding depth should the limit switch fail. In special circumstances, the bridge, trolley, and winch can be operated manually using a handwheel on the motor shaft.

Spent Fuel Pit Bridge

The spent fuel pit bridge (Figure 9.1.4-4) is a wheel-mounted walkway, spanning the shared spent fuel pit. The bridge carries an electric monorail hoist on an overhead structure. The fuel assemblies are moved within the spent fuel pit by means of a long-handled tool suspended from the hoist. The hoist travel and tool length are designed to limit the maximum lift of a fuel assembly's active fuel region to a safe shielding depth, Section 9.1.4.3.4.

New Fuel Elevator

The new fuel elevator consists of a box-shaped elevator assembly with its top end open. It is sized to contain one fuel assembly.

The new fuel elevator is used to lower a new fuel assembly to the bottom of the fuel transfer canal where it is transported by the spent fuel pit bridge hoist. The new fuel elevator is not intended to be used to raise irradiated fuels. The new fuel elevator may be used for fuel reconstitution with appropriate safeguards in place.

Fuel Transfer System

The fuel transfer system (Figure 9.1.4-1) includes an electric driven transfer car that runs on tracks extending from the upending frame in the refueling canal through the transfer tube to the upending frame in the transfer canal. The upender in the refueling canal receives a fuel assembly in the vertical position from the manipulator crane. The fuel assembly is lowered to a horizontal position for passage through the transfer tube and is then raised to a vertical position by the upender in the fuel transfer canal. The spent fuel pit bridge moves the fuel assembly to the spent fuel storage racks.

During reactor operation, the transfer car is stored in the fuel transfer canal. A blind flange is bolted to the refueling canal end of the transfer tube when reactor containment integrity is required. The end of the tube outside the containment is normally closed by a gate valve when not in refueling operation.

Rod Cluster Control Changing Fixture

RCC elements may be transferred from one fuel assembly to another by means of the RCC changing fixture (Figure 9.1.4-5). Five major subassemblies comprise the changing fixture including: (1) frame track structure, (2) carriage, (3) guide tube, (4) gripper, and (5) drive mechanism. The carriage is a movable container supported by the frame and track structure. The tracks provide a guide for the four flanged carriage wheels and allow horizontal movement of the carriage during changing operations. Positioning stops on both the carriage and frame locate each of the three carriage compartments directly below the guide tube. Two of these compartments are designed to hold individual fuel assemblies while the third is made to support a single RCC element. Situated above the carriage and mounted on the refueling canal wall is the guide tube. This assembly provides for the guidance and proper orientation of the gripper and RCC element as they are being raised or lowered. The gripper is a pneumatically actuated mechanism responsible for engaging the RCC element. It has two flexure fingers which can be inserted into the top of the RCC element when air pressure is applied to the gripper piston. Normally the fingers are locked in a radially extended position. Mounted on the operating deck is the drive mechanism assembly. Its components include: (1) a manual carriage drive mechanism, (2) a revolving stop operating handle, (3) a pneumatic selector valve for actuating the gripper piston, and (4) an electric hoist for elevation control of the gripper.

Portable Rod Cluster Control Changing Tool

A portable RCC changing tool that functions in a manner similar to the stationary RCC change fixture is normally used. The tool is lowered onto a fuel assembly in the spent fuel racks. The gripper is then inserted into the RCC hub and actuated to engage. The gripper and RCC element are then withdrawn from the fuel assembly and into a guide structure in the lower portion of the tool. Once the RCC element is fully withdrawn from the fuel, the tool is raised to permit movement to another fuel assembly. Lowering of the tool into the top nozzle of the fuel assembly allows the RCC element to be inserted into the fuel and allows the gripper mechanism to be disengaged.

Spent Fuel Handling Tool

This tool is used to handle new and spent fuel in the spent fuel pit. It is a manually actuated tool on the end of a long pole suspended from the spent fuel pit hoist. An operator on the spent fuel pit bridge guides and operates the tool.

Thimble Plug Handling Tool

This tool is used to transfer thimble plugging devices between fuel assemblies. It is a manually actuated tool on the end of a long pole, suspended from either the spent fuel pit hoist or manipulator crane auxiliary hoist.

Burnable Poison Handling Tool

This tool is used to transfer burnable poison rods between fuel assemblies. It is a manually actuated tool on the end of a long pole suspended from the spent fuel pit hoist.

New Fuel Assembly Handling Fixture

This short-handled tool is used to handle new fuel on the operating deck of the fuel storage building, to remove the new fuel from the shipping container, and to facilitate inspection and storage of the new fuel and loading of fuel into the new fuel elevator.

Temporary Tooling

Occasionally temporary tooling such as aluminum conduit poles with attachments are used to retrieve objects, provide lighting, perform visual examinations, etc. Such tooling is used for auxiliary purposes not associated with fuel movement.

Reactor Vessel Head Lifting Device

The reactor vessel head lifting device (Figure 9.1.4-6) consists of a welded and bolted structural steel frame with suitable rigging to enable the crane operator to lift the head and store it during refueling operations. The lifting device is permanently attached to the reactor vessel head. Attached to the head lifting device are the monorail and hoists for the reactor vessel stud tensioners.

Reactor Internals Lifting Device

The reactor internals lifting device (Figure 9.1.4-7) is a structural frame suspended from the overhead polar crane. The frame is lowered onto the guide tube support plate of the internals, and is manually bolted to the support plate by three bolts. Bushings on the frame engage guide studs in the vessel flange to provide guidance during removal and replacement of the internals package.

Reactor Vessel Stud Tensioner

Stud tensioners (Figure 9.1.4-8) are employed to secure the head closure joint at every refueling. The stud tensioner is a hydraulically operated device that uses oil as the working fluid. The device permits preloading and unloading of the reactor vessel closure studs at cold shutdown conditions. Stud tensioners minimize the time required for the tensioning or unloading operations. The studs are tensioned to their operational load in sequential steps to prevent high stresses in the flange region and unequal loadings in the studs.

9.1.4.3 Design Evaluation

9.1.4.3.1 Safe Handling

The manipulator crane design includes the following provisions to ensure safe handling of fuel assemblies:

1. Bridge, trolley, and winch drives are mutually interlocked, using redundant interlocks, to prevent simultaneous operation of any two drives.

2. Bridge and trolley drive operation is prevented except when both gripper tube up position switches are actuated.

3. An interlock is supplied which prevents the opening of a solenoid valve in the air line to the gripper except when zero suspended weight is indicated by a force gage. As backup protection for this interlock, the mechanical weight actuated lock in the gripper prevents operation of the gripper under load even if air pressure is applied to the operating cylinder.

4. Two redundant excessive suspended weight switches open the hoist drive circuit in the up direction when the loading is in excess of 110 percent of a fuel assembly weight.

5. An interlock of the hoist drive circuit in the up direction permits the hoist to be operated only when either the open or closed indicating switch on the gripper is actuated.

   The hoist-gripper position interlock consists of two separate circuits that work in parallel such that one circuit must be closed for the hoist to operate. If one or both interlock circuits fail in the closed position an audible and visual alarm on the console is actuated.

6. An interlock of the bridge and trolley drives prevents the bridge drive from traveling beyond the edge of the core unless the trolley is aligned with the refueling canal centerline. The trolley drive is locked out when the bridge is beyond the edge of the core.

7. Suitable restraints are provided between the bridge and trolley structures and their respective rails to prevent derailing due to the safe shutdown earthquake. The manipulator crane bridge and trolley are restrained on the rails; horizontally by two pairs of guide rollers at each wheel on one track only. The rollers are attached to the bridge track at the wheels and contact the vertical face of the rail to prevent horizontal movement; and vertically by anti-rotation bars, in the vicinity of each wheel at all four wheel locations. The anti-rotation bars are 1 1/2 inch thick carbon steel bars bolted to the track and extending under the rail flange, to prevent lifting of any wheel from the rail. The manipulator crane is designed to prevent disengagement of a fuel assembly from the gripper under the safe shutdown earthquake.

8. The main and auxiliary hoists are equipped with two independent braking systems. A solenoid released spring set electric brake is mounted on the motor shaft. This brake operates in the normal manner to release upon application of current to the motor and set when current is interrupted. The second brake is a mechanically actuated load brake which is internal to the hoist

gear box that sets if the load starts to overhaul the hoist. It is necessary to apply torque from the motor to raise or lower the load. In raising, the motor cams the brake open, in lowering, the motor slips the brake allowing the load to lower. This brake actuates upon loss of torque from the motor for any reason and is not dependent on any electrical circuits. On the main hoist the motor break is rated at 350 percent operating load and the mechanical brake at 300 percent.

The fuel hoist system is supplied with redundant paths of load support such that failure of any one component will not result in free fall of the fuel assembly. Two wire ropes are anchored to the winch drum and carried over independent sheaves to a load equalizing mechanism on the top of the gripper tube. In addition, supports for the sheaves and equalizing mechanism are backed up by passive restraints to pick up the load in the event of failure of this primary support. Each cable system is designed to support 13,750 pounds separately or 27,500 pounds acting together.

The working load of fuel assembly plus gripper is approximately 2500 pounds.

The gripper itself has four fingers gripping the fuel, any two of which will support the fuel assembly weight.

The gripper and hoist system are routinely load tested to $\geq$2750 pounds.

The following safety features are provided for the fuel transfer system control circuit:

1. Transfer car operation is possible only when both lifting arms are in the down position.

2. The remote control panels (one on the refueling canal side and one on the spent fuel pit side) have a transfer car control that prevents operation of the transfer car in either direction until the control function is enabled on both panels. This prevents the spent fuel pit side operator from moving the transfer car until the reactor side operator has completed fuel movement.

3. Transfer car operation is possible only when the transfer tube valve position switch indicates the valve is fully open.

4. The refueling canal lifting arm is interlocked with the manipulator crane. The lifting arm cannot be operated unless the manipulator crane gripper tube is in the fully retracted position or the crane is over the core.

5. All fuel handling tools and equipment handled over an open reactor vessel are designed to prevent inadvertent decoupling from crane hooks (i.e., lifting rigs are pinned to the crane hook and safety latches are provided on hooks that support tools).

6. Verification that the transfer car is at either end of its travel is required prior to operating the lifting arm.

Tools required for handling internal reactor components are designed with fail safe features that prevent disengagement of the component in the event of operating mechanism malfunction. These safety features apply to the control rod drive shaft unlatching tool. The air cylinders actuating the gripper mechanism are equipped with backup springs which close the gripper in the event of loss of air to the cylinder. Air valves are equipped with safety locking rings to prevent inadvertent actuation.

9.1.4.3.2 Seismic Considerations

The maximum design stress for the structures and for all parts involved in gripping, supporting, or hoisting the fuel assemblies is 1/5 ultimate strength of the material. This requirement applies to normal working load and emergency pullout loads, when specified, but not to earthquake loading. To resist safe shutdown earthquake forces, the equipment is designed to limit the stress in the load bearing parts to 0.9 times the yield stress for a combination of normal working forces plus safe shutdown earthquake forces.

9.1.4.3.3. Containment Pressure Boundary Integrity

The fuel transfer tube which connects the reactor cavity / refueling canal (inside the reactor containment) and the fuel transfer canal (outside the containment) is closed on the refueling canal side by a blind flange when containment integrity is required. Two seals are located around the periphery of the blind flange with leak-check provisions between them.

9.1.4.3.4 Radiation Shielding

During transfer of a spent fuel assembly, the gamma dose rate from the assembly itself is calculated to be 2.5 mrem/hr or less at a distance of 3 feet above the surface of the water. This dose rate is based on maintaining an adequate water level for shielding above the fuel assembly during all handling operations.

The two cranes used to lift spent fuel assemblies are the manipulator crane and the spent fuel pit bridge hoist. The manipulator crane contains positive stops which prevent the top of a fuel assembly from being raised above the water level needed for shielding in the refueling cavity. The hoist on the spent fuel pit bridge moves spent fuel assemblies with a long-handled tool. Hoist travel and tool length limit the maximum lift of a fuel assembly in the spent fuel pit to maintain water coverage needed for shielding.

9.1.4.4 Tests and Inspections

As part of normal plant operations the fuel-handling equipment is inspected for operating conditions prior to each refueling and dry cask storage (Reference Section 9.1.5) operation.

During the operational testing of this equipment, procedures are followed that will affirm the correct performance of the fuel handling system interlocks.

9.1.5 Independent Spent Fuel Storage Installation (ISFSI)

9.1.5.1 Regulatory Basis

Under 10 CFR 72.210, SQN is issued a general license for the storage of spent fuel in an Independent Spent Fuel Storage Installation (ISFSI). An ISFSI is a complex that is designed and constructed for the interim storage of spent nuclear fuel, high-level radioactive waste, solid reactor-related GTCC waste, and other radioactive materials associated with spent fuel and reactor-related GTCC waste storage. TVA selected the HI-STORM 100 Cask System and the HI-STORM FW System for use at the SQN ISFSI to maintain adequate on-site spent fuel storage capacity. Upon NRC approval of the Final Safety Analysis Report (FSAR) for the HI-STORM 100 Cask System, the NRC issued Certificate of Compliance (CoC) Docket No. 72-1014 and Safety Evaluation Report (SER) Docket No. 72-1014 for use of the HI- STORM 100 Cask System. Likewise, upon NRC approval of the FSAR for the HI-STORM FW System, the NRC issued CoC Docket No. 72-1032 and SER Docket No. 72-1 032 for use of the HI-STORM FW System. As a General Licensee, SQN is authorized to use the HI- STORM 100 Cask System and the HI-STORM FW System in accordance with the appropriate documents for each dry cask storage system:

- NUREG-1536, Standard Review Plan for Dry Cask Storage Systems
- CoC 72-1014 (HI-STORM 100 Cask System), containing:
    - ❖ Appendix A: Technical Specifications

- SQN 10 CFR 72.212 Evaluation Report for the HI-STORM FW System

9.1.5.2 System Description

The HI-STORM 100 Cask System used at SQN is comprised of a stainless steel multipurpose canister (MPC-32), a transfer cask (HI-TRAC 125D), and a HI-STORM 100 Cask System metal/concrete overpack. The MPC-32 fuel basket provides criticality control and can hold 32 PWR spent fuel assemblies or radioactive materials associated with spent fuel and reactor-related waste components. The outer shell, top lid, bottom baseplate, closure ring, and associated welds constitute the MPC-32 confinement boundary which precludes radioisotopes leakage into the environment, provides the heat transfer medium from the contents to the environment, and provides an inert environment to prevent corrosion of the stored fuel. The HI-TRAC 125D transfer cask holds the MPC-32 during spent fuel loading, processing, and unloading operations and provides ALARA for personnel in accordance with 10 CFR 20. The HI-TRAC 1250 is used to transfer the MPC-32 to and from the cask pit pool and the HI-STORM 100 Cask System overpack in accordance with 10 CFR 72 for onsite storage or to an off-site shipment cask licensed under 10 CFR 71. The MPC-32 is stored inside the HI-STORM 100 Cask System overpack for protection against extreme natural phenomena, tornado generated missiles, radiological shielding, and allows for the transfer of heat from the stored fuel to the environs.

The HI-STORM FW System which is also used at SQN is comprised of a stainless steel multi-purpose canister (MPC-37), a transfer cask (HI-TRAC VW), and a HI-STORM FW System metal/concrete overpack. The MPC-37 fuel basket provides criticality control and can hold 37 PWR spent fuel assemblies or radioactive materials associated with spent fuel and reactor-related waste components. The outer shell, top lid, bottom baseplate, closure ring, and associated welds constitute the MPC-37 confinement boundary which precludes radioisotopes leakage into the environment, provides the heat transfer medium from the contents to the environment, and provides an inert environment to prevent corrosion of the stored fuel. The HI-TRAC VW transfer cask holds the MPC-37 during spent fuel loading, processing, and unloading operations and provides ALARA for personnel in accordance with 10 CFR 20. The HI-TRAC VW is used to transfer the MPC-37 to and from the cask pit pool and the HI-STORM FW System overpack in accordance with 10 CFR 72 for onsite storage. The MPC-37 is stored inside the HI-STORM FW System overpack for protection against extreme natural phenomena, tornado generated missiles, radiological shielding, and allows for the transfer of heat from the stored fuel to the environs.

The MPCs (32/37), the transfer casks (HI-TRAC 125D / HI-TRAC VW). and the overpacks (HI-STORM 100 Cask System / HI-STORM FW System) are not interchangeable components between the dry cask storage systems. The HI-STORM 100 Cask System components (HI-TRAC 1250, MPC-32, and HI-STORM 100 Cask System overpack) are used together and the HI-STORM FW System components (HI-TRAC VW, MPC-37, and HI-STORM FW System overpack) are used together.

The SQN ISFSI is located within the existing protected 10 CFR 50 property. southeast of the Unit 2 reactor building. The ISFSI storage pad (see Figure 2.1.2-1) consists of eight (8) sections, which is sufficient to store 90 overpacks (either HI-STORM 100 Cask System or HI-STORM FW System overpacks). In addition to the storage pad, the ISFSI is surrounded by protected fencing and monitored by various security systems.

As stated, the shipping cask (i.e., MPC-32) is designed in accordance with the requirements of 10 CFR 71 and 10 CFR 72. A cask drop could lead to potential fuel damage. An analysis (Reference Calculation SQS2-0226) was performed for a cask drop accident containing 32 assemblies, each assembly having a minimum of 3 years decay since removal from the reactor. The analysis assumed all assemblies were ruptured. Such an accident is bounded by a Fuel Handling Accident (a single assembly accident with only 100 hours decay, see UFSAR section 15.4.5). Table 9.1.5-1 compares the gap activities of a single assembly with 100 hours decay to that of 32 assemblies with 3 years decay.

The HI-TRAC VW transfer cask and the HI-STORM FW overpack, which contain an MPC-37 will be moved with lifting equipment that shall have redundant drop protection features, which prevent uncontrolled lowering of the load. All lifting appurtenances used with the HI-TRAC VW transfer cask and HI-STORM FW overpack are designed in accordance with NUREG-0612 and ANSI N14.6, as

applicable. Also, each lift of an MPC, a HI-TRAC VW transfer cask, or any HI-STORM FW overpack will be made in accordance to the SQN heavy loads requirements and procedures. ·The use of an equivalent single-failure-proof crane for dry cask lifts in the Auxiliary Building assures a drop of an MPC-37 will not occur due to a single failure of the lifting system. Therefore, a cask drop of an MPC-37 that could lead to potential fuel damage is not postulated. Although this is not a credible event in the Holtec FSAR, Reference calculation SQS20226 concluded that the dose consequence of an MPC-32 and -37 cask drop is bounded by a Fuel Handling Accident involving a single assembly as described in UFSAR section 15.5.6.

A detailed description of the HI-STORM 100 Cask System is provided in Holtec International FSAR for the HI-STORM 100 Cask System (HI-2002444). Whereas, a detailed description of the HI-STORM FW System is provided in Holtec International FSAR for the HI-STORM FW System (HI-2114830).

9.1.5.3 Dry Cask Storage Operations

a. The transfer cask and multi-purpose canister (MPC) are placed in a cask work area (CWA) on the auxiliary building refueling floor by the auxiliary building overhead crane with a lift yoke attached to the crane hook using site established safe load path.

b. Activities associated with the preparation of the transfer cask such as inspections, partial filling of neutron shield water jacket with demineralized water, placing the MPC into the transfer cask, partial filling of the MPC with borated water, installation of the annulus over pressure system, installation of the inflatable annulus shield, etc. will be performed in the CWA.

c. After the transfer cask preparations are completed, the transfer cask and MPC are moved from the CWA to the cask stand in the shallow end of the cask loading area.

d. To prevent submerging the main hoist crane hook in the deep end of the cask loading area, a lift yoke extension will be installed between the crane hook and the lift yoke.

e. With these lifting devices in place, the transfer cask and MPC are moved from the shallow end cask stand to the deep end cask stand. The cask support stand in the deep end of the cask loading area is ergonomically sized such that the top of the MPC is positioned approximately level with the top of the spent fuel pool fuel racks.

f. Under water cameras and surveillance will be used as needed to ensure placement of the transfer cask, verify lift yoke is engaged or disengaged, verify MPC lid placement, monitor fuel loading, etc.

g. The gate between the cask loading area and spent fuel pit is not to be installed.

h. Using the spent fuel pit bridge and manipulator crane, spent fuel assemblies are transferred from the spent fuel storage racks to the MPC wherein 10 CFR 72 regulation is in effect. After the spent fuel assemblies are loaded, the MPC lid is placed on the MPC. Radiation monitoring may be performed prior to transfer cask and MPC breaching the pool surface.

i. Following verification of MPC lid placement and after dose rate measurements has determined that it is safe to continue, the transfer cask and loaded MPC are placed back on the shallow end cask stand where radiation monitoring, connection of pump down hoses, removal of the lift yoke extension, etc. takes place. Note that the 10 CFR Part 50 Technical Specification (TS) (Reference TS 3.7.13) requirement of maintaining 23 feet of water shielding no longer applies.

j. After radiation dose rate measurements confirm that it is safe to remove the transfer cask from the cask loading area, the transfer cask and loaded MPC are placed back in the CWA where the next phase of decontamination of the transfer cask, disengagement of the annulus overpressure system, and MPC closure operation are performed.

k. After the MPC lid is seal welded, the MPC is hydrostatically tested, drained, dried and filled with helium.

l. The transfer cask and MPC are moved to the auxiliary building railroad bay where the MPC is transferred to the HI-STORM overpack.

m. The HI-STORM overpack is transported to the ISFSI and placed at a designated location.

n. If necessary, unloading operations are performed using similar methodology in reverse.

9.1.5.4 Evaluation of the Reactor Power & ISFSI Facilities Interface Documents

Analyses used to demonstrate ISFSI compliance to 10 CFR 50 and 10 CFR 72 regulations are listed in Table 9.1.5-2. These analyses address SSCs that are shared or utilized to facilitate SQN 10 CFR 50 Reactor Power and 10 CFR 72 ISFSI facilities. This section is not intended to be all inclusive of design features between the two facilities however, this listing provides examples of SSCs having design basis requirements in both the 10 CFR 50 and 10 CFR 72 regulations. The applicability of these regulations also includes the associated drawings and procedures of the commonly shared SSCs. Therefore, implementing a change, test, or experiment for these shared SSCs shall require a 10 CFR 50.59 review and a 10 CFR 72.48 review. This position demonstrates compliance with 10 CFR 50 Appendix A, GDC-5 and 10 CFR 72.122 Paragraphs (d), (e), and (k) (4).

Discharge Scenarios

Case 1: Normal Full Core Discharge

The entire core (193 fuel assemblies) from one reactor unit is transferred to the pool after twelve days of decay in the reactor. The total fuel transfer time is assumed to be 36 hours for 193 bundles. 113 assemblies of the core are reloaded into the reactor 30 days after completion of download to the pool. The total reload time is assumed to be 21.1 hours. The total duration of the outage is assumed to be 60 days.

Two discrete analyses have been performed for Case 1 assuming two cooling trains in operation and one cooling train in operation. These two evaluations and denoted as Case 1a and Case 1b, respectively.

Case 2: Back-to-Back Normal Full Core Discharge

Eighteen days after the end of the outage described in Case 1, the other unit has a scheduled outage. Transfer time parameters and the number of fuel assemblies moved are the same as in Case 1.

Two discrete analyses have also been performed for Case 2 assuming two cooling trains in operation and one cooling train in operation. These two evaluations are denoted as Case 2a and Case 2b, respectively.

Case 3: Unplanned Full Core Offload

Sixty days after the end of the back-to-back normal refueling outage (Case 2 above), the first unit has an unplanned shutdown. The full core transfer to the pool begins 12 days after the shutdown and is completed in 36 hours. All fuel assemblies in the discharged core are conservatively assumed to have 1260 full power days of operation.

9.2 WATER SYSTEMS

9.2.1 Component Cooling System

9.2.1.1 Design Bases

The CCS is designed for operation during all phases of plant operation and shutdown.

The CCS is designed to remove residual and sensible heat from the Reactor Coolant (RC) System via the Residual Heat Removal System (subsection 5.5.7) during plant cooldown; cool the spent fuel pit water and the letdown flow for the Chemical and Volume Control System; provide cooling to dissipate waste heat from various plant components; and provide cooling for safeguard loads after an accident.

The systems served by the CCS are:

1. Reactor Coolant System
2. Residual Heat Removal System
3. Chemical and Volume Control System
4. Waste Disposal System
5. Sampling System
6. Safety Injection System
7. Spent Fuel Pool Cooling and Cleanup System
8. Containment Spray System

Since heat from these systems is transferred by the component cooling water to the Essential Raw Cooling Water (ERCW) System (Subsection 9.2.2) via the component cooling heat exchangers, the CCS serves as an intermediate system between systems it serves and the ERCW System (the heat sink for the CCS). This double barrier arrangement reduces the probability of leakage of potentially radioactive water to the ERCW System and to the river or atmosphere.

The CCS design is based on a maximum ERCW temperature of 87°F.

The Component Cooling Water System is designed such that no single active or passive failure will interrupt cooling water to both A and B safeguard trains. One safeguard train is capable of providing sufficient heat removal capability for reactor cooldown.

The CCS pumps and required motor-operated valves will be automatically transferred to emergency onsite power upon loss of offsite power.

9.2.1.2 System Description

The CCS shown in Figures 9.2.1-1 through 9.2.1-4 is a closed-loop, two train cooling system consisting of five CCS pumps, four thermal barrier booster pumps, three pairs of plate heat exchangers (PHEs), two surge tanks, CCS pump seal water collection unit, and associated valves, piping and instrumentation serving both units. The heat exchangers are designated as Heat Exchangers 1A1/1A2, 2A1/2A2 and OB1/OB2. PHEs 1A1/1A2 serves train A loads in unit 1, PHEs 2A1/2A2 serves train A loads in unit 2, and PHEs OB1/OB2 serves train B loads in both units.

During normal operation, the system is designed to provide component cooling water at a temperature that ranges from approximately 35°F to 95°F. This temperature varies depending on the equipment heat loads and the ERCW System temperature. During normal operations, CCS Train B temperature may track ERCW temperature to a minimum of 35°F. CCS Train A heat loads are sufficient to maintain CCS temperature above 40°F. During a unit shutdown, the component cooling water temperature can approach 120°F when the ERCW System is at the design basis temperature of 87°F. During a loss-of-coolant accident (LOCA-Recirc), CCS temperature may reach 104.5°F. System design pressure and temperature are 150 lb/in^{2}g and 200°F respectively, except part of the RC pumps thermal barrier cooling water piping inside containment, which is designed for 2485 lb/in^{2}g and 650°F, and the thermal barrier booster pump discharge piping up to the RC pumps thermal barrier inlet check valves, which is designed for 200 lb/in^{2}g and 200°F. To prevent overpressure of thermal barrier cooling water discharge line subsequent to a thermal barrier tube rupture and containment isolation, this line is designed to contain pressure and temperature equal to the RC System. The supply line to the thermal barrier is protected from this high pressure by two check valves located at the RC pump connection. The design pressure (200 lb/in^{2}g) for the Thermal Barrier Booster Pump discharge piping up to the RC pump thermal barrier inlet check valves was selected to accommodate the additional head provided by the booster pumps. The design pressure (150 lb/in^{2}g) for the remainder of the CCS was selected to exceed the maximum operating pressure applied to the system.

Under normal power operation, the CCS will require the use of one component cooling water pump (i.e., 1A-A, or 1B-B in unit 1 and 2A-A or 2B-B in unit 2) and the CCS heat exchangers in train A of each unit. One additional CCS pump may be needed in the unit carrying the SFP heat exchanger. Normally, only CCS pump C-S will be aligned to the train B headers. During stages of operation when the required flowrate exceeds the design flowrate of one pump, it may be necessary to use two component cooling water pumps. Either pumps 1B-B or 2B-B can be realigned to the train B headers if necessary. Pump C-S shall normally be powered from train B electrical circuits. However, the electrical system shall be designed so that the power feed can be switched to train A. Valves can be repositioned upon loss of train B to align pump C-S to either train A header and thereby provide additional train A capacity if needed.

Either unit's CCS A train can supply both spent fuel pit heat exchanger loads. Remote-operated valving is provided to transfer the supply line to the heat exchangers to the A train header of the other unit if the heat and flow loads so require. The return line must be aligned to the CCS pump suction by locally opening and closing the appropriate valves. If train A should be lost, spent fuel pit cooling may be provided from CCS plate heat exchangers OB1 and OB2 by locally opening the appropriate valves to interconnect the train A and train B headers. This will require realignment of pump 1B-B or 2B-B to plate heat exchangers OB1 and OB2.

For minimum rate cooldown, two pumps and one CCS heat exchanger pair may be required to remove the residual heat and the aligned component loads; however, unit cooldown procedures and the CCS design allow assignment of a pump and heat exchanger pair to each train of the safeguards system thereby increasing cooldown capability. A surge tank is provided for each unit, and each tank is separated into two parts by a baffle providing separate minimum surge volume for each safeguard cooling train.

Since portions of the CCS are required for post-accident removal of decay heat from the reactor, these portions are considered engineered safety features and are therefore designed to meet the single active or passive failure criteria. Either unit (accident unit) may be aligned with two completely independent cooling system Trains (A and B) serving safeguard equipment and one train serving miscellaneous service components of a unit. The third component cooling heat exchanger pair (OB1 and OB2) and CCS pump (C-S) are aligned to the accident unit during the

safety injection phase of a LOCA to establish the cooling train serving train "B" safeguard equipment. The CCS B Train pump (1B-B, 2B-B) is normally aligned through the A Train CCS heat exchangers (1A1/1A2, 2A1/2A2). This alignment provides flow through the CVCS seal water heat exchanger for attendant equipment cooling of CCP B-B main flow upon loss of A Train Power. The component cooling heat exchanger pair and CCS pump or pumps normally assigned to the unit supply cooling water to "A" safeguard equipment also supply miscellaneous service components of that unit. Each safeguard cooling train consists of one pump, one heat exchanger pair, and a separate compartment in the unit surge tank. Each safeguard cooling train is capable of fulfilling cooling requirements for the accident unit; therefore, the second train provides 100 percent redundancy and can be placed in service if desired to increase system cooling capability. The spent fuel pit cooling supply can be aligned to either unit; therefore, it will be aligned to the non-accident unit in order to provide immediate CCS pump redundancy.

Cooling water for the CCS heat exchangers is supplied from the ERCW System ensuring a continuous source of cooling medium.

During normal conditions component cooling water can be provided for the following equipment:

1. Residual heat removal heat exchangers.
2. Reactor coolant pump thermal barriers.
3. Reactor coolant pump upper oil heat exchangers.
4. Reactor coolant pump lower oil heat exchangers.
5. Seal water heat exchanger.
6. Spent fuel pit heat exchangers.
7. Sample heat exchangers and hot sample chiller.
8. Letdown heat exchanger.
9. Residual heat removal pump seal water heat exchanger.
10. Safety injection pumps mechanical seal coolers.
11. Charging pumps mechanical seal coolers.
12. Waste gas compressors.
13. Post accident sample coolers.
14. Excess letdown heat exchanger.
15. Containment spray pump oil and seal jacket heat exchangers.

Component cooling water is circulated first through the component cooling system heat exchangers, to the components using the cooling water, and finally back to the pump suction. The surge tank for each unit is separated into two sections by a baffle. Each section is tied into the pump suction lines from safeguard trains. This tank accommodates expansion and contraction of the system water due to temperature changes or in leakage, as well as providing a continuous water supply until a small leak in the system can be isolated. Because the surge tank is normally vented to the building atmosphere, a radiation monitor is provided in each component cooling water heat exchanger pair discharge line. These monitors actuate an alarm and close the appropriate surge tank vent valve when the radiation reaches a preset level above the normal background.

Cooling water is available to all components served by the system, even though one or more of the components may be isolated. The system is provided with adequate valves to permit realignment or isolation of equipment and cooling water headers. (Valves are actuated to provide the residual heat exchangers with cooling water during startup, cooldown, and loss- of-coolant accident.)

Normal system makeup is provided from the demineralized water system. Emergency makeup is provided from the ERCW System through a metered spool piece.

The component cooling water contains a corrosion inhibitor to protect the carbon steel piping. The component cooling water chemistry for normal operation of the plant is specified in the plant chemistry program.

The CCS system characteristics used as the basis for CCS pump procurement are shown in Figure 9.2.1-5. Pump logic is shown in Figure 9.2.1-7.

9.2.1.3 Components

Component Cooling System codes and classification are given in Section 3.2. Equipment design parameters are given in Table 9.2.1-1.

9.2.1.3.1 Component Cooling Heat Exchangers

The three pairs of component cooling water heat exchangers are of the plate type. ERCW circulates through alternating plates to remove the heat from the CCS which circulates through the remaining plates. See Table 9.2.1-1.

For equipment maintenance reasons, the Component Cooling System (CCS) may occasionally be operated with only one of the two heat exchangers that comprise a pair for each train in service. This is subject to limitations on the temperature of the ERCW to the CCS heat exchangers.

9.2.1.3.2 Component Cooling Pumps

The five component cooling water pumps which circulate water through the component cooling loops are horizontal centrifugal units of standard commercial construction. The pump motors receive electric power from normal or emergency sources. Each of the four normally assigned pumps (2 per unit) is connected to one of the four shutdown boards. The fifth pump can be powered from either of two assigned shutdown boards.

9.2.1.3.3 Thermal Barrier Booster Pumps

The four booster pumps (2 per unit) circulate cooling water through the reactor coolant pump thermal barriers. The booster pumps provide additional head overcoming the head loss through the thermal barriers to allow the CCS pumps to operate at a lower total head, supplying the remaining component cooling loops at a lower operating pressure. One booster pump supplies the thermal barrier requirements (160 gal/min) for each unit. A second pump is assigned to each unit to provide 100 percent redundancy. RCP TB flow can be maintained without the TBB Pumps to support the RCP's safety functions, (reference 3). The pumps are horizontal centrifugal units of standard commercial construction. The pump motors receive electric power from normal or emergency sources. Pump logic is shown in Figure 9.2.1-6.

9.2.1.3.4 Component Cooling Surge Tanks

The component cooling water surge tanks accommodate changes in component cooling water volume.

Each unit is provided with one tank for unit separation. Each tank has an internal baffle divider to provide two separate surge volumes for safeguard train separation within each unit. This arrangement provides redundancy for a passive failure during recirculation following a LOCA.

9.2.1.3.5 Valves

Valves used in the CCS are of standard commercial grade carbon and stainless steel construction. Self-actuated spring-loaded relief valves are provided for lines and components that could be pressurized beyond their design pressure by improper operation or malfunction.

A relief valve has been provided on the CCS piping downstream of the excess letdown heat exchanger. This relief valve has been sized to relieve in leakage from a heat exchanger tube leak while the CCS side is isolated.

Except for the normally closed makeup line, equipment vent and drain lines and flood mode spool pieces, there are no connections between the component cooling water and other systems. The equipment vent and drain lines outside the containment have manual valves which are normally closed unless the equipment is being vented or drained for maintenance or repair.

Relief valves other than those on the CCS surge tanks or excess letdown heat exchangers have been sized to relieve the volumetric expansion occurring if the exchangers' CCS side is isolated while high temperature coolant flows through the other side. Discharged water either bypasses the downstream isolation valve and returns to the system or is directed to the waste disposal system.

Relief valves on the component cooling surge tanks are sized to relieve the maximum flow rate of water which enters the surge tank following a tube rupture in the residual heat removal heat exchanger. The set pressure is set below the design pressure of the surge tank. The discharge of these valves is directed to the floor drain collector tank.

The surge tank vent-overflow line, which is open to the auxiliary building atmosphere, is equipped with an air-operated valve that closes automatically if radiation is detected in the system. A vacuum breaker valve is also provided to prevent collapsing the tank in the event of a large loss of water in the system.

Additional discussion on valves is provided in Section 9.2.1.7.6.

9.2.1.3.6 Piping

Component Cooling Water System piping is principally seamless carbon steel, ASTM A 106, Grade B, with welded joints and connections except flanges at components which might require removal for maintenance. The thermal barrier relief valves are threaded. CCS piping is standard weight except the RCP thermal barrier piping which is schedule 160 from the upstream check valve to the last containment isolation valve.

9.2.1.4 Safety Evaluation

The CCS is a two-train system, each train having the capability to provide the maximum cooling water requirement for both units under any credible plant conditions. These equipment trains are sufficiently independent to guarantee the availability of at least one train at any time. The

system has been analyzed for "worst case" heat loads under combinations of maximum river water temperature, design basis accident conditions, normal cooldown requirements, power train failures, etc., for both units. It is found through these analyses that sharing of this system by the two nuclear units does not introduce factors that prevent the system from performing its required function for plant design basis condition.

Component cooling water pumps, heat exchangers, and associated valves, piping, and instrumentation that are located outside the containment are available for maintenance and inspection during power operation. Maintenance on a pump or heat exchanger is practical while redundant equipment is in service subject to limitations of the technical specifications.

Sufficient cooling capacity is provided to fulfill system requirements under normal and accident conditions. Adequate safety margins are included in the size and number of components to preclude the possibility of a component malfunction adversely affecting operation of safeguards equipment. Active system components considered vital to the cooling function are redundant. Any single active or passive failure in the system will not prevent the system from performing its design function. Should a single failure result in the loss of a train of equipment (A or B) the other train is available for handling all required heat loads. The alignment of the CCS 1B and 2B pumps through the A train CCS heat exchangers (1A1/1A2, 2A1/2A2) and the CVCS seal water heat exchanger provides single active failure protection (in the short term) for CCP miniflow cooling. (References 4, 5, 6, & 7)

The component cooling water pumps are automatically placed on emergency power in the event of loss of offsite power; therefore, the minimum safeguards requirements are met with regard to supply of component cooling water. Separate trains provide component cooling water to the Engineered Safety Features. Each train services its safety-related cooling loads associated with the same train.

9.2.1.5 <u>Leakage Provisions</u>

To minimize the possibility of leakage from piping, valves, and equipment, welded joints are used wherever possible. Flanged joints are used at flood mode connections, flow element connections, and to facilitate inspection/maintenance where a component must be removed from the system such as for butterfly valves and pumps.

A seal leakage collection station is provided to collect seal leakage from the component cooling pumps and return it to the system via the CCS surge tanks. The collection station consists of one collection tank and two seal leakage return pumps. The pumps alternate operation to return equal seal leakage volume to each unit surge tank. This system is not safety related.

Safety grade make-up to the CCS is provided by ERCW through a metered spool piece connection at the CCS surge tanks. Normal makeup is provided by the demineralized water system to the surge tanks.

The component cooling water could become contaminated with radioactive water due to one of the following conditions:

1. A leak in any heat exchanger tube in the Chemical and Volume Control System, Residual Heat Removal System, Sampling System, or the Spent Fuel Pit Cooling System.
2. A leaking cooling coil for the thermal barrier cooler on a reactor coolant pump.
3. Seal heat exchanger leakage from various system pumps.

9.2.1.6 Incidental Control

If out leakage occurs anywhere in the system, detection is accomplished by falling level in the surge tank which will actuate a low level alarm in the control room. Level alarms from the sumps to which this water will drain also serve as leak indicators. In-leakage is detected by a high-level alarm in the surge tanks and radiation monitoring. Leak detection and control is provided by level instrumentation for the Train A side of either surge tank, which contains the Class G sample heat exchangers and chiller package. The leaking portion of the system can be located by visual inspection, radiation monitoring, leak tests, and isolated if necessary.

9.2.1.7 Instrument Applications

9.2.1.7.1 General Description

The CCS, being a water heat transfer system, uses inputs of flow, level, pressure, and temperature for instrumentation. Electric power to the transducers in the instrumentation loops is the same as the equipment being served. Loss of a power train would result in only loss of instrumentation and control of equipment that is no longer functional. Control of the system is through air-and motor-operated valves.

9.2.1.7.2 Flow Instrumentation

Flow instrumentation is provided to monitor the essential portions of the CCS. Local instrumentation is provided for the inlet flow to the plate HX pairs. Instruments are provided to monitor the flow at the outlet of other safety-related heat exchangers in the main control room. Instrumentation is also provided to monitor the flow in the safeguards equipment supply headers, Reactor Building supply headers, and the miscellaneous equipment supply headers from the main control room.

Flow instrumentation is provided on the RCP thermal barrier supply and discharge piping to initiate isolation of the CCS flow upon indication of a thermal barrier leak sensed by a flow mismatch. This flow mismatch signal initiates closure of redundant supply valves to the RCP thermal barriers.

9.2.1.7.3 Level Instrumentation

Surge tank level measurements are used to monitor and control the total amount of water in the system. Should there be leakage into the system, the level will rise and activate a high-level switch for annunciation in the control room. Indication of exact level is displayed in both the main and auxiliary control rooms. Leakage out of the system is detected by a low-level switch which activates valve LCV-70-63 to provide demineralized water makeup to the system. A low-low signal on the Train A side of either surge tank indicates a probable break in the Class G sample cooler/chiller piping and causes an automatic closure of valves FCV-70-215 and FCV-70-216.

9.2.1.7.4 Pressure Instrumentation

Local pressure indication for the suction and discharge of the pumps and the main supply header to various plant equipment is provided for all CCS pumps and the thermal barrier booster pumps. Pressure indication in the main and auxiliary control rooms is not required in order to mitigate any accident scenario. Pressure indication is used to monitor pump developed head to ensure that the minimum pump flow is met. The main control room contains pressure indication and low pressure annunciation for the Train A discharge header for Units 1 and 2, but not for the Train B common header. High-High discharge pressure annunciation is provided in the main control room for each CCS pump.

9.2.1.7.5 Temperature Instrumentation

Temperature instrumentation is provided to monitor the essential portions of the CCS. Instrumentation is provided to monitor the temperature of each phase of the CCS pump motor stator windings and each CCS pump motor bearing. Monitoring instrumentation is also provided at the outlet of each CCS heat exchanger pair and each RHR heat exchanger. Readout for the above instrumentation is provided in the main control room. Local provisions are made for temperature measurement at the outlet of all other safety-related heat exchangers.

9.2.1.7.6 Valves

Most of the valves in the system are manual valves used for sampling, venting, and testing. Motor-operated, non-throttling, fail as-is type valves are used mostly to isolate sections of the system. All control switches are located in either the main control room, the auxiliary control station, or both. Some motor-operated valves are equipped with local control switches to facilitate maintenance and testing. Valve LCV-70-63 is an automatic air-operated, fail-closed, makeup water level control valve for the surge tank. Valve FCV-70-66 is an air-operated, fail-closed, vent valve for the surge tank that closes on a high radiation signal. Valve FCV-70-85 is an air-operated, fail-closed, containment isolation valve to the excess letdown heat exchanger. Valves FCV-70-215 and FCV-70-216 are automatic air operated isolation valves on the upstream and downstream side of the Class G sample coolers, respectively, which close upon a low-low level signal from the Train A side of the surge tank. Additional containment isolation valves are provided for CCS lines penetrating containment (i.e., RCP thermal barrier, RCP oil coolers, excess letdown HX). Throttling valves are used for process control.

9.2.1.7.7 Conclusion

Since CCS is a safety buffer system between the radioactive primary water and the raw cooling water, the instrumentation provides the necessary data and controls for the operator to ensure the functional safety of the system.

9.2.1.8 Malfunction Analysis

A failure analysis of pumps, heat exchangers, valves, and piping is presented in Table 9.2.1-2.

9.2.1.9 Tests and Inspections

Active components of the CCS are periodically tested, as applicable, in accordance with Technical Specifications and ASME Section XI requirements. Containment isolation valves are tested periodically (see technical specifications and 6.2.4). Tests of the transfer system between normal and emergency power sources are conducted in accordance with Technical Specifications. Visual inspections and preventive maintenance are conducted in accordance with approved plant maintenance program procedures. The design codes for the CCS piping and components are given in Section 3.2.

9.2.2 Essential Raw Cooling Water (ERCW)

9.2.2.1 Design Bases

The ERCW System is designed to supply cooling water to various heat loads in both the primary and secondary portions of each unit. Provisions are made to ensure a continuously available flow of cooling water to those systems and components necessary for plant safety during either

normal operation or under accident conditions. Sufficient redundancy of piping and components is provided to ensure that cooling is maintained to vital loads at all times.

9.2.2.2 System Description

Prior to initial fuel loading of unit 2, a separate ERCW pumping station housing pumps for the ERCW System was constructed and placed into operation. The new ERCW station draws water directly from the river, thereby eliminating any dependence upon the CCW pumping station fore bay, the former ERCW pumps located in the CCW pumping station or the entire AERCW System which has been abandoned. The ERCW headers in the old pumping station can be utilized as a system cross-tie.

The ERCW System consists of eight ERCW pumps, four traveling water screens, four screen wash pumps, and four strainers located with the ERCW pumping station, and associated piping and valves as shown in Figures 9.2.2-1 through 9.2.2-5. The design data for all pumps required for the system operation is shown in Table 9.2.2-1. Pump logic is shown in Figure 9.2.2-6.

The eight ERCW pumps are mounted on the ERCW pumping station deck at elevation 720.0 and are protected by external walls from the effects of probable maximum flood plus wave run up to elevation 726.8. (The 1998 reanalysis determined that the new probable maximum flood elevation plus wave runup is 723.8. See Section 2.4.3.)

The ERCW system is designed to supply water to the following essential components:

1. Component cooling heat exchangers
2. Containment spray heat exchangers
3. Emergency diesel generators
4. Emergency makeup for steam generators via the Auxiliary Feedwater System
5. Emergency makeup for Component Cooling System
6. Control Building Air-Conditioning Systems
7. Auxiliary Building space coolers (for safeguard equipment)
8. Containment Ventilation System coolers
9. Auxiliary control air compressors
10. Reactor coolant pump motor coolers
11. Control rod drive ventilation coolers
12. Spent fuel pit heat exchangers*
13. Sample heat exchangers*
14. Reactor coolant pump thermal barriers*
15. Ice machine refrigeration condensers*
16. Residual heat removal heat exchangers*
17. Station air compressors (alternate supply)

*Provided with ERCW only during Stage II Flood Mode alignment.

The CCS heat exchangers and the other components are shown on the ERCW System flow diagram (Figures 9.2.2-1 through 9.2.2-5).

Typically only loads on the system during normal operations include the component cooling heat exchangers, centrifugal charging pump gear and oil coolers, RCP motor coolers, control rod drive ventilation coolers, the Air-Conditioning and Ventilation Systems (including the upper and lower containment coolers, various room and area coolers, and the instrument room coolers water chiller units), and the auxiliary control air compressors. Additional loads may be imposed during surveillance and test conditions. The ERCW System also acts as an alternate source for water supplied to the Auxiliary Feedwater System pump suction and the station air compressors.

The ERCW pumping station is located within the plant intake skimmer structure, and has direct communication with the main river channel for all reservoir levels including loss of downstream dam. The ERCW station and all equipment therein remain operable during the probable maximum flood. The system has the ability to remain operational during flood and loss of downstream dam. The normal minimum reservoir elevation is 675’. The ERCW system shall operate and deliver its rated flow when the reservoir is at the minimum design elevation of 639’. Section 2.4.11 discusses low water considerations. Section 2.4.A discusses the flood protection plan. Section 2.4.11.5.1 discusses two-unit operation.

The ERCW supply temperature maximum is 87°F.

Supply water for the ERCW pumps enters the pumping station through each of four traveling water screens directly into a corresponding ERCW pump pit from which two ERCW pumps take suction.

Water is supplied to the auxiliary building from the ERCW pumping station through four independent sectionalized supply headers designated as 1A, 2A, 1B, and 2B. Four ERCW pumps are assigned to train A, and four to train B. The two headers associated with the same train (i.e., 1A/2A or 1B/2B) are cross-tied upstream of the Auxiliary Building to provide greater flexibility. This allows one supply header to be out of service (e.g., strainer maintenance), subject to ultimate heat sink limitation. The two 6” ERCW ESF headers and also the two 24” main supply headers associated with the same train (i.e., 1A/2A or 1B/2B) are cross-tied in the Auxiliary Building. All of the crossties may be in or out of service with no restrictions. These crossties exist to facilitate maintenance and modification activities and improve system hydraulic performance. Isolation of segments of the ERCW system may be performed in unit outages or with both units online subject to various restrictions on the ultimate heat sink temperature.

The following list identifies the component configuration required to meet the Design Function of a single ERCW Loop with one operating ERCW pump:

For Unit 1 Train A One Pump Operation:

ERCW flow is isolated to the following components:

- 2A-A Diesel Generator Heat Exchangers;
- Unit 2 Containment Spray Heat Exchanger 2A;
- Unit 2 TDAFW Pump from the "2A" ERCW Main Supply Header;
- Lower Containment Vent Cooler 2A, Control Rod Drive Vent Cooler 2A, and Reactor Coolant Pump 2-1 Motor Cooler;
- Lower Containment Vent Cooler 2C, Control Rod Drive Vent Cooler 2C, and Reactor Coolant Pump 2-3 Motor Cooler;
- Upper Containment Vent Cooler 2A;
- Upper Containment Vent Cooler 2C; and
- Incore Instrumentation Room Water Coolers 2A.

The following components are in service:

- Train A ERCW yard header crosstie;
- Train A ERCW 16-inch Auxiliary Building header crosstie; and
- Train A ERCW 6-inch Engineered Safety Features (ESF) header crosstie.

For Unit 1 Train B One Pump Operation:

ERCW flow is isolated to the following components:

- 2B-B Diesel Generator Heat Exchangers;
- Unit 2 Containment Spray Heat Exchanger 2B;
- Unit 2 TDAFW Pump from the "2B" ERCW Main Supply Header;
- Lower Containment Ventilation Cooler 2B, Control Rod Drive Vent Cooler 2B, and Reactor Coolant Pump 2-2 Motor Cooler;
- Lower Containment Ventilation Coolers 2D, Control Rod Drive Vent Cooler 2D, and Reactor Coolant Pump 2-4 Motor Cooler;
- Upper Containment Ventilation Coolers 2B;
- Upper Containment Ventilation Coolers 2D;
- Incore Instrumentation Room Water Coolers 2B;
- ERCW flow to the 1B Control Rod Drive Vent Cooler.

The following components are in service:

- Train B ERCW yard header crosstie;
- Train B ERCW 16-inch Auxiliary Building header crosstie;
- Train B ERCW 6-inch Engineered Safety Features (ESF) header crossties.

For Unit 2 Train A One Pump Operation:

ERCW flow is isolated to the following components:

- 1A-A Diesel Generator Heat Exchangers;
- Unit 1 Containment Spray Heat Exchanger 1A;
- Unit 1 TDAFW Pump from the "1A" ERCW Main Supply Header;
- Lower Containment Vent Cooler 1A, Control Rod Drive Vent Cooler 1A, and Reactor Coolant Pump 1-1 Motor Cooler;
- Lower Containment Vent Cooler 1C, Control Rod Drive Vent Cooler 1C, and Reactor Coolant Pump 1-3 Motor Cooler;
- Incore Instrumentation Room Water Coolers 1A.

The following components are in service:

- Train A ERCW yard header crosstie;
- Train A ERCW 16-inch Auxiliary Building header crosstie; and
- Train A ERCW 6-inch Engineered Safety Features (ESF) header crosstie.

For Unit 2 Train B One Pump Operation:

ERCW flow is isolated to the following components:

- 1B-B Diesel Generator Heat Exchangers;
- Unit 1 Containment Spray Heat Exchanger 1B;
- Unit 1 TDAFW Pump from the "1B" ERCW Main Supply Header;
- Lower Containment Ventilation Cooler 1B, Control Rod Drive Vent Cooler 1B, and Reactor Coolant Pump 1-2 Motor Cooler;
- Lower Containment Ventilation Coolers 1D, Control Rod Drive Vent Cooler 1D, and Reactor Coolant Pump 1-4 Motor Cooler;
- Incore Instrumentation Room Water Coolers 1B.

The following components are in service:

- Train B ERCW yard header crosstie;
- Train B ERCW 16-inch Auxiliary Building header crosstie;
- Train B ERCW 6-inch Engineered Safety Features (ESF) header crossties.

During all conditions of operation, the discharge from the various heat exchangers served by the ERCW System will go to a seismically-qualified open basin with overflow capability and then flow by gravity to the return channel of the natural draft Cooling Towers of the CCW System.

The ERCW System piping is arranged in four headers (1A, 1B, 2A, and 2B) each serving certain components in each unit as follows: Note that use of the crossties described above may modify some of these descriptions.

1. Each header supplies ERCW to one of the two containment spray heat exchangers associated with each unit.

2. The primary cooling source for each of the diesel generator heat exchangers is from the Unit 1 headers. Each diesel also has an alternate supply from the unit 2 headers of the opposite train.

3. The normal cooling water supply to CCS heat exchangers 1A1 and 1A2, 2A1 and 2A2, and 0B1 and 0B2, is from ERCW headers 2A, 2A, and 2B, respectively.

4. Each A and B supply header in each unit header provides a backup source of feedwater for the turbine-driven auxiliary feed pumps in the respective unit.

5. Each of the two discharge headers provides a backup source of feedwater for the motor-driven auxiliary feedwater pumps in each unit.

6. Headers 1A and 1B provide ERCW cooling water to the Control Room and Control Building Electrical Board Room Air-condition Systems.

7. Each A and B header in each unit supplies ERCW cooling water to the Auxiliary Building ventilation coolers for safeguard equipment, the containment ventilation system coolers, the RCP motor coolers, the control rod drive vent coolers, and the containment instrument room cooler's water chillers in the respective unit.

8. Headers 1A and/or 1B provide an alternate source of cooling water for the station air compressors.

9. Headers 1A and 2B provide ERCW cooling water for the shutdown board room air-conditioners and auxiliary control air compressors.

10. Headers 2A and 2B provide ERCW cooling water for the emergency gas treatment room coolers and boric acid transfer and unit 2 auxiliary feedwater pump space coolers.

11. Headers 1A and 1B provide ERCW cooling water for the Component Cooling System pumps and Unit 1 auxiliary feedwater pump space coolers.

12. Under flood conditions, each header would provide water to the spent fuel pit heat exchangers, reactor coolant pump thermal barriers, ice machine refrigeration condensers, and sample heat exchangers, and the residual heat removal heat exchangers as needed.

The headers are arranged and fitted with isolation valves such that a rupture in any header can be isolated and will not jeopardize the safety functions of the other headers. The operation of two pumps on one plant train is sufficient to supply all cooling water requirements for the 2-unit plant for unit cooldown, refueling, or post-accident operation. However, additional pumps may be started, if available, for unit cooldown or refueling. Two pumps per train operate during the hypothetical, combined accident and loss of normal power if each diesel generator is in operation. In an accident the safety injection signal automatically starts two pumps on each train, thus providing full redundancy. Such an arrangement would assure adequate cooling water under both normal and emergency conditions. During single unit outages, one pump on each ERCW train can supply sufficient cooling water, subject to restrictions on the ultimate heat sink supply temperature.

The ERCW System design basis is for operation under the worst initial condition of operation. This condition is assumed to be the low probability combination of a design basis earthquake coincident with a loss-of-coolant accident in one unit, abrupt loss of the downstream dam, loss of emergency power train, shutdown of the other unit in hot standby and loss of all offsite power.

The ERCW pumps, their traveling water screens, screen wash pumps, and strainers are protected against the probable maximum flood level. The deck elevation 720 is above the probable maximum flood still water elevation of 719.6 and below the elevation including wave runup of 723.8, but it is protected from flooding by the outside walls. The traveling screen wells extend above the deck elevation and above the design basis surge level. The wall penetration for normal water drainage from the deck is below the design basis flood elevation, but it is designed for sealing in the event of a flood. All other exterior penetrations of the station below the probable maximum flood are permanently sealed. Redundant pumps are provided on the deck and in the interior rooms to remove rainfall on the deck and water seepage. All pump motors, screen motors, screen wash pump motors, sump pumps, and backwashing strainer motors are supplied with power from normal and emergency sources, thereby ensuring a continuous flow of cooling water under all conditions.

Since there are two independent power trains, four of the eight ERCW pumps will be assigned to train A (1A/2A) and four to train B (1B/2B). Likewise, two of the associated ERCW MCCs are assigned to train A and two to train B. Because the mechanical loads powered from each power train feed into a header/piping system that is shared among both units, there is no need to have unit separation on the associated power sources. The normal and alternate power source for each ERCW MCC are provided by the same train from each unit. Two each of the traveling screens, screen wash pumps, and strainers will be assigned to the power train corresponding to that of the ERCW pumps which this equipment serves.

9.2.2.3 Safety Evaluation

The ERCW is a two-train system, each train having the capability to provide the maximum required cooling water requirement for both units under any credible plant condition. These equipment trains are sufficiently independent to guarantee the availability of at least one train at any time. The system has been analyzed for "worst case" heat loads under combinations of maximum river water temperature, design basis accident conditions, normal cooldown requirements, power train failures, etc., for both units. It is found through these analyses that sharing of this system by the two nuclear units does not introduce factors that prevent the system from performing its required function for plant design basis condition. Sufficient pump capacity is included to provide design cooling water flows under all conditions and the system is arranged in such a way that even loss of a complete header or one supply source can be isolated in a manner that does not jeopardize plant safety.

The ERCW System has eight pumps (four pumps per train). However, minimum combined safety requirements for one "accident" unit and one "non-accident" unit, or two "non-accident" units, are met by only two pumps on one plant train. The A and B ERCW headers each have two pumps that are assigned to an emergency diesel generator on loss of offsite power. Total loss of one train, or the loss of an entire plant emergency power train will not prevent safe shutdown of either unit under any credible plant condition. Thus, sharing of the ERCW does not compromise safety relative to that of a unitized system.

The only single component carrying loads from two units is the CCS heat exchanger pair OB1/OB2 which serves the Train B safeguards (i.e., engineered safety features equipment) for both units. Should a single failure of this heat exchanger pair or connecting pipe result in the loss of both the B safeguard trains, the A safeguard trains are capable of unit cooldown independent of the B trains. In all other places where a single failure could affect both units, the other train will remain fully functional and is capable of supporting unit cooldown independent of the failed train.

Under extreme flood conditions, the ERCW System provides a heat sink for all closed cycle cooling systems required for this particular condition. The system is designed to continue operation during the post-flood condition in which the loss of the downstream dam has also been assumed.

The system is designed to furnish a continuous supply of cooling water under normal conditions, as well as under the following extreme circumstances:

1. Tornado or other violent weather conditions which might disrupt normal offsite power. The ERCW pumps are shielded from tornadic winds and missiles by the surrounding structure and have alternate feeds from the diesel generators which are housed in a structure also designed for these conditions. In addition, the pumps on power Train A are separated from those on Train B by walls on the pumping station deck.

2. Earthquake with or without failure of main river dams above and below the site. Safe shutdown is assured by designing the ERCW pumping station, ERCW pumps, ERCW station traveling screens and screen wash pumps, and associated piping and structures to Class I seismic requirements. The ERCW pumping station is designed and located so as to maintain direct communication with the main river channel at minimum possible water level resulting from loss of the dams.

   A pipe rupture in the non-seismically qualified ERCW piping located in the turbine building is of no consequence because the ERCW piping is normally isolated.

3. Probable Maximum Flood with the coincident or subsequent loss of the upstream and/or downstream dams. To meet this condition the ERCW pumps, traveling screens, and screen wash pumps are protected from the probable maximum flood by the ERCW pumping station. The 27-hour flood warning period provides a more than adequate time period for cooling water system alignment, even assuming an initial difficulty in opening one of the non-redundant, manually-operated, butterfly valves. The construction of these valves is such that a failure which could preclude manual operation is extremely unlikely. However, if this did happen, the valve installation is such that rapid replacement (within a few hours) or repair can be accomplished with a minimum of manpower and equipment. Once cooling flow is established and adjusted, operation of any non-redundant valve is not required. During flood mode operation, all active components of the ERCW supply are redundant, and can therefore tolerate a single failure in the short or long term. A passive failure, consistent with the 50 gal/min loss rate specified in FSAR subsection 3.1.1, can be tolerated for an indefinite period without interrupting the required flow. The ERCW System would not furnish feedwater to the steam generators during the probable maximum flood. This would be provided by the Fire Protection System (subsection 9.5.1), by the method described in subsection 2.4A.2.2. During flood mode operations a single line, conforming to the single failure criteria outlined in FSAR Section 3.1.1, supplies cooling water to the spent fuel pit heat exchangers.

The availability of water for the most demanding condition on the ERCW System is based on the following events occurring simultaneously:

1. Loss of offsite power
2. Loss of downstream dam
3. Loss of two diesel generator units serving the same power train.
4. Design basis earthquake

Diesel generators are used to supply power for the pumps and valves in case of loss of offsite power. The loss of two diesel generators means that cooling water must be supplied with two ERCW pumps operating through two headers on the same plant train. Under all plant conditions, the yard header cross-tie in the CCW Pumping Station may remain open. Within limitations based on the ultimate heat sink temperature, an ERCW train may remain operable with a strainer isolated for maintenance by use of this cross-tie. The two 6” ERCW ESF headers and also the two 24” main supply headers associated with the same train (i.e., 1A/2A) are also cross-tied in the Auxiliary Building. These crossties may be in or out of service with no restrictions. These cross-ties exist to facilitate maintenance and modification activities.

Certain combined modes of operation under the above circumstances are not within the design capability of the ERCW System. The modes that cannot be adequately supplied are simultaneously shutdown/cooldown of both units or one unit in shutdown/cooldown and the

other in a LOCA. In each of these situations a unit that is not in an accident mode can be maintained at hot standby, if necessary, until heat loads are low enough or if already shutdown, maintained in safe shutdown or allowed to return to hot standby depending on the heat load. The design maximum heat load rejected to the ERCW System occurs with one unit in an accident mode and the other hot standby. The availability of adequate ERCW flow to remove the maximum heat loads is periodically verified. If 2-unit shutdown is required, the cooldown time will be extended. A malfunction analysis for the ERCW System is presented in Table 9.2.2-2.

9.2.2.4 Incident Control

In order to preclude leakage of radioactivity from the containment, all supply lines to the containment are provided with double isolation by use of a check valve and motor-operated valve or two motor-operated valves on separate power trains. The discharge lines are double protected by use of two motor-operated valves operated on separate power trains.

Radiation detectors are installed in each discharge header at a point downstream of the last equipment discharge point and just prior to exit from the Auxiliary Building.

9.2.2.5 Instrument Applications

9.2.2.5.1 General Description

ERCW instrumentation and controls for equipment supplied for a particular ERCW main supply header are powered from the same electrical power source as the pumps which normally supply the water to that header. Therefore, loss of one power train would result in the loss of only the instrumentation and controls associated with one ERCW header. Motor operated containment isolation valves are arranged and powered such that isolation may be accomplished utilizing either one of the available power trains. The safety related display instrumentation for Post Accident Monitoring is discussed in Section 7.5. Auxiliary controls (see Section 7.4) are provided for all devices which are required for operation in the event of a Main Control Room evacuation.

9.2.2.5.2 Pressure Instrumentation

Pressure transmitters are provided on each ERCW pump discharge line and main supply header for displaying pressures locally and in the main control room, as well as actuating main control room annunciators for high and low pressure conditions. The screen wash pumps of the ERCW pumping station are manually operated during normal and accident conditions. The screen wash pumps and traveling screens of the ERCW are also exercised at regular intervals to maintain functionality and cleanliness. Screen wash pump discharge pressure switches are utilized to start the traveling screen motor when screen wash pressure has been established. Pressure and differential pressure indicators are provided for each ERCW strainer to locally monitor strainer pressure. Backwashing of the ERCW strainers during normal and accident conditions is performed manually. Local pressure test points are provided on the ERCW inlet and outlet of each air conditioner condensing unit.

9.2.2.5.3 Flow Instrumentation

Flow elements and transmitters are provided for each ERCW main supply header to display the flow rates. The ERCW flow rate through each containment spray exchanger is displayed in the

MCR. The ERCW flow rate through each CCS HTX pair can be determined from flow indicators displayed in the MCR. Local flow indicators are provided for the flow rate through the emergency diesel engine heat exchangers, each lower containment cooling header, and each upper containment ventilation cooler. Flow elements are provided in the discharge lines of all other coolers and heat exchangers for use during testing and system balancing.

9.2.2.5.4 Temperature Instrumentation

Two of four ERCW supply header temperatures are input to the plant computer, which is available in the main control room. Local temperature indicators are provided for the discharge from each emergency diesel engine heat exchanger and all air conditioner condensing units. Temperature test wells are provided on the inlet of each air conditioner condensing unit and the discharge side of each pump motor cooler, and control rod drive cooler. Temperature test wells are also provided in the inlet and discharge lines for all space coolers, room coolers, and upper and lower containment ventilation coolers, and in the main supply and return header.

9.2.2.5.5 Control Valves

All active ERCW air-operated and motor-operated valves whose positions are required to be known by the MCR operators have their open and closed positions displayed in the Main Control Room and/or Auxiliary Control Stations by means of lights incorporated either on the controlling hand switch, a valve status light subpanel, or motor control center. The position of motor-operated valves depowered for Appendix R are indicated by a rotating mimic position symbol. All air operated temperature and flow control valves are designed to fail open on loss of electrical power and/or operating air, thereby providing maximum ERCW cooling flow to the equipment being supplied.

ERCW is supplied to each upper and lower containment ventilation cooler. A throttle action type valve controlled by a non-safety related temperature indicating controller or manual valves are provided for controlling the flow through the associated cooling coils. Manual safety-related overrides to fail open the lower containment ventilation cooler valves are provided by means of hand switches in the Auxiliary Control Room and MCR.

ERCW is supplied to each control rod drive ventilation cooler. A throttle action type valve controlled by a temperature indicating controller is provided for the control rod drive ventilation cooler. Manual and/or automatic override to fully close the control valve is provided by means of a hand switch and/or logic signal.

ERCW is supplied to each air conditioner condensing unit through an automatic water regulating valve controlled by cooling coil pressure. ERCW is supplied to each additional cooler or heat exchanger through an on-off action type valve controlled by either a hand switch, a temperature switch, a manual valve, a logic signal, or various combinations of these.

9.2.2.6 Corrosion, Organic Fouling, and Environmental Qualification

TVA has determined that long-term operation of the plant could result in unacceptably high amounts of internal corrosion in carbon steel piping. This could have a severely detrimental effect on the ability of the system to supply adequate cooling water to all of the essential loads required for accident initiation. This problem has been resolved by implementing a periodic

surveillance test program to measure flows and by changing from carbon steel to stainless steel pipe as required to maintain adequate flow.

Control of organic fouling is provided by use of strainers in the supply headers and biocide treatments. Asiatic clams will be controlled by a combination of straining and biocide treatments. Microbiologically induced corrosion (MIC) will be controlled by injecting biocide.

Each supply header section (1A, 2A, etc.) is provided with a strainer (manual continuous backwash type) capable of removing particles and organic matter larger than 1/32-inch diameter. These strainers are located in the ERCW pumping station downstream of the ERCW pumps.

All pumps and valves exposed to atmospheric conditions are designed to operate under the most extreme climatic conditions of temperature, humidity, wind velocity, etc., that are expected to prevail in the southeastern United States.

9.2.2.7 Tests and Inspections

The completed piping system was hydrostatically tested prior to station startup. Components are designed for inservice inspection and testing in accordance with ASME B&PV Code, Section XI, Rules for Inservice Inspection of Nuclear Power Plant Components. All components, switchovers, starting controls, and the integral systems are tested periodically.

In accordance with Generic Letter 89-13, a continuing program will be maintained to perform periodic inspections of the ERCW intake structure for biological fouling mechanisms, sediment and corrosion. In addition, a continuing test/inspection program will be maintained to verify the heat transfer capability of all safety-related heat exchangers included in the GL 89-13 program.

9.2.2.8 Design Codes

The design codes for the ERCW piping, and components are given in Section 3.2.

9.2.3 Demineralized Water Makeup System

The Demineralized Water Makeup System is a non-safety related shared system serving both units.

9.2.3.1 Design Bases

The system is designed to supply the requirements for high purity water for makeup to the steam generators, the Primary Water System, and the Demineralized Water System for cask decontamination, cleaning, flushing, and makeup for miscellaneous services.

9.2.3.2 System Description

The system consists of two separate water treatment facilities and a demineralized water storage and distribution system. The original water treatment facility is housed within the turbine building and a newer water treatment facility is housed within a separate building located in the yard. The new facility has the capability to be supplied from a vendor.

Flow diagrams are shown in Figures 9.2.3-1 and 9.2.3-2.

1. Demineralized Water System - Turbine Building

   The demineralized water system located in the Turbine Building is no longer used as a means of high quality clarified water.

2. Demineralized Water Makeup System - Yard - South of Powerhouse

   The demineralized water makeup system outside of the Turbine Building is primarily housed in a single structure. It consists of a vendor system which supplies the TVA demineralized water storage and distribution system.

3. Demineralized Water Storage and Distribution System

   The demineralized water storage and distribution system is supplied by the demineralized water makeup systems located in the yard south of the powerhouse. It consists of a 10,000 gallon demineralized water tank (DI Head Tank), a 500,000 gallon demineralized water storage tank (DWST), a 15,000 gallon cask decontamination tank, main piping loop, pumps, and headers and valves. The loop supplies water for various services. The service includes supplying water to emergency showers, eye wash stations, laboratory sinks, cask wash down room, fuel transfer canals, and various tanks and equipment.

   The main piping loop is supplied from the demineralizer storage tank (DI Head Tank). Makeup water for the condensate storage tanks is supplied from the demineralized water makeup system located in the yard south of the powerhouse. Washdown water for the cask washdown room is supplied from the cask decontamination tank. Makeup for the primary water storage tank is supplied directly from the loop.

   Storage tanks and system principal piping material are aluminum except piping inside reactor containment which is stainless steel. The piping is TVA Class G or H except the reactor containment isolation valves and connecting piping which are TVA Class B.

9.2.3.3 <u>Safety Evaluation</u>

The Demineralized Water Makeup Systems are not required for maintenance of plant safety in the event of an accident and is not a part of the Engineered Safety Systems; therefore, the reactor containment isolation valves and the piping connecting the valves are the only portions of these systems which have a Nuclear Safety Class designation in accordance with TVA Classification B. There are no safety related implications due to sharing these systems between the two units.

All pipe hangers and supports in the Control Building, Auxiliary Building, and Reactor Buildings are designed for seismic loading to prevent damage to adjacent safety-related equipment necessary for the safe shutdown of the plant in case of a nuclear accident.

9.2.3.4 Test and Inspection

Prior to startup all piping and equipment was tested. After startup routine visual inspection of the system components and instrumentation is adequate to verify system operability.

9.2.3.5 Instrumentation Applications

Instrumentation is provided for the new treatment plant operation and to maintain storage tank levels.

High and low water levels in both the demineralized water (DI Head Tank) and cask decontamination tanks are alarmed in the Main Control Room.

9.2.4 Potable and Sanitary Water Systems

9.2.4.1 Potable Water System

9.2.4.1.1 Design Bases

The purpose of this system is to furnish potable water to all potable water usage points.

The initial quantity of potable water required was approximately 20,000 gallons to fill two-10,000 gallon storage tanks in the Turbine Building and the system piping. The average daily requirement varies according to plant operation and fluctuations in the plant personnel population. The potable water supply source is a local public utility district. This arrangement accommodates a wide fluctuation in the daily usage of potable water.

9.2.4.1.2 System Description

TVA has contracted with the Hixson Utility District to supply potable water to the Sequoyah Nuclear Plant. This utility district water system is classified as an approved system by the Tennessee Department of Public Health and Environment.

Static pressure at the plant site is reduced before distribution and is further reduced at several points in the system. The potable water supply flows by utility pressure to the two-10,000 gallon storage tanks in the Turbine Building. The Yard Distribution System conveys potable water to the various buildings and to other points of usage.

Most fixtures are supplied from a return line from the storage tanks to prevent depleting the chloride residual in the tanks. Other fixtures which are remote from the return line are supplied by the supply line to the storage tanks.

There are no potable water lines in the Reactor Building.

9.2.4.1.3 Safety Evaluation

To insure against plant contamination of the Hixson Utility District, a backflow prevention valve is installed at the point where the Sequoyah Potable Water System connects with the Hixson Utility District. Backflow preventers are also installed at various points in the plant system as required. Potable water lines are sterilized before use.

Potable water lines that extend into the Auxiliary Building to serve the battery rooms have shutoff valves in the Control Building. These lines are run under the control room area to prevent damage in case of a ruptured line.

The radiochemical laboratory, the hot instrument shop, and the titration room sinks in the Auxiliary Building are supplied potable water from a valved connection in the Service Building.

Potable water fixtures in the Control Building are supplied potable water from a valved connection in the Turbine Building.

There are no safety-related implications due to sharing this system between the two units.

9.2.4.1.4 Tests and Inspections

All Potable Water Systems are initially pressure tested. Routine maintenance is provided as needed. Where piping is in walls, the tests are made prior to erection of masonry walls. Fixtures are accessible for inspection during normal operation.

9.2.4.1.5 Instrumentation Applications

Water supply flow to the two potable water storage tanks is controlled by a flow control valve located near the tanks and actuated by level switches. Level control switches on one tank actuate an alarm in the turbine building on high and low level in the tanks.

9.2.4.2 Sanitary Water System

9.2.4.2.1 Design Bases

The maximum quantity of sanitary water to be handled, treated and disposed of, or pumped offsite is approximately 70,000 gallons per day.

The Sanitary Water Treatment System is an aerobic treatment system. Sewage collected onsite can be pumped offsite to the Soddy-Daisy regional or Moccasin Bend sewage treatment systems.

System design and construction meets the requirements of the Tennessee Department of Health and Environment.

9.2.4.2.2 System Description

Sewage is processed by:

a) septic tank / drain fields
b) septic tank / evapotranspiration fields
c) the Soddy-Daisy sewage treatment facility
d) the Moccasin Bend sewage treatment facility, and
e) the existing SQN sewage treatment facility.

Sewage to be sent offsite to the Soddy-Daisy or Moccasin Bend treatment facilities is monitored for radioactivity. Should abnormal levels of radioactivity occur this sewage will be processed through the existing onsite treatment facility.

9.2.4.2.3 Safety Evaluation

Containment is provided on the sanitary water drain between the Auxiliary Building and the Control Building by means of a running trap inside the Auxiliary Building. Potable water drips in the trap to keep it full at all times. A needle valve is used to control the flow of water. All plumbing fixtures and water coolers are installed with a trap in the drain line or an integral part of the fixture when connected to sanitary drains.

These traps prevent fumes, odors, or gases from coming back through the fixtures.

9.2.4.2.4 Tests and Inspection

All embedded lines and fittings were tested for leaks while still exposed.

The sanitary water system has no physical connections with any radwaste systems; however, the raw sanitary water discharge from the various site facilities is periodically sampled at selected points and tested for the presence of potential radiological contamination. Sampling frequency and sampling/testing methods are established in accordance with approved plant procedures. The results of these tests are reported periodically to the cognizant regulatory agencies.

9.2.4.2.5 Instrumentation Applications

Level switches are provided at pumping stations for control of pumps and alarms.

9.2.5 Ultimate Heat Sink

The ultimate heat sink (subsequently referred to as "sink") for a nuclear plant is that complex of water sources and associated retaining structures used to remove waste heat from the plant. The sink used in the initial operation of Sequoyah Nuclear Plant was modified early in plant life when a new, independent Essential Raw Cooling Water (ERCW) pumping station was made effective (for details see Section 9.2.2). Throughout the plant's life, the sink is designed to perform two principal safety functions: (1) dissipation of residual and auxiliary heat after reactor shutdown, and (2) dissipation of residual and auxiliary heat after an accident.

9.2.5.1 Design Basis

The sink was designed to comply with the regulatory position in NRC Regulatory Guide 1.27 Revision 0, dated March 23, 1972, and stated below:

1. The ultimate heat sink[1] should be capable of providing sufficient cooling for at least 30 days (a) to permit simultaneous safe shutdown and cooldown of all nuclear reactor units that it serves, and maintain them in a safe shutdown condition, and (b) in the event of an accident

in one unit, to permit control of that accident safely and permit simultaneous safe shutdown and cooldown of the remaining units and maintain them in a safe shutdown condition. Procedures for assuring a continued capability after 30 days should be available.

[1]The ultimate heat sink is that complex of water sources, including associated retaining structures, and any canals or conduits connecting the source with, but not including, the intake structures of nuclear reactor units. If cooling towers or portions thereof are required to accomplish the sink safety functions, they should satisfy the same design requirements as the sink.

2. The ultimate heat sink should be capable of withstanding the effects of the most severe natural phenomena associated with this location, other applicable site related events, reasonably probable combinations of less severe phenomena or events where this is appropriate to provide a consistent level of conservatism, and a single failure of man-made structural features without loss of the capability specified in regulatory position 1 above.

3. The ultimate heat sink should consist of at least two sources of water, including their retaining structures, each with the capability to perform the safety function specified in regulatory position 1 above unless it can be demonstrated that there is an extremely low probability of losing the capability of a single source. There should be at least two canals or conduits connecting the source(s) with the intake structures of the nuclear power units, unless it can be demonstrated that there is extremely low probability that a single canal can fail entirely from natural phenomena. All water sources and their associated canals or conduits should be highly reliable and should be separated and protected such that failure of any one will not induce failure of any other.

4. The technical specifications for the plant should include actions to be taken in the event that conditions threaten partial loss of the capability of the ultimate heat sink or if it temporarily does not satisfy regulatory positions (1) and (3) above during operation.

9.2.5.2 Safety Evaluation

This safety evaluation, is sectionalized to correspond with the points of the preceding regulatory position.

1. The cooling water requirements for the most demanding accident shutdown and cooldown of the plant's reactors are presented in subsection 9.2.2. The adequacy of the Tennessee River to provide this amount of water, and therefore to satisfy regulatory position (1) is confirmed in subsections 2.4.11.1 and 2.4.11.3.

2. Under the most adverse events expected at the site or a reasonable combination of less severe events and any single failure of a man-made feature, the sink is designed to retain its capability to perform the specified safety functions. The most severe natural phenomena (including flood, drought, tornado, wind, and earthquake) conceivable to occur at this site are thoroughly discussed in Chapter 2. The new ERCW pumping station provides ERCW for both normal and emergency plant conditions. With the new ERCW station in operation, the sink's safety functions are insured for all of the plant design basis events, including those extreme natural phenomenon credible to occur at this site.

As stated previously, the ERCW pumps are protected from the design basis flood including the effects of wind waves, and therefore they will be capable of functioning in all flood conditions up to and including the design basis flood (see subsection 9.2.2). The water intake to the ERCW pumping station and the area outside the station intake was dredged to form a channel that will provide free access to the river. This channel was dredged to a sufficient width eliminating the possibility of channel blockage due to an earth- or mud-slide. The channel will be monitored and dredged as required to maintain free access to the river. Therefore, adequate water will be available to the ERCW pumps at all times including the loss of downstream dam for any reason. The unlikely occurrence of the SSE could significantly affect the sink only by causing failure of the downstream dam and/or upstream dams. For the resulting low and/or high water event, water will be available to the intake at all times. A seismically induced disturbance of the rock surfaces could only block a small percentage of the intake channel due to its highly conservative width. Also, a tornado cannot interrupt the ERCW supply to the station.

For an evaluation of barge impact and explosion hazards see subsection 2.2.3.

TVA regulation of the Tennessee River is such that drought will not jeopardize the sink's capability required in regulatory position 1; this is historically confirmed by the data in subsection 2.4.11.3.

The sink is designed to withstand a 95 mph basic wind or the most severe tornado, including the associated missile spectrum, without loss of the capability to provide an adequate supply of cooling water to the Essential Raw Cooling Water System.

The most severe combination of events considered credible to the heat sink would be the simultaneous occurrence of the SSE, and loss of downstream dams with water temperature at 87°F. Under this extreme situation, the sink retains the capability of regulatory position (1). The sink provides water to the ERCW system as described in Section 9.2.2.

Refer to subsection 2.4.11.6 for additional discussion of the requirements for maintaining sink dependability.

3. The Tennessee River is the common supply for all plant cooling water requirements. Total interruption of this supply is incredible. Additionally, the integrity of the river's dams is not essential for safe reactor shutdown and cooldown.

4. The limiting conditions and surveillance requirements for the ERCW System are given in the SQN Technical Specifications. The limiting conditions for the plant's flood protection program are also given in the SQN Technical Requirements Manual.

9.2.6 Condensate Storage Facilities

9.2.6.1 Design Bases

The condensate storage facilities handle treated water and are designed to provide (1) water for initial charging of the secondary system, (2) makeup water when water treatment plant is being regenerated, or is out of service, (3) water to replace that lost from the system by safety valve or relief valve operation, and (4) an adequate quantity of water for emergency cooling (Auxiliary Feedwater System).

9.2.6.2 System Design Description

The condensate storage facility has two site fabricated condensate storage tanks ('A' and 'B') each with a minimum as-designed capacity of 385,000 gallons.

The condensate storage tanks are connected to the condenser hotwell and hotwell pumps discharge for the addition and dumping of water, respectively, to maintain water inventory in the secondary system. Storage tank level is maintained by makeup from water treatment plant.

The condensate storage tanks provide the primary source of water for the auxiliary feedwater pumps. A minimum usable level of 240,000 gallons is required per the technical specifications for an operable tank (see Section 10.4.7.2).

The condensate storage tanks are made from ASTM A 283 carbon steel plate with inside coating of epoxy-phenolic resin to prevent corrosion. Connections are available on the storage tanks and in the condensate system for introducing low-pressure nitrogen into the tanks for purging the tanks of air (i.e. oxygen). The tanks are constructed to AWWA Standard D100 for steel tanks. Pressure relief and vacuum venting is provided.

9.2.6.3 Safety Evaluation

The condensate storage tanks are the primary source of clean water supply for the auxiliary feedwater pumps, and a storage reservoir for secondary system water. The tanks are nonsafety class tanks.

Two additional sources of water supply are provided for the Auxiliary Feedwater System. Interconnections with the ERCW (safety class 2b) are made in the AFW suction piping to the pumps, and fire protection (nonsafety class) provides a direct source to the steam generators for flood mode operation. Safety is the principal consideration whereas the cleanliness of the steam generator is of secondary importance.

Protection for the Condensate Storage Tanks from tornado wind driven missiles is provided to the extent described in Subsection 3.5.2.22. There is no physical separation barrier between the tanks. The AFW suction piping originates inside each tank and then continues into the Turbine Building in a pipe trench covered with removable steel covers. The piping from the tanks and in the Turbine Building are seismically qualified to the requirements of Design Criteria SQN-DC-V-48.0. The water in this tank is not normally radioactive. However, in the event of a steam generator tube leak, this tank will become radioactive by way of the condensate system. The maximum level of contamination in the condensate storage tank would be comparable to that of the main condenser (Subsection 10.4.1).

A tank rupture would allow the water to be drained to the turbine building sump or to the river by way of the holding pond. The radiological consequences of this are less than other postulated accidents discussed in Chapter 15. The tanks are located in the plant yard adjacent to the south wall of the turbine building. Ice formation in the tanks can be prevented, if necessary, by recirculation of water through the condensate transfer pumps. Tank instrumentation is insulated and heat traced for freeze protection.

Tank repairs necessitated by damage or leaks can be made after closing the defective tanks isolation valves in the interconnecting headers, and transferring water from the defective tank to the other storage tank using the condensate transfer pumps. Excess water can be drained to waste through normally locked tank drain valves to the yard drainage system.

9.2.6.4 Tests and Inspections

The condensate storage tanks are tested during the pre-operational test program for both the condensate system and the Auxiliary Feedwater System.

9.2.6.5 Instrument Applications

The level of each storage tank is indicated on Units 1 and 2 main control boards and on a local panel in the area of the transfer pumps. These level signals are received from electronic level transmitters which also provide the signals for the annunciation in the main control room of an abnormal tank water level. Each tank is equipped with side-mounted displacement type level switches which provide a signal for annunciation in the main control room. The set point for these switches will be set outside the high and low set points of the electronic level switch and will be used as a backup for them. Continuous tank level indication is provided locally at each tank.

9.2.7 Raw Cooling Water System

The Raw Cooling Water System is a shared system serving both units. See Table 9.2.7-1 for pump design data.

9.2.7.1 Design Basis

1. The Raw Cooling Water System is capable of supplying the flow requirements of the equipment it serves during the full range of operation, at a maximum temperature of 84.5°F. The components listed in Section 9.2.7.2 may operate in reduced capacity at 87°F, if excess raw cooling water is not available.

2. The system will not function during maximum flood; therefore, provisions are made for a cross-connection to the ERCW System for cooling water to the package chillers in the Auxiliary Building if this condition occurs.

3. The system will not be available during a loss of offsite power condition.

4. All piping and valves of this system in Class I structures shall be seismically supported to the extent that they are prohibited from becoming missiles to equipment of other systems.

9.2.7.2 System Description

The Raw Cooling Water System, shown on Figures 9.2.7-1 through 9.2.7-4, furnishes cooling water to the following:

1. Turbine oil heat exchangers.
2. Generator stator heat exchangers.
3. Generator hydrogen heat exchangers.
4. Feedwater turbine heat exchangers.
5. Generator exciter heat exchangers.
6. Electrical bus heat exchangers.
7. Electrohydraulic control heat exchangers.
8. Vacuum priming pump seal water makeup.
9. Water treatment plant makeup.

10. Condenser vacuum pump heat exchangers.
11. Package chillers.
12. Hydrogen seal oil heat exchangers.
13. Injection water pumps.
14. Pumps and other miscellaneous equipment.
15. Station air compressors

The system consists of pumps, strainers, and associated valves and piping. The raw water strainers and pumps are located in the Turbine Building. River water from both condenser circulating water intake conduits is supplied to the strainers through a 36-inch manifold which is common to Units 1 and 2.

Units 1 and 2 have a common strainer manifold and pump suction manifold, with an isolation valve on the strainer supply manifold at each CCW conduit interface.

Control of organic fouling is provided by use of strainers in the supply header and biocide treatments. Asiatic clams and zebra mussels are controlled by a combination of straining and biocide treatment. Microbiologically induced corrosion (MIC) is controlled by injecting biocides.

All raw cooling water pumps discharge into a common loop header in the Turbine Building. Sectionalizing and isolating valves are provided in the loop header to allow for isolating segments of the system for maintenance without removing the system from service and to provide for increasing velocity and/or reversing flow to flush Asiatic clams and sediment from the headers. Flush lines are returned to the condenser circulating water discharge conduits.

Four strainers are provided for the two units. Three are required for the designed capacity, and one is a common spare. Five raw cooling water pumps are provided with one being a common spare. Peak summer river temperatures may require the operation of all the pumps and strainers. Isolation valves are located to permit maintenance at all pumps, strainers, and heat exchangers.

9.2.7.3 Safety Evaluation

The Raw Cooling Water System is not required for maintenance of plant safety in the event of an accident; therefore, there are no safety-related implications due to sharing this system between the two units.

9.2.7.4 Test and Inspections

All system piping and components are hydrostatically tested prior to station startup and are accessible for periodic inspection after startup.

9.2.7.5 Instrument and Controls

The strainers are monitored by a pressure differential switch which actuates an alarm locally and in the Main Control Room to indicate when the strainers need backwashing. The pressure differential is between the strainer inlet and outlet manifolds.

The pump suction header pressure is monitored by a pressure switch that operates a low pressure alarm in the Main Control Room, thus denoting impending pump cavitation.

The five pumps, including one spare, are common to both units and are designated A, B, C, D, and E. They can be controlled locally or from the main control room, the control room being the normal point of operation. Electrically the pumps are arranged for alternate usage and thus to equalize wear.

Pumps are put into operation as required to maintain discharge header pressure and one of the non-operating pumps may be selected for standby to start automatically when the discharge header pressure drops to a preset level.

Two of the cooling water control loops (turbine oil and generator hydrogen coolers) may be controlled from the main control room by temperature indicator controllers. These two control loops are contained within the plant Distributed Control System (DCS). These controls are needed during startup to change the viscosity of the turbine lubricating oil and to adjust the generator heat removal.

Temperature indicators and test wells are installed at the cooling water inlets and outlets of the various heat exchangers for operation and testing.

Flow meter orifice flanges are installed in the cooling water discharge supply to many of the heat exchangers for use in heat balance and performance tests.

COMPONENT COOLING WATER SYSTEM
MALFUNCTION ANALYSIS

Component	Malfunction	Comments and Consequences
1. Pump	Rupture of a pump casing	Isolate pump and start redundant pump. Minimum requirements need only 3 out of 5 pumps.
2. Pump	Pump fails to start	Start other pump. One pump will supply sufficient flow for one operating unit except for startup and shutdown. For these modes the SFP load must be transferred to the unit with two operating pumps. Two pumps are aligned with each unit.
3. Pump	Manual valve on a pump Suction line closed	This will be prevented by prestartup and operational checks. Further, during normal operation each pump will be monitored by suction and discharge pressure readings which will indicate if pump flows are sufficient. If valve cannot be opened use other pump.
4. Pump	Isolation valve on discharge line closed or check valve sticks closed	Same as Item 3.
5. Heat exchanger	Tube, shell or plate rupture	Isolate and valve in spare exchanger.
6. Heat exchanger vent or drain valve	Left open	This will be prevented by prestartup and operational checks. On the inservice cooling water heat exchanger such a situation would be readily assessed by makeup requirements to system. On the out-of-service cooling heat exchangers such a situation would be assessed during periodic testing.

MALFUNCTION ANALYSIS

Component	Malfunction	Comments and Consequences
7. Engrg safeguard cooling header	Header or pipe rupture	Isolate and valve in backup cooling loop. Each cooling loop provides 100 percent capacity to sustain a LOCA. If the pipe rupture occurs during a normal unit shutdown when both safeguard cooling headers are in operation, cooldown will continue at a reduced rate to extend the cooldown time period.
8. Miscellaneous equipment cooling header	Header or pipe rupture	Isolate and repair. All equipment supplied by the cooling water header can be removed from service, since none is associated with safeguard functions.
9. CCS pump	Loss of power to pump	Use spare pump.

9.3 PROCESS AUXILIARIES

9.3.1 Compressed Air System

9.3.1.1 Design Basis

The Compressed Air (CA) System is common to both units and is divided into two subsystems; the Station Control and Service Air (SCSA) System, and the Auxiliary Control Air (ACA) Systems for emergency use. The SCSA System is designed to supply adequate compressed air capacity for general plant service, instrumentation, testing, and control. Breathing Air Stations (BAS) are provided for personnel working in airborne contaminated environments. The BAS are temporarily connected to the service air portion of the SCSA System when in use. Each ACA System supplies air to the Essential Air Distribution System of Units 1 and 2. The ACA systems ensure that vital equipment requiring control air will have a continuous air supply under design basis conditions, including safe shutdown earthquake and maximum possible flood.

9.3.1.2 System Description

SCSA System

Station control and service air is supplied by two motor-driven reciprocating compressors, two motor-driven centrifugal compressors, and one motor-driven rotary screw compressor. The system includes normal accessory equipment such as cylinder cooling equipment, aftercoolers, and safety relief valves. Refer to Figures 9.3.1-1 and 9.3.1-2.

The four station control air compressors and one dedicated service air compressor discharge into two redundant headers which are provided with manual isolation valves. These headers feed the two control air receivers which in turn supply air through redundant headers to the control air station. The control air station contains three complete trains of prefilters, dryers, and afterfilters.

Manual bypasses are provided around each dryer train element for emergency operation. The control air is then piped through headers to valves, controllers, instruments, etc. throughout the plant.

Service air is supplied to the service air receiver by a single header and by the single rotary screw compressor, and is not processed through dryers and filter trains as is done for the control air. Service air is supplied through a pressure control valve which closes if control air pressure drops below a specified set point, thus ensuring that control air requirements take precedence over service air requirements. Service air is piped from the receiver to service outlets and miscellaneous equipment throughout the plant.

ACA System

Auxiliary control air is supplied by two motor-driven, nonlubricated, single stage, reciprocating compressors. Each compressor is sized to supply one ESF train the total safety-related control air requirements of both units in the event of an accident, flood, or loss of the SCSA System. The ACA System is separated into two independent trains each containing its own compressor,

aftercooler, receiver, dryer, and filters. Manual bypasses are provided around each dryer train for emergency operation and to facilitate dryer maintenance. The auxiliary control air piping is arranged so that the auxiliary receivers are charged from the nonqualified SCSA System during normal operation. Electric power for the auxiliary systems is provided from both normal and emergency sources. The ACA System components located in Class I structures are designed to Class I seismic requirements, except for the piping and components downstream of the moisture traps and moisture trap bypass valves which are designed to Class I (L) requirements. The ACA System is Class IE except for the air dryers. The ACA system is automatically isolated from the SCSA System upon loss of air from the SCSA system. Refer to Table 9.3.1-1 for ACA design information and Figure 9.3.1-3.

SCSA and ACA Systems

The dryer and filter trains for both the Station Control and Service, and Auxiliary Air Systems are designed to give compressed air of high instrument quality. The prefilters are designed to remove liquid water entrainment and other foreign matter from the compressed air stream. The air dryers dry the air to a sufficiently low dewpoint. The discharge of the dryers is routed through an afterfilter which removes particles of desiccant and other foreign matter. The air quality and dew point are tested in accordance with periodic instructions.

9.3.1.3 Safety Evaluation

SCSA System

The SCSA System is designed to provide a highly reliable source of compressed air for plant uses. The station control and service air compressors are powered from diverse electrical sources. Two compressors are powered from the Turbine Building common board, two from shutdown boards, and the other from the Hot Shop Low Voltage Switchgear Board. The CA System contains sufficient receiver capacity to supply air for a short period of time. The loss of all station control and service air compressors would result in the shutdown of both units after this reserve is expended. Loss of system pressure from an accident such as a pipe break would result in the shutdown of both units if the break was not manually isolated before system pressure falls below minimum operating level. At this point, the ACA Systems would provide air to the essential components for safe shutdown.

The control air dryers are divided into three independent units (with two normally in service) each containing a prefilter, dryers, and afterfilter. The control air dryer station is arranged such that any component can be bypassed if necessary, or components of both can be used to make a complete unit.

The SCSA System compressors and dryer units are located on elevation 685.0 in the Turbine Building. This area is not a Class I structure and is below plant grade. Therefore, the SCSA System must be considered inoperable during (or after) a seismic event and flooding above plant grade.

The SCSA System has no safety-related requirement. It normally supplies air to both trains of the ACA System but is automatically isolated from the SCSA System when the air pressure reduces below an acceptable value.

A HELB in containment could result in a consequential break in the SCSA piping. A consequential failure of the SCSA piping inside containment along with a failure to close of the SCSA outboard CIV results in a SCSA leak to the containment.

In the event of the above described accident scenario, operators isolate the SCSA leak on the accident unit by either manually closing a valve upstream of the stuck open CIV or by shutting down the station air compressors. If the station air compressors are shutdown prior to performing an emergency shutdown of the non-accident unit or if an operator error results in an isolation of the control air supply to the non-accident unit, then at-worst, a SAR Condition II event is induced on the non-accident unit.

ACA Systems

The ACA systems are two independent subsystems located on elevation 734.0 of the Auxiliary Building. This is a seismic Class I structure and above maximum possible flood elevation. The two independent auxiliary systems are powered from separate emergency electrical power sources to prevent a single failure or power loss rendering the system inoperable.

The ACA Systems are designed to Class I seismic requirements (except for the piping downstream of the moisture traps and moisture trap bypass isolation valves which is Class I {L}). A single failure cannot render both systems inoperable since they are completely separated.

The auxiliary compressors start automatically upon loss of air from the SCSA System for any reason at a predetermined pressure. The ACA System is automatically isolated from the SCSA System whenever the system pressure falls below a designated pressure. The ACA System is sized and equipped so that ample system capacity is provided for both units under all design basis accident conditions. Redundancy and train separation has been provided in the ACA System to the extent that no initial “design basis event” followed by an arbitrarily selected “single active failure” will prevent the system from performing its necessary safety functions.

Air cylinders, accumulators, and regulators are provided for the steam-driven auxiliary feedwater pump level control valves. These allow the valves to be manually closed during a total loss of all offsite and onsite alternating current power (excluding vital instrument power). The same air cylinders provide a backup manual air source for the turbine driven and motor driven auxiliary feedwater pump control valves that are located inside the West Valve Vault (steam generators 1 and 4).

Air cylinders located above maximum postulated flood level separate from the accumulators are connected to ACA tubing in order to provide the steam-driven auxiliary feedwater pump level control valves and steam generator loop 2 & 3 atmospheric relief valves with compressed air for backup manual control. A safety related TVA Class C 3-Way valve isolates the backup manual control equipment from normally operating ACA system and therefore these air cylinders and associated instrumentation do not affect design basis functions of any other systems.

The auxiliary control air compressor's suction is taken from a nonfiltered area. Calculations were performed to verify that the amount of radioactivity introduced into the main control room habitability area during an accident condition is not significant.

The ACA Systems ensures plant safe shutdown and accident mitigation assuming a failure of the SCSA System and a single failure on one redundant train of the ACA System.

9.3.1.4 Tests and Inspections

All system components were tested prior to plant operation both under normal conditions and simulated accident conditions. Periodic tests are performed to ensure proper operation of the ACA System and isolation valves.

In accordance with Generic Letter 88-14, routine air quality testing and set point verification of moisture elements in the ACA and SCSA Systems are performed.

9.3.1.5 Instrumentation Applications

SCSA System

Local indication is provided at various points in the system for temperature, pressure. Pressure indication is provided in the MCR. Audible alarms are produced in the main control room for low

compressor oil pressure, high oil temperature, and high air pressure for each of the four SCSA compressors. Closure of the service air isolation valve is also annunciated in the control room.

ACA Systems

The auxiliary air compressors are started upon loss of air pressure from the SCSA system. Local position lights give indication upon closure of isolation valves between the SCSA and ACA Systems. Audible alarms are produced in main control room for compressor high air temperature, compressor low oil level, high dewpoint of control air, and low control air pressure. There is local indication of air pressure at various points and in the MCR. The safety-related display instrumentation for Post Accident Monitoring is discussed in Section 7.5.

9.3.2 Process Sampling System

9.3.2.1 Design Basis

The sampling system is designed to obtain samples from the various process systems in each of the two units. The samples are obtained in the secondary chemistry sampling facility, hot sample room, post accident sampling facility, condensate demineralizer building, and locally (grab samples) for laboratory analysis. The waste gas analyzer also obtains samples see Section 11.3. This system has no safety-related functions (except as necessary for containment isolation, SG isolation, etc.). During a Loss-of-Coolant Accident (LOCA), this system is isolated at the containment boundary for these samples which originate within containment. Sampling system discharges are designed to limit flows under normal operation and anticipated malfunctions or failure to preclude any fission product release in excess of the limits stated in 10 CFR 20.

9.3.2.2 System Description

The sampling system consists of the following types of collection areas and equipment:

1. The hot sample room where primary side and steam generator blowdown samples are routed for grab sampling and online analysis. Radioactive grab samples are taken to the radiochemical laboratory for analysis. Selected variables will be monitored by Chemistry in order to detect any that exceed established limits.

2. Local grab samples may be taken throughout the plant for detailed chemical and radiochemical analysis.

3. The Gas Analyzer System monitors the Gaseous Waste Disposal Decay Tanks for hydrogen and oxygen concentrations in a nitrogen atmosphere. The concentrations are indicated and alarmed at the analyzer and waste disposal panel 0-L-2A.

4. Secondary chemistry lab where online Condensate and Feedwater system samples are processed for automatic analysis of several variables such as pH, conductivity (specific and cation), etc.

The liquid sampling system is operated manually throughout the full range of power operations. All sample lines originating within containment have air-operated or solenoid isolation valves near the sample point and inside and outside containment for containment isolation. All sample lines originating outside containment have manual isolation valves, except the volume control tank vent and RHR miniflow lines which have air-operated or solenoid isolation valves. All air-operated or solenoid isolation valve handswitches are located on a wall panel at the hot

sample room. Each sample line to the secondary chemistry lab or hot sample room cubicles has a pressure, a temperature, and a flow indicator. An auxiliary feedwater pump start will close the steam generator blowdown (SGB) isolation valve and the SGB 1 thru 4 sampling isolation valves. Sample lines, whether local or in a sample room have pressure throttling valves and heat exchangers (if required).

SGB samples are rough cooled using RCW in the 690' elevation penetrations room. Local sample stations there will allow the plant to conduct corrosion products monitoring analysis or other local sample operation.

To ensure a representative sample is obtained, sample takeoff points are on or above the centerline of horizontal pipes. Prior to collecting a sample, each sample line is purged according to sample line length and diameter to ensure a representative sample is obtained. The sample volume is dependent on the chemical analysis to be run.

Sample locations are listed in Table 9.3.2-1 for the safety related systems giving the sampled system, sample location, sample type (local, secondary chemistry sampling facility, hot sample room, or gas analyzer). Sufficient secondary side sampling capability exists to ensure secondary side and SG water quality requirements. All sampling lines attached to TVA class A or B systems are class B from the root valve to (but not including) the sampling station, or through the first normally closed valve, or through the second containment isolation valve. Sampling lines attached to TVA class C or D systems are class C from the root valve to (but not including) the sample station, or through the first normally closed valve. Lines and valves forming a part of primary containment isolation are TVA class B. All remaining sample lines are TVA class G or TVA class H. The sample piping and equipment, where applicable, meets the following codes:

a. NEMA SG-5 and IC-1

b. ASME Boiler and Pressure Vessel Code, Section III (applicable sections) and Section IX (applicable sections)

c. ANSI B31.1, B31.7, and B16.5

d. IEEE

e. ASTM

f. SAMA PUB19 and PMC20-2-1970

g. National Electric Code (NFPA 70 ANSI C1)

The hot sample room cubicles must be able to withstand a 1.0 g horizontal force to ensure their stability during a seismic event. Also, the hot sample room cubicle entry block valves meet ASME Section III, Code Class 2, Paragraph NC-3676, with applicable "N" stamp.

The reactor coolant hot leg samples have the capability of being taken during a maximum flood condition.

9.3.2.3 <u>Safety Evaluation</u>

All sample lines have the required indicators, pressure throttling valves, heat exchangers, etc., to ensure plant operator safety when collecting samples.

The hot sample room has the following special safety features (due to handling primary loop samples):

a. For normal operations, samples lines from the RCS hot legs contain a delay coil to provide 40-second sample transit time within containment plus a 20-second transit time from containment to the hot sample cubicles (allows for decay N-16).

b. Hot sample room Cubicles 1A and 2A contain the most highly radioactive fluids. Cubicles 1A and 2A have a 2-inch lead shield behind the front plate of the cubicles. Sample lines to these sinks are equipped with stainless steel sample cylinders.

c. All cubicles are designed to permit collection of a sample behind a shatterproof glass window.

d. All cubicles have individual exhaust hoods and fans equipped with HEPA filters.

e. All entry block valves meet the ASME Section III Code (described in Section 9.3.2.2).

The presence of high pressure and temperature sample lines outside reactor containment is not hazardous because of their limited flow capacity and nonessential nature.

9.3.2.4 Tests and Inspections

Test for this system, covered by the preoperational testing program, were performed before initial plant startup. Periodic inspection and maintenance will be performed after plant operation begins to ensure proper operation of sampling system equipment.

9.3.2.5 Instrumentation Applications

On-line analysis equipment includes the gas analyzer, and the automatic analyzers and/or recorders (conductivity, pH, cation conductivity, sodium, hydrazine, dissolved oxygen) located in the secondary chemistry lab, condensate demineralizer building, and hot sample room sample cubicles as applicable.

9.3.3 Equipment and Floor Drainage System

9.3.3.1 Design Bases - Auxiliary Turbine and Reactor Building

Within the Reactor and Auxiliary Buildings, equipment drains and floor drains were originally designed so that tritiated liquids (defined as liquids whose tritium concentration is 10 percent or more of the reactor water tritium concentration) could be handled separately from nontritiated liquids, insofar as practical. However, segregation of the liquids is not required for processing or recovery.

Equipment drains and floor drains are routed to collector tanks in which the liquid can be held pending further treatment.

Turbine Building drains are collected in the Turbine Building sump or discharged directly to various ponds or CCW discharge. Non-radioactive raw cooling water booster pump skid drains, SGB sample panel drains, and auxiliary feedwater pump leakoff drains are also collected in the Turbine Building sump. The sump level is controlled by a high-low level switch which energizes the sump pumps.

The sump effluents can be routed to the CCW discharge or the yard drainage pond or the low volume waste treatment pond. Oil and chemical wastes are similarly collected and disposed of in an approved manner.

9.3.3.2 System Design - Auxiliary and Reactor Building

The liquid drains can be segregated into two basic systems. The first system primarily collects tritiated water. This system is further divided into aerated liquids, which are collected in the tritiated drain collector tank and deaerated liquids, which are collected in the reactor coolant drain tank or the CVCS holdup tank. The second system primarily collects nontritiated water in the floor drain collector tank, or hot shower tank. The flow diagrams are contained in Figures 9.3.3-1 and 9.3.3-2. The drain sump in the TDAFW pump room collects TDAFW condensate and seal leakoff for routing up to the Turbine Building sump.

9.3.3.2.1 Drains From Lowest Floor Level in the Auxiliary Building

In the Auxiliary Building, most equipment is located at an elevation which permits gravity feed into the desired drain collector tank. However, since the drain collector tanks are located on the lower floors, the drains on the lower floors cannot be gravity fed to a drain collector tank. Therefore, drains on these floor are collected in the AB Floor and Equipment Drain Sump (ABFEDS) and then pumped to a drain collector tank. Only a common sump for both tritiated and nontritiated liquids is provided on this floor. The sump is pumped to the tritiated drain collector tank, or the floor drain collector tank if the water is nontritiated. Pumping nontritiated liquid to the floor drain collection tank is preferred.

9.3.3.2.2 Residual Heat Removal Pump Compartment

Each residual heat removal pump is located in a separate curbed compartment designed to control any leakage. There is a small sump located in each compartment that flows to the ABFEDS. There is a leak detector located in each RHR compartment sump which sounds a flooding alarm. Flooding of the RHR compartment has been evaluated and the maximum flooding condition will have no impact on RHR operation. The source of flooding is due to a crack in the RHR discharge piping in that individual compartment. In this condition the opposite RHR train will remain operable. Additionally there are large blow out panels to the passive sump for large leaks.

9.3.3.2.3 CVCS Holdup Tank Compartment and Tritiated Drain Collector Tank Room

The CVCS holdup tanks are located in separate watertight rooms designed to contain the tank contents should a tank rupture. The tritiated drain collector tank is in a sunken room designed to contain the tank volume should there be a rupture. There is a drain with a normally closed valve from each room to the ABFEDS. In case of a rupture, the valve would keep the water within the room until the additional volume of water could be handled by the drain collection system.

In the Tritiated System, there are both open and closed drains. The open drains are defined as drains being open to the atmosphere and usually empty into a funnel connected to the embedded drain header. The closed drains are connected directly to the drain header and are not open to the atmosphere. All of the embedded drain headers are routed to an 8-inch collection header at the tritiated drain collector tank. The headers have a blind flange at each end to aid in cleaning.

The outlet from the 8-inch collection header to the tritiated drain collector tank is a 4-inch pipe welded to the upper half of the 8-inch pipe. A water seal in the 8-inch pipe is provided at all times. Some equipment drains are piped to the sump tank to ensure gravity flow. The sump tank is pumped to the tritiated drain collector tank.

9.3.3.2.4 Floor Drain Collection Tank

The floor drain collector tank, besides receiving all of the floor drains, also collects nontritiated and nonchromated open and closed equipment drains. These drains are piped to an 8-inch header at the floor drain collector tank where a water seal is maintained at all times. The 8-inch header has a 4-inch pipe welded to the top half which discharges to the floor drain collector tank. The use of floor drains have been limited to areas where an emergency need for them exists.

9.3.3.2.5 Volume Control Tanks

The volume control tanks are located in rooms with a curb to contain the liquid in case of a rupture. A floor drain is provided and piped separately to the floor drain collector tank in order to drain the room as fast as practical.

9.3.3.2.6 Boric Acid Tanks

The boric acid tanks are enclosed by a curb designed to contain the acid should there be a major tank leak. A number of floor drains are located within this area with a valve on the drain header to the floor drain collector tank. This valve permits the containment of the boric acid until it can be pumped by a portable pump to other storage tanks. In case there were no storage tanks available, the acid can be diluted or neutralized if necessary before being released to the floor drain collector tank.

9.3.3.3 Drains - Reactor Building

There are five sumps and one drain tank inside each reactor building, each with a specific purpose.

Containment (RHR) sump: This sump is discussed in detail in Section 6.3.2. It is located inside the polar crane wall and is used to collect large volumes of water from an accident/rupture inside the crane wall for accident mitigation and long term cooling of the core.

Containment Pit (Keyway) sump: This sump has no drain lines leading to it. It collects water below the core from liner leakage and guide tube leakage. This water is then transferred by manual, local operation of a pump located in the raceway, to the Auxiliary Reactor Building Floor & Equipment Drain Sump (Pocket Sump).

Auxiliary Reactor Building Floor & Equipment Drain Sump (ARBFEDS or Pocket Sump): This sump collects drainage from inside the crane wall, containment pit sump, and other miscellaneous drains. Provisions for retaining the ECCS / LOCA inventory inside the crane wall for the containment (RHR) sump is provided.

Reactor Building Floor & Equipment Drain Sump (RBFEDS or Raceway Sump): Drains not sent to the above sumps are piped to this sump. This sump automatically pumps liquid to the Tritiated Drain Collect Tank (TDCT) in the Auxiliary Building. If the liquid is not tritiated it can be pumped to the Floor Drain Collect Tank (FDCT).

Annulus Sump: The annulus floor drains are piped to this small sump which empties by gravity to the Auxiliary Buildings passive sump. A loop seal is provided in the line.

Reactor Coolant Drain Tank (RCDT): Most equipment inside containment contains tritiated, deaerated liquids. These liquids are piped to the reactor coolant drain tank and pumped to the CVCS holdup tanks, or the tritiated drain collection tank in the Auxiliary Building.

9.3.3.4 <u>Design Evaluation</u>

The system design has incorporated features to segregate the drains and contain them in such a manner as to minimize leakage of fluid or fumes to the atmosphere. This has been accomplished with the use of water seals or traps in most drain lines where there is a possibility of cross ventilation. For those areas where seals may not be installed and the possibility exists for cross ventilation, area radiation monitors are located throughout the Auxiliary Building to alert personnel for leaving the area. See Chapter 11 for more indepth evaluation.

9.3.3.5 <u>Tests and Inspections</u>

For those drains containing a water seal or trap where there may be a possibility for significant cross ventilation, periodic monitoring will be performed to ensure seal exists.

9.3.3.6 <u>Instrumentation Application</u>

Instrumentation related to this system is described in Chapter 11, Radioactive Waste Management.

9.3.3.7 <u>Drains - Auxiliary Building</u>

The following tanks are located inside the Auxiliary Building and are used to collect fluids from tritiated and non-tritiated sources.

Chemical Drain Tank (CDT): Collects water mainly from the radiochemical laboratory.
See Chapter 11.

Hot Shower Drain Tank (HSDT): Collect water from the decon hot shower and sink in the service building. See Chapter 11.

CVCS Holdup Tank (RHT): Collects deaerated tritiated reactor grade water from the NSSS.

Auxiliary Building Sump Tank: Collects deaerated tritiated reactor grade water from the NSSS in the west section of the Auxiliary Building, and then pumps it to the TDCT.

Floor Drain Collection Tank (FDCT): Collects non tritiated drainage from equipment and floor drains.

Tritiated Drain Collect Tank (TDCT): Collects areated tritiated water in the Auxiliary Building, via the Drain Header (DH), from the RCDT and Raceway Sump inside containment, and from the auxiliary Building Sump Tank and Passive Tank.

Component Cooling Pump Seal Drain Tank (CCSDT): Collects seal leakage from CCS pumps and returns this leakage to the CCS surge tank.

Turbine-Driven Auxiliary Feed Water Pump Room Sumps (TDAFWP Room Sumps): Collects nontritiated water from the TDAFWP seals and turbine condensate and pumps it to the TB sump.

Auxiliary Building Passive Drain Header (Unit 1): Collects water from the Motor-Driven Auxiliary Feed Water pumps seal drains, the common unit Raw Cooling Water Booster Pumps' skid drains, and the Corrosion Products Monitor drains. A temporary-use manifold allows RADCON-approval drainage (for example, Cycle Outage Ice Melt) to be discharged to the Turbine Building Sump. The header penetrates the Auxiliary/Turbine Building wall connecting to an existing drain (old titration room drain) and travels by gravity to the Turbine Building's Station Sump.

Auxiliary Building Passive Drain Header (Unit 2): Collects water from the Motor-Driven Auxiliary Feed Water pumps seal drains, Corrosion Products Monitor drains, and Steam Generator Blow Down sampling from the Unit 1 and Unit 2 Hot Sample Room's booths including the sampling from the Ion Chromatography Analyzers. A temporary-use manifold allows RADCON-approved drainage (for example, Cycle Outage Ice Melt) to be discharged to the Station Sump. The header connects to the Control Building sump discharge and drains by gravity to the Turbine Building's Station Sump.

Auxiliary Building Floor & Equipment Drain Sump (AB F&E Dr. Sump): Collects tritiated and nontritiated water from some Auxiliary Building floor drains and equipment drains and pumps it to the FDCT.

Auxiliary Building Passive Sump (Passive Sump): Collects water from annulus drain sumps, and blowout panels located in the floors of the pipe chases, and the Containment Spray and RHR pump rooms. This sump drains to the AB F&E Dr. Sump through a normally closed crosstie valve. The passive sump has no pumps for water removal.

9.3.4 Chemical And Volume Control System (CVCS)

The Chemical and Volume Control System (CVCS), shown in Figures 9.3.4-1 through 9.3.4-4 is designed to provide the following services to the Reactor Coolant System (RCS):

1. Maintenance of programmed water level in the pressurizer, i.e., maintain required water inventory in the RCS.

2. Maintenance of seal-water injection flow to the reactor coolant pumps.

3. Control of reactor coolant water chemistry conditions, activity level, soluble chemical neutron absorber concentration and makeup.

4. Option of processing of excess reactor coolant.

5. Emergency core cooling - part of the system is shared with the Emergency Core Cooling System (ECCS). Refer to Section 6.3.

6. Degas the Reactor Coolant System.

9.3.4.1 Design Bases

Quantitative design parameters are given in Table 9.3.4-1 with qualitative descriptions given below. The design codes of the components in the system are given in Section 3.2.

Reactivity Control

The CVCS regulates the concentration of chemical neutron absorber in the reactor coolant to control reactivity changes resulting from the change in reactor coolant temperature between cold shutdown and hot full-power operation, burnup of fuel and burnable poisons, xenon transients, control rod adjustment, and from the buildup of fission products in the fuel.

Reactor Makeup Control

1. The CVCS is capable of borating the RCS through two flow paths and from two boric acid sources.

2. The amount of boric acid stored in the CVCS always exceeds that amount required to borate the RCS to cold shutdown concentration assuming that the control assembly with the highest reactivity worth is stuck in its fully withdrawn position. This amount of boric acid also exceeds the amount required to bring the reactor to hot shut-down and to compensate for subsequent xenon decay.

3. The CVCS is capable of counteracting inadvertent positive reactivity insertion caused by the maximum boron dilution accident (see Chapter 15).

Regulation of Reactor Coolant Inventory

The CVCS maintains the coolant inventory in the RCS within the allowable pressurizer level range for all normal modes of operation including startup from cold shutdown, full power operation and plant cooldown. This system also has sufficient makeup capacity to maintain the minimum required inventory in the event of minor leaks (see SQN "Technical Specifications" for a discussion of maximum allowable RCS Leakage).

The CVCS flow rate is based on the requirement that it permit the RCS to be heated to or cooled from hot standby condition at the design rate and maintain pressurizer level with the operating band.

Reactor Coolant Purification

The CVCS removes fission products, corrosion products, and zinc from the reactor coolant during operation of the reactor. The CVCS can also remove excess lithium from the reactor coolant, keeping the lithium concentration within the desired limits for pH control (see Table 5.2.3-3).

The CVCS is capable of removing fission and activation products, in ionic form or as particulates, from the reactor coolant in order to provide access to those process lines carrying reactor coolant during operation and to reduce activity releases due to leaks.

Chemical Additions for Corrosion Control

The CVCS provides a means for adding chemicals to the RCS which control the pH of the coolant during initial startup and subsequent operation, scavenge oxygen from the coolant during startup, control the oxygen level of the reactor coolant due to radiolysis during all operations subsequent to startup, and modifies the primary system corrosion film layer.

The CVCS is capable of maintaining the oxygen content and pH of the reactor coolant within limits specified on Table 5.2.3-3.

Seal Water Injection

The CVCS is able to supply filtered water to each reactor coolant pump seal, as required by the reactor coolant pump design.

Emergency Core Cooling

The centrifugal charging pumps in the CVCS also serve as the high-head safety injection pumps in the ECCS. Other than the centrifugal charging pumps and associated piping and valves, the CVCS is not required to function during a loss-of-coolant accident, LOCA. During a LOCA, the CVCS is isolated except for the centrifugal charging pumps, its miniflow, and the piping in the safety injection and seal injection flow paths.

9.3.4.2 System Description

The CVCS is shown in Figures 9.3.4-1 through 9.3.4-4 with system design parameters listed in Table 9.3.4-1. The CVCS consists of several subsystems: the charging, letdown and seal water system; the chemical control, purification and makeup system.

9.3.4.2.1 Charging, Letdown and Seal Water System

The charging and letdown functions of the CVCS are employed to maintain a programmed water level in the RCS pressurizer, thus maintaining proper reactor coolant inventory during all phases of plant operation. This is achieved by means of a feed and bleed process during which the feed rate is automatically controlled based on pressurizer water level. The bleed rate can be chosen to suit various plant operational requirements by selecting the proper combination of letdown orifices in the letdown flow path.

Reactor coolant is discharged to the CVCS from the reactor coolant loop piping between the reactor coolant pump and the steam generator; it then flows through the shell side of the regenerative heat exchanger where its temperature is reduced by heat transfer to the charging flow passing through the tubes. The coolant then experiences a large pressure reduction as it passes through the letdown orifice(s) and flows through the tube side of the letdown heat exchanger where its temperature is further reduced to the operating temperature of the mixed bed demineralizers (< 140°F) by component cooling water. Downstream of the letdown heat exchanger a second pressure reduction occurs. This second pressure reduction is performed by the low pressure letdown valve, the function of which is to maintain upstream pressure to prevent flashing downstream of the letdown orifices.

The coolant normally flows through one of the mixed bed demineralizers. The flow may then pass through the cation bed demineralizer which is used intermittently when additional purification or chemical control of the reactor coolant is required.

The coolant then flows through the reactor coolant filter and into the volume control tank through a spray nozzle in the top of the tank. The gas space in the volume control tank is filled with hydrogen. The partial pressure of hydrogen in the volume control tank determines the concentration of hydrogen dissolved in the reactor coolant.

The charging pumps normally take suction from the volume control tank and return the cooled, purified reactor coolant to the RCS through the charging line. Normal charging flow is handled by one of the two charging pumps. The bulk of the charging flow is pumped back to the RCS through the tube side of the regenerative heat exchanger. The letdown flow in the shell side of the regenerative heat exchanger raises the charging flow to a temperature approaching the reactor coolant temperature. The flow is then injected into a cold leg of the RCS. Two charging

paths are provided from a point downstream of the regenerative heat exchanger with air operated valves. A flow path is also provided from the regenerative heat exchanger outlet to the pressurizer spray line. An air operated valve in the spray line is employed to provide auxiliary spray to the vapor space of the pressurizer. This provides a means of depressurization near the end of plant cooldown, when the reactor coolant pumps are not operating and as required in emergency procedures.

A portion of the charging flow is directed to the reactor coolant pumps (normally 8 gpm per pump) through a seal water injection filter. It is injected between the pump shaft bearings and the thermal barrier cooling coil. Here the flow splits and a portion (normally 5 gpm per pump) enters the RCS around the thermal barrier. The remainder of the flow is directed up the pump shaft cooling the lower bearing, and to the No. 1 seal leakoff. The No. 1 seal leak-off flow discharges to a common manifold, joins the excess letdown piping, exits from the containment, and then passes through the seal water return filter and the seal water heat exchanger to the suction side of the charging pumps, or by alternate path to the volume control tank. A very small portion of the seal flow leaks through to the No. 2 seal. The No. 2 seal is provided with a stand pipe for back pressure. A No. 3 seal provides a final barrier to leakage to containment atmosphere. The No. 2 seal stand pipe flows are discharged to the reactor coolant drain tank in the Waste Disposal System. The No. 3 seal leak-off flows are discharged to the containment floor and equipment drain sump.

An alternate letdown path from the RCS is provided in the event that the normal letdown path is inoperable or pressure is low enough that adequate flow cannot be obtained through the letdown orifice. Reactor coolant can be discharged from a cold leg to flow through the tube side of the excess letdown heat exchanger where it is cooled by component cooling water. Downstream of the heat exchanger a remote-manual control valve controls the letdown flow. The flow normally joins the No. 1 seal discharge manifold and passes through the seal water return filter and heat exchanger to the suction side of the charging pumps. The excess letdown flow can also be directed to the reactor coolant drain tank. Under normal conditions when the normal letdown line is not available, the normal purification path is also not in operation. Therefore, this alternate condition would allow continued power operation for a limited period of time, dependent on RCS chemistry and activity, while RCP seal injection continues. The excess letdown flow path is also used to provide additional letdown capability during the final stages of plant heatup. This path removes some of the excess reactor coolant due to expansion of the system as a result of the RCS temperature increase.

Surges in RCS inventory due to load changes are accommodated for the most part in the pressurizer. The volume control tank provides surge capacity for reactor coolant expansion not accommodated by the pressurizer. If the water level in the volume control tank exceeds the normal operating range, a controller in the DCS modulates a three way valve downstream of the reactor coolant filter to divert a portion of the letdown to the holdup tanks. If the high-level limit in the volume control tank is reached, an alarm is actuated in the control room and the entire letdown flow is automatically diverted to the holdup tanks.

Low level in the volume control tank initiates makeup from the reactor makeup control system. The reactor makeup control system is contained within the plant Distributed Control System (DCS). At a lower level, an alarm is actuated in the control room. If the reactor makeup control system does not supply sufficient makeup to keep the volume control tank level from falling to a lower level, an emergency low level signal from both level controllers causes the suction of the charging pumps to be transferred to the refueling water storage tank.

An electrical interlock exists so that upon spurious closure of either volume control tank outlet valve, the opposite train refueling water storage tank valve will automatically open to provide suction flow to the centrifugal charging pumps in order to prevent damage to the centrifugal charging pump resulting from a loss of suction flow.

9.3.4.2.2 Chemical Control, Purification and Makeup System

pH Control

The pH control chemical employed is lithium hydroxide. This chemical is chosen for its compatibility with the materials and water chemistry of borated water/stainless steel/zirconium/inconel systems. In addition, lithium is produced in the core region due to irradiation of the dissolved boron in the coolant.

The concentration of lithium in the RCS is maintained in the range specified for pH control Section 5.2.3. If the concentration exceeds this range, as it may during the early stages of a core cycle, the cation bed demineralizer is employed in the letdown line in series operation with a mixed bed demineralizer. Since the amount of lithium to be removed is small and its buildup can be readily calculated, the flow through the cation bed demineralizer is not required to be full letdown flow. If the concentration of lithium is below the specified limits, lithium hydroxide can normally be introduced into the RCS via the chemical mixing tank and charging flow.

Oxygen Control

During reactor startup and shutdown, hydrazine may be employed as an oxygen scavenging agent. The hydrazine solution is introduced into the RCS in the chemical mixing tank, and may be introduced via the RHR system during shutdown.

Dissolved hydrogen is employed to control and scavenge oxygen produced due to radiolysis of water in the core region. Sufficient partial pressure of hydrogen is maintained in the volume control tank such that the specified equilibrium concentration of hydrogen is maintained in the reactor coolant. A pressure control valve can be adjusted to provide the correct equilibrium hydrogen concentration in the volume control tank.

Reactor Coolant Purification

Mixed bed demineralizers are provided in the letdown line to provide cleanup of the letdown flow. The demineralizers remove ionic corrosion, fission, activation products, and zinc. Typically, one demineralizer is maintained in continuous service and can be supplemented intermittently by the cation bed demineralizer, if necessary, for additional purification. The cation resin removes principally cesium isotopes and lithium from the purification flow. The second mixed bed demineralizer serves as a standby unit for use if the operating demineralizer becomes exhausted during operation. The demineralizers are automatically isolated on high letdown temperature.

During RHR shutdown operation, cleanup flow from the Residual Heat Removal System is supplied to the letdown line upstream of the letdown heat exchanger. The flow passes through the letdown heat exchanger, a mixed bed demineralizer, and the reactor coolant filter to the volume control tank. The fluid is then returned to the Reactor Coolant System via the normal charging route. To accelerate shutdown cleanup letdown and associated charging flow may be increased beyond the normal flow rates (see Table 9.3.4-1). Alternately, the RHR cleanup flow can be diverted to the holdup tanks in the CVCS letdown path.

Filters are provided at various locations to ensure filtration of particulate and resin fines and to protect the seals on the reactor coolant pumps.

Fission gases and hydrogen are removed from the system for plant shutdown via the volume control tank to the Waste Disposal System.

Chemical Shim and Reactor Coolant Makeup

The soluble neutron absorber (boric acid) concentration and the reactor coolant inventory are controlled by the reactor makeup control system. In addition, for emergency boration and makeup, the capability exists to provide refueling water or boric acid directly to the suction of the charging pump.

The boric acid is stored in three boric acid tanks (shared between both units). Four boric acid transfer pumps are provided, two per unit. One pump of each pair is aligned with one boric acid tank and normally runs continuously to provide recirculation of the boric acid tank. One of the second pumps of each pair is aligned with the third boric acid tank and recirculates with service being transferred as operation requires. Manual or automatic initiation of the reactor makeup control system activates high speed operation of the inservice pump to provide makeup of boric acid solution as required.

The primary makeup water pumps, taking suction from the primary makeup water storage tank, are employed for various makeup and flushing operations. Normally, a primary makeup water pump runs continuously and provides flow to the boric acid blender as needed.

The flow from the boric acid blender is directed to either the suction manifold of the charging pumps or the volume control tank through the letdown line and spray nozzle.

During reactor operation, changes are made in the reactor coolant boron concentration for the following conditions:

1. Reactor startup - boron concentration must be decreased from shutdown concentration to achieve criticality and maintain T-average on program.

2. Load follow - boron concentration may be either increased or decreased to adjust T-average and compensate for the xenon transient following a change in load.

3. Fuel burnup - boron concentration must be decreased to compensate for fuel burnup and the buildup of fission products in the fuel.

4. Cold shutdown - boron concentration must be increased to the cold shutdown concentration.

The reactor makeup control system consists of a group of instruments arranged to provide a manually pre-selected makeup composition to the charging pump suction header or the volume control tank. The makeup control functions are those of maintaining desired operating fluid inventory in the volume control tank and adjusting reactor coolant boron concentration for reactivity control.

1. Automatic Makeup

   The "automatic makeup" mode of operation of the reactor makeup control system provides boric acid solution preset to match the boron concentration in the RCS. The automatic

makeup compensates for minor leakage of reactor coolant without causing significant changes in the coolant boron concentration.

Under normal plant operating conditions, the mode selector switch and makeup stop valves are set in the "automatic makeup" position. A preset low level signal from the volume control tank level controller (contained within the DCS) causes the automatic makeup control action to switch a boric acid transfer pump to high speed operation, open the makeup stop valve to the charging pump suction, open the boric acid control valve and the primary makeup water control valve. Since a primary water pump runs continuously, automatic starting of this pump is not required. The flow controllers (also contained within the DCS) then blend the makeup stream according to the preset concentration. Makeup addition to the charging pump suction header causes the water level in the volume control tank to rise. At a preset high level point, the makeup is stopped, the primary makeup water control valve closes, and the makeup stop valve to charging pump suction closes. The boric acid transfer pump can then be manually returned to low speed operation.

If the automatic makeup fails or is not aligned for operation and the tank level continues to decrease, a low level alarm is actuated. Manual action may correct the situation or, if the level continues to decrease, an emergency low level signal from both channels opens the valves in the refueling water supply line to the charging pumps and closes the valves in the volume control tank outlet line.

2. Dilution

The "dilute" mode of operation permits the addition of a preselected quantity of primary makeup water at a pre-selected flow rate to the RCS. The operator sets the mode selector switch to "dilute", the primary makeup water flow controller set point to the desired flow rate, the primary water batch integrator (contained within the DCS) to the desired quantity and initiates system start. This opens the primary makeup water control valve to the volume control tank. The operating primary makeup water pump then delivers water to the volume control tank. From here the water goes to the charging pump suction header. Excessive rise of the volume control tank water level is prevented by automatic actuation (by the tank level controller) of a three-way diversion valve which routes the reactor coolant letdown flow to the holdup tanks. When the preset quantity of water has been added, the batch integrator causes the control valve to close.

3. Alternate Dilution

The "alternate dilute" mode of operation is similar to the dilute mode except a portion of the dilution water flows directly to the charging pump suction and a portion flows into the volume control tank via the spray nozzle and then flows to the charging pump suction.

4. Boration

The "borate" mode of operation permits the addition of a preselected quantity of boric acid solution at a preselected flow rate to the RCS. The operator sets the mode selection switch to "borate", the boric acid flow controller set point to the desired flow rate, the boric acid batch integrator (contained within the DCS) to the desired quantity, and initiates system start.
This opens the makeup stop valve to the charging pumps suction

and switches the boric acid transfer pump to high speed operation, which delivers boric acid solution to the charging pumps' suction header.

The total quantity added in most cases is so small that it has only a minor effect on the volume control tank level. When the preset quantity of boric acid solution is added, the batch integrator closes the makeup valve to the suction of the charging pumps. The boric acid transfer pump can be returned to low speed operation.

5. Manual

The "manual" mode of operation permits the addition of a preselected quantity and blend of boric acid solution to the volume control tank (VCT), refueling water storage tank, to the holdup tanks, or to some other location via a temporary connection. While in the manual mode of operation, automatic makeup to the RCS is precluded. With the exception of the VCT, the discharge flow path must be aligned by opening manual valves in the desired path.

The operator then sets the mode selector switch to "manual", the boric acid and primary makeup water flow controllers to the desired flow rates, the boric acid and primary makeup water batch integrators to the desired quantities and actuates the makeup start switch. The start switch actuates the boric acid flow control valve and the primary makeup water flow control valve to the boric acid blender and switches the boric acid transfer pump to high speed operation. One primary makeup water pump runs continuously.

When the preset quantities of boric acid and primary makeup water have been added, the boric acid and primary makeup water flow control valves close. This operation may be stopped manually by actuating the makeup stop switch. The boric acid pump can then be manually returned to low speed operation.

If either batch integrator is satisfied before the other has recorded its required total, the pump and valve associated with the integrator which has been satisfied will terminate flow. The flow controlled by the other integrator will continue until that integrator is satisfied.

6. Alarm Functions

The reactor makeup control is provided with alarm functions to call the operator's attention to the following conditions:

a) Deviation of primary makeup water flow rate from the control set point.

b) Deviation of boric acid flow rate from control set point.

c) High level in the volume control tank. This alarm indicates that the level in the tank is approaching high level and a resulting 100 percent diversion of the letdown stream to the holdup tanks.

d) Low level in the volume control tank. This alarm indicates that the level in the tank is approaching the emergency low level which will result in realignment of charging pump suction to the refueling water storage tank.

9.3.4.2.3 Boron Recovery System

The boron recovery system collects borated water that results from the following plant operations for both units. In each of these operations, the excess reactor coolant is diverted from the letdown line to the holdup tanks as a result of high volume control tank level.

1. Dilution of reactor coolant to compensate for core burnup

2. Load follow

3. Hot shutdowns and startups

4. Cold shutdowns and startups

5. Refueling shutdown and startup.

Excess liquid effluents containing boric acid flow from the RCS through the letdown line and are collected in the holdup tanks. As liquid enters the holdup tanks, the nitrogen cover gas is displaced to the gas decay tanks in the Waste Disposal System through the waste gas vent header. The concentration of boric acid in the holdup tanks may vary throughout core life from the refueling concentration to essentially zero at the end of the core cycle. A holdup tank recirculation pump is provided to transfer liquid from one holdup tank to another.

Liquid effluent in the holdup tanks can be processed by the liquid radwaste system as discussed in Chapter 11.

9.3.4.2.4 Layout

The volume control tank is located above the charging pumps to provide sufficient net positive suction head (NPSH). All parts of the charging and letdown system are shielded as necessary to limit dose rates during operation with one percent fuel defects assumed. The regenerative heat exchanger, excess letdown heat exchanger, letdown orifices, and seal bypass orifices are located within the reactor containment. All other system equipment is located inside the auxiliary building.

9.3.4.2.5 Component Description

A summary of principal component design parameters is given in Table 9.3.4-2 and design codes are given in Section 3.2.

All CVCS piping that handles radioactive liquid is austenitic stainless steel. All piping joints and connections are welded, except where flanged connections are required to facilitate equipment removal for maintenance and hydrostatic testing.

Charging Pumps

Two charging pumps are supplied to inject coolant into the RCS and RCP seals. The pumps are of the single speed, horizontal, centrifugal type. There is a minimum flow recirculation line to protect the centrifugal charging pumps from a closed discharge valve condition. Charging flow rate is determined from a pressurizer level signal. The means of flow control is accomplished by

a modulating valve on the discharge side of the centrifugal pumps. The centrifugal charging pumps also serve as high head safety injection pumps in the Emergency Core Cooling System. All parts in contact with the reactor coolant are fabricated of austenitic stainless steel or other material of adequate corrosion resistance. The pump logic is shown in Figure 9.3.4-5.

Boric Acid Transfer Pumps

Two horizontal, centrifugal, two speed pumps with mechanical seals are supplied for each unit. One pump of each pair is aligned with one boric acid tank and runs continuously to provide recirculation of the boric acid system, and boric acid tank. A second pump is aligned with the third boric acid tank and runs continuously to provide recirculation. The other is considered a standby pump. Manual or automatic initiation of the reactor makeup control system will activate both of the running pumps for that unit to the higher speed to provide normal makeup of boric acid solution as required. For emergency boration, supplying boric acid solution to the suction of the charging pump can be accomplished by manually actuating one or two pumps. The transfer pumps also function to transfer boric acid solution from the batching tank to the boric acid tanks. In addition to the automatic actuation by the makeup control system, and manual actuation from the main control board, these pumps may also be controlled locally. The pump logic is shown in Figure 9.3.4-6.

All parts in contact with the boric acid solution are of austenitic stainless steel.

Gas Stripper Feed Pumps

Gas stripper feed pump A or B transfers the HUT contents to the tritiated drain collector tank via the drains or vents of the evaporator feed ion exchange beds or evaporator feed filters. Additionally, the gas stripper feed pumps can be utilized to supply water directly to the RAD DI, and provide flushing of piping prior to transferring water from the Holdup Tanks to the refueling transfer canal for refueling. The third pump (C) is a standby and is available for operation in the event either operating pump malfunctions. These centrifugal pumps are constructed of austenitic stainless steel.

Holdup Tank Recirculation Pump

The recirculation pump is used to mix the contents of a holdup tank for sampling or to transfer the contents of a holdup tank to another holdup tank. The pump is the centrifugal type, manually actuated, with all wetted surfaces constructed of austenitic stainless steel.

Monitor Tank Pumps

The two monitor tank pumps discharge water from the monitor tank. The pumps are constructed of austenitic stainless steel.

Regenerative Heat Exchanger

The regenerative heat exchanger is designed to recover heat from the letdown flow by reheating the charging flow, which reduces thermal shock on the charging penetrations into the reactor coolant loop piping.

The letdown stream flows through the shell of the regenerative heat exchanger and the charging stream flows through the tubes. The unit is constructed of austenitic stainless steel, and is of all welded construction.

The temperatures of both outlet streams from the heat exchanger are monitored with indication in the control room. A high temperature alarm is provided on the main control board if the temperature of the letdown stream exceeds desired limits.

Letdown Heat Exchanger

The letdown heat exchanger cools the letdown stream to the operating temperature of the mixed bed demineralizers. Reactor coolant flows through the tube side of the exchanger while component cooling water flows through the shell side. All surfaces in contact with the reactor coolant are austenitic stainless steel, and the shell is carbon steel.

The low pressure letdown valve, located downstream of the heat exchanger, maintains the pressure of the letdown flow sufficiently high to prevent two phase flow.

The letdown temperature control indicates and controls the temperature of the letdown flow exiting from the letdown heat exchanger. The temperature sensor, which is part of the CVCS, provides input to the valve controller in the Component Cooling System. The letdown exit temperature is controlled by regulating the component cooling water flow through the letdown heat exchanger. Temperature indication is provided on the main control board. These controls reside in the DCS.

Excess Letdown Heat Exchanger

The excess letdown heat exchanger cools reactor coolant letdown flow equivalent to the nominal seal injection flow which flows downward into the reactor coolant pump system.

The excess letdown heat exchanger can be utilized when normal letdown is temporarily out of service or it can be used to supplement letdown during heatup. The letdown flows through the tube side and component cooling water is circulated through the shell side of the heat exchanger. All surfaces in contact with reactor coolant are austenitic stainless steel and the shell is carbon steel. All tube joints are welded.

A temperature detector measures the temperature of excess letdown downstream of the excess letdown heat exchanger. Temperature indication and high temperature alarm are provided on the main control board.

A pressure sensor indicates the pressure of the excess letdown flow downstream of the excess letdown heat exchanger and excess letdown control valve. Pressure indication is provided on the main control board.

Seal Water Heat Exchanger

The seal water heat exchanger is designed to cool fluid from three sources: reactor coolant pump seal water returning to the CVCS, reactor coolant discharged from the excess letdown heat exchanger, and centrifugal charging pump mini flow. Reactor coolant flows through the tube side of the heat exchanger and component cooling water is circulated through the shell

side. The design flow rate is equal to the sum of the excess letdown flow, maximum design reactor coolant pump seal leakage, and mini flow from one centrifugal charging pump. The unit is designed to cool the above flow to the temperature normally maintained in the volume control tank. All surfaces in contact with reactor coolant are austenitic stainless steel and the shell is carbon steel.

Volume Control Tank

The volume control tank provides surge capacity for part of the reactor coolant expansion volume not accommodated by the pressurizer. When the level in the tank reaches the high level setpoint, the remainder of the expansion volume is accommodated by diversion of the letdown stream to the holdup tanks. It also provides a means for introducing hydrogen into the coolant to maintain the required equilibrium concentration of hydrogen and is used for degassing the reactor coolant. It also serves as a head tank for the charging pumps.

A spray nozzle located inside the tank on the letdown line nozzle provides liquid to gas contact between the incoming fluid and the hydrogen atmosphere in the tank.

For degassing, the tank is provided with a remote operated solenoid valve backed up by a pressure control valve in series which ensures that the tank pressure does not fall below minimum operating pressure during degassing to the Waste Disposal System. Relief protection, gas space sampling, and nitrogen purge connections are also provided.

Volume control tank pressure and temperature are monitored with indication given in the control room. Alarm is given in the control room for high and low pressure conditions and for high temperature.

Two level channels govern the water inventory in the volume control tank. These channels provide local and remote level indication, level alarms, level control, makeup control, and emergency makeup control.

If the volume control tank level rises above the normal operating range, one channel provides an analog signal to a proportional controller which modulates the three-way valve downstream of the reactor coolant filter to maintain the volume control tank level within the normal operating band. The three-way valve can split letdown flow so that a portion goes to the holdup tanks and a portion to the volume control tank. This proportional controller is contained within the DCS.

If the modulating function of the valve fails and the volume control tank level continues to rise, the high level alarm will alert the operator to the malfunction and the letdown flow can be manually diverted to the holdup tanks. If no action is taken by the operator and the tank level continues to rise, the full letdown flow will be automatically diverted.

During normal power operation, a low level in the volume control tank initiates auto makeup which injects a pre-selected blend of boron and water into the charging pump suction header. When the volume control tank is restored to normal, auto makeup stops.

If the automatic makeup fails or is not aligned for operation or the tank level continues to decrease, a low level alarm is actuated. Manual action may correct the situation or, if the level continues to decrease, an emergency low level signal from both level channels opens the stop valves in the refueling water supply line and closes the stop valves in the volume control tank outlet line.

Boric Acid Tanks

Three boric acid tanks are shared by Units 1 and 2. One tank supplemented by additional makeup from either: (1) the common boric acid tank and/or batching, or (2) borated water from the refueling water storage tank, provides sufficient boric acid solution for cold shutdown of one unit even if the most reactive control rod is not inserted. One tank supplies boric acid for each reactor coolant makeup system during normal operation, while the third tank serves as a spare.

The concentration of boric acid solution in storage is maintained between 3.5 and 4.0 percent by weight. Periodic manual sampling and corrective action, if necessary, insures that these limits are maintained. As a consequence, measured amounts of boric acid solution can be delivered to the reactor coolant to control the chemical poison concentration. The combination overflow and breather vent connection has an in-line HEPA filter to trap off-gas radioactive particulates before ducting into the auxiliary building exhaust.

Two 100 percent capacity electric immersion heaters in each boric acid tank are normally de-energized and available when the Auxiliary Building temperature drops. The immersion heaters are manually controlled at local panels. The heaters are sheathed in austenitic stainless steel. The solubility limit for 4.0 weight percent boric acid is reached at a temperature of 58 degrees F. This temperature is sufficiently low that the normally expected ambient temperatures within the auxiliary building will maintain boric acid solubility.

A temperature detector provides temperature measurement of each tank's contents. Local temperature indication is provided and high and low temperature alarms are indicated on the main control board.

A level detector indicates the level in each boric acid tank. Level indication with high, and low level alarms is provided on the main control board. The low level alarm is set to provide a margin to the base of the tank, which provides suction head to the boric acid transfer pumps.

Batching Tank

The batching tank is used for mixing a makeup supply of boric acid solution for transfer to the boric acid tanks. The tank may also be used for solution storage.

A local sampling point is provided for verifying the solution concentration prior to transferring. The tank is provided with an agitator to improve mixing during batching operations and an electric heater for heating the boric acid solution. Some heating of the pure water may be required.

Chemical Mixing Tank

The primary use of the chemical mixing tank is in the addition of lithium hydroxide solutions for pH control and hydrazine solution for oxygen scavenging.

Holdup Tanks

Two holdup tanks are shared between Units 1 and 2. The holdup tanks hold radioactive liquid which enters from the letdown line and other primary side sources. The liquid is released from the RCS during startup, shutdowns, load changes, and from boron dilution to compensate for

burnup. The tanks can also be utilized as a source of water for the refueling canal to support maintenance and refueling activities. When it is necessary to empty the fuel transfer canal, one of the tanks can be used to store the canal water.

Monitor Tank

The monitor tank accumulates liquid from the Waste Disposal System for sampling. After sampling, the condensate can be pumped to allow processing, pumped to the holdup tanks, to the primary water storage tank, or to the environment.

Mixed Bed Demineralizers

Two flushable mixed bed demineralizers assist in maintaining reactor coolant purity. A hydrogen-form or lithium-form cation resin and hydroxyl form anion resin are charged into the demineralizers. The anion resin is converted to the borate form in operation. Both types of resin remove fission and corrosion products. The resin bed is designed to reduce the concentration of ionic isotopes in the purification stream, except for cesium, yttrium and molybdenum, by a minimum factor of 10.

Each demineralizer has sufficient capacity for approximately one core cycle with one percent of the rated core thermal power being generated by defective fuel rods. One demineralizer serves as a standby unit for use if the operating demineralizer becomes exhausted during operation.

A temperature sensor measures temperature of the letdown flow downstream of the letdown heat exchanger and controls the letdown flow to the mixed bed demineralizers by means of a three-way valve. If the letdown temperature exceeds the allowable resin operating temperature, the flow is automatically bypassed around the demineralizers to the VCT. Temperature indication and high alarm are provided on the main control board. The air operated three-way valve failure mode directs flow to the volume control tank.

Cation Bed Demineralizer

A flushable cation resin bed in the hydrogen form is located downstream of the mixed bed demineralizers and is used intermittently to control the concentration of Li^7 which builds up in the coolant from the B10 (n, α) Li^7 reaction. The demineralizer also has sufficient capacity to maintain the Cesium-137 concentration in the coolant below 1.0 μCi/cc with one percent of the rated core thermal power being generated by defective fuel. The resin bed is designed to reduce the concentration of ionic isotopes, particularly cesium, yttrium, and molybdenum by a minimum factor of 10.

The cation bed demineralizer has sufficient capacity for approximately one core cycle with one percent of the rated core thermal power being generated by defective fuel rods.

Reactor Coolant Filter

The reactor coolant filter is located in the letdown line, upstream of the volume control tank. The filter collects resin fines and particulates from the letdown stream. The nominal flow capacity of the filter is greater than the maximum purification flow rate.

Two local pressure indicators are provided to show the pressures upstream and downstream of the reactor coolant filter and thus provide filter differential pressure.

Seal Water Injection Filters

Two seal water injection filters are located in parallel in a common line to the reactor coolant pump seals to collect particulate matter that could be harmful to the seal faces. Each filter is sized to accept flow in excess of the normal seal water flow requirements.

A differential pressure indicator monitors the pressure drop across each seal water injection filter and gives local indication with high differential pressure alarm on the main control board.

Seal Water Return Filter

The filter collects particulates from the reactor coolant pump seal water return and from the excess letdown flow. The filter is designed to pass flow in excess of the sum of the excess letdown flow and the maximum design leakage from the reactor coolant pump seals.

Two local pressure indicators are provided to show the pressures upstream and downstream of the filter and thus provide the differential pressure across the filter.

Boric Acid Filter

The boric acid filter, when aligned, collects particulates from the solution being pumped to the charging pump suction or boric acid blender. The filter is designed to pass the design flow of two boric acid transfer pumps operating simultaneously. Local pressure indicators indicate the pressure upstream and downstream of the boric acid filter and thus differential pressure. A bypass alignment is provided in the event the boric acid filter is unavailable.

Boric Acid Blender

The boric acid blender promotes mixing of boric acid solution and primary makeup water for the reactor coolant makeup circuit. The blender consists of a conventional pipe-tee. A sample point is provided in the piping just downstream of the blender.

Letdown Orifices

The three letdown orifices are arranged in parallel and serve to reduce the pressure of the letdown stream to a value compatible with the letdown heat exchanger design. Two of the three are sized such that either can pass normal letdown flow. One or both standby orifices may be used with the normally operating orifice in order to increase letdown flow such as during reactor heatup operations or maximum purification. This arrangement also provides a full standby capacity for control of letdown flow. Orifices are placed in and taken out of service by remote manual operation of their respective isolation valves.

A flow monitor provides indication in the control room of the letdown flow rate and high flow alarm to indicate unusually high flow.

A low pressure letdown controller controls the pressure downstream of the letdown orifice to prevent flashing of the letdown liquid. Pressure indication and high pressure alarm are provided on the main control board. This letdown pressure controller is contained within the DCS.

Temperature Monitoring

Thermocouples are provided at various locations in the Auxiliary Building to monitor the ambient air temperature. The air temperature is representative of the temperature of the boric acid solution which operates at ambient temperatures. These thermocouples are run to a local recorder that has an alarm in the control room in the event that the ambient conditions begin to approach the solubility temperature of the boric acid solution.

Valves

Valves, other than diaphragm valves, that perform a modulating function are equipped with a stuffing box containing two sets of packing and an intermediate leakoff connection or a set of packing without an intermediate leakoff connection. Valves are normally installed such that, when closed, the high pressure is not on the packing. Basic material of construction is stainless steel for all valves which handle radioactive liquid or boric acid solution.

Isolation valves are provided for all lines entering the reactor containment. See Subsection 6.2.4.

Relief valves are provided for lines and components that might be pressurized above design pressure by improper operation or component malfunction.

1. Charging Line Downstream of Regenerative Heat Exchanger

   If the charging side of the regenerative heat exchanger is isolated while the hot letdown flow continues at its maximum rate, the volumetric expansion of coolant on the charging side of the heat exchanger is relieved to the Reactor Coolant System through a spring loaded check valve. The spring in the valve is designed to permit the check valve to open in the event that the differential pressure exceeds the design pressure differential.

2. Letdown Line Downstream of Letdown Orifices

   The pressure relief valve downstream of the letdown orifices protects the low pressure piping and the letdown heat exchanger from overpressure when the low pressure piping is isolated. The capacity of the relief valve exceeds the maximum flow rate through all letdown orifices. The valve set pressure is equal to the design pressure of the letdown heat exchanger tube side.

3. Letdown Line Downstream of Low Pressure Letdown Valve

   The pressure relief valve downstream of the low pressure letdown valve protects the low pressure piping, demineralizers, and filter from overpressure when this section of the system is isolated. The capacity of the relief valve exceeds the maximum flow rate through all letdown orifices. The valve set pressure is equal to the design pressure of the demineralizers.

4. Volume Control Tank

   The relief valve on the volume control tank permits the tank to be designed for a lower pressure than the upstream equipment. This valve has a capacity equal to the summation of the following items: maximum letdown, normal seal water return, excess letdown, maximum flow from one RCP floating ring seal, and nominal flow from one primary water pump. The valve set pressure equals the design pressure of the volume control tank.

5. Charging Pump Suction

   A relief valve on the charging pump suction header relieves pressure that may build up if the suction line isolation valves are closed or if the system is overpressurized. The valve set pressure is equal to the design pressure of the associated piping and equipment.

6. Seal Water Return Line (Inside Containment)

   This relief valve is designed to relieve overpressurization in the seal water return piping inside the containment if the motor-operated isolation valve is closed. The valve is designed to relieve the total leakoff flow from the No. 1 seals of the reactor coolant pumps plus the design excess letdown flow.

7. Seal Water Return Line (Charging Pumps Bypass Flow)

   This relief valve protects the seal water heat exchanger and its associated piping from overpressurization. If either of the isolation valves for the heat exchanger are closed and if the bypass line is closed, the piping could be overpressurized by the bypass flow from the centrifugal charging pumps. The valve is sized to handle the full bypass flow with all centrifugal pumps running. The valve is set to relieve at the design pressure of the heat exchanger.

<u>Piping</u>

All Chemical and Volume Control System piping handling radioactive liquid is austenitic stainless steel. All piping joints and connections are welded, except where flanged connections are required to facilitate equipment removal for maintenance and hydrostatic testing.

<u>Resin Fill Tank</u>

The resin fill tank is used to charge fresh resin to the demineralizers. The tank has a conical bottom connected to a line with a dump valve. This line may be connected to the fill line of the demineralizer being serviced. Demineralized water is added to the tank to produce a resin slurry which can then be sluiced from the tank into a demineralizer by opening the dump valve.

<u>Chemical Mixing Tank Orifice</u>

An orifice is provided in the piping upstream of the mixing tank. This orifice limits the flow rate through the tank to 2 gpm to avoid slugging the pump seals with concentrated chemicals.

Boric Acid Tank Orifice

Each boric acid tank orifice is designed to pass the minimum flow required to provide sufficient recirculation through the piping and tanks with the transfer pumps. The orifice is constructed of austenitic stainless steel.

Seal Water Return Bypass Orifice

An orifice in each reactor coolant pump No. 1 seal-bypass line may be placed in service only during startup or shutdown, when the reactor coolant system pressure is low and temperature limits are being approached on the No.1 seal and/or pump radial bearing. The bypass flow is necessary to ensure adequate flow for cooling of the pump's lower radial bearing. The orifice is a plug-type, constructed of austenitic stainless steel and designed to pass adequate flow at the differential pressure corresponding to the lowest reactor coolant system pressure allowable for pump operation.

Reactor Coolant Pump Seal Standpipe

The standpipes maintain a head of water between the No. 2 and 3 seals of the reactor coolant pumps to control leakage from the reactor coolant pumps.

9.3.4.2.6 System Operation

Reactor Startup

Reactor startup is defined as the operations which bring the reactor from cold shutdown to normal operating temperature and pressure. The following provides a typical sequence of events. The exact startup sequence will vary depending on the shutdown conditions.

It is assumed that:

1. Normal residual heat removal is in progress.

2. Reactor Coolant System boron concentration is at the cold shutdown concentration.

3. Reactor makeup control system is set to provide makeup at the cold shutdown concentration.

4. Reactor Coolant System is either water solid or drained to minimum level for the purpose of refueling or maintenance. If the Reactor Coolant System is water solid, system pressure is controlled by letdown through the Residual Heat Removal System and through the low pressure letdown valve in the letdown line.

5. The charging and letdown lines of the Chemical and Volume Control System are filled with coolant at the cold shutdown boron concentration. The letdown orifice isolation valves are closed.

If the Reactor Coolant System requires filling and venting, the procedure is as follows:

1. One charging pump is started, which provides blended flow from the reactor makeup control system at the cold shutdown boron concentration.

2. The vents on the head of the reactor vessel and pressurizer are opened.

3. The Reactor Coolant System is filled and the vents closed.

The system pressure is raised by using the charging pump and controlled by the low pressure letdown valve. When the system pressure is adequate for operation of the reactor coolant pumps, including seal water flow, the pumps are briefly operated and the RCS vented sequentially until all gases are cleared from the system. Final venting takes place at the pressurizer.

An alternate means of venting the RCS without the use of the RCPs is via the Reactor Coolant Vacuum Refill System (RCVRS). The RCVRS is connected to the pressurizer relief tank and is designed to remove air and noncondensable gases from the RCS by applying a vacuum to the RCS in Mode 5. The gases will be drawn from the steam generator tubes to the reactor vessel head and pressurizer. The RCSHV valves and pressurizer power operator relief valves (PORV) are opened to allow the gases to flow through the pressurizer relief tank to the RCVRS suction header. After the gases are removed, the vacuum is maintained until the RCS is filled.

After the filling and venting operations are completed, charging and letdown flows are established. Pressurizer heaters are energized and steam formation in the pressurizer is accomplished by control of the charging flow and letdown flow. When the pressurizer water level reaches the no-load programmed set point, the pressurizer level control can be shifted to control the charging flow to maintain programmed level. The reactor coolant pumps are started, the plant enters hot shutdown, and the Residual Heat Removal System is isolated from the RCS.

The reactor coolant boron concentration can now be reduced by operating the reactor makeup control system in the "dilute" mode. During heatup, the appropriate combination of letdown orifices is used to provide necessary letdown flow. Prior to or during the heating process, the CVCS is employed to obtain the correct chemical properties in the RCS. The reactor makeup control system is operated to ensure correct control rod position. Chemicals are added through the chemical mixing tank as required to control reactor coolant chemistry such as pH and dissolved oxygen content. Hydrogen overpressure is established in the volume control tank to assure the appropriate hydrogen concentration in the reactor coolant.

The reactor coolant boron concentration is corrected to the point where the control rods may be withdrawn and criticality achieved or the control rods withdrawn and the RCS diluted to achieve criticality. Nuclear heatup may then proceed with corresponding manual adjustment of the reactor coolant boron concentration to balance the temperature coefficient effects and maintain the control rods within their operating range.

<u>Power Generation and Hot Standby Operation</u>

Base Load

At a constant power level, the rates of charging and letdown are dictated by the requirements for seal water to the reactor coolant pumps and the normal purification of the RCS. One charging pump is employed and charging flow can be controlled automatically from pressurizer level. Adjustments in boron concentration are made to compensate for core burnup and to maintain the control groups within their allowable limits. Rapid variations in power demand can

be accommodated automatically by control rod movement. If variations in power level occur, and the new power level is sustained for long periods, some adjustment in boron concentration may be necessary to maintain the control groups within their maneuvering band.

During normal operation, normal letdown flow is maintained and one mixed bed demineralizer is in service. Reactor coolant samples are taken periodically to check boron concentration, lithium concentration, zinc concentration, water quality, and activity level.

Load Changes

A power reduction will initially cause a xenon buildup followed by xenon decay to a new, lower equilibrium value. The reverse occurs if the power level increases; initially, the xenon level decreases and then it increases to a new and higher equilibrium value associated with the amount of the power level change.

The reactor makeup control system can be used to vary the reactor coolant boron concentration to compensate for xenon transients occurring when reactor power level is changed.

The operators maintain Δ I on program by manual/auto rod motion and sufficient boration / dilution to maintain TAVE on program.

During power ascension, the reactor coolant expands as its temperature rises. The pressurizer absorbs most of this expansion as the level controller raises the level setpoint to the increased level associated with the new power level. The remainder of the excess coolant is letdown and stored in the volume control tank and/or HUT. During this period, the flow through the letdown orifice remains constant and the charging flow is reduced by the pressurizer level control signal, resulting in an increased temperature at the regenerative heat exchanger outlet. The temperature controller downstream from the letdown heat exchanger increases the component cooling water flow to maintain the desired letdown temperature.

During power reduction, the charging flow is increased to make up for the coolant contraction not accommodated by the programmed reduction in pressurizer level.

Hot Standby

If required, for periods of maintenance, or following reactor trips, the reactor can be held subcritical, but with the capability to return to power. During this hot standby period, temperature is maintained at no-load T_{avg} by initially dumping steam to remove core residual heat, or at later stages, by running reactor coolant pumps to maintain system temperature.

Following shutdown, xenon buildup occurs and increases the degree of shutdown ($\Delta k/k$). The effect of xenon buildup is to increase the degree of shutdown ($\Delta k/k$) to a maximum at about eight hours following shutdown from equilibrium full power conditions. If hot shutdown is maintained past this point, xenon decay results in a decrease in degree of shutdown. Since the $\Delta k/k$ value of the initial xenon concentration is high (assuming that an equilibrium concentration had been reached during operation), boration of the reactor coolant is necessary to counteract the xenon decay and maintain shutdown.

If rapid recovery is required, dilution of the system may be performed to counteract this xenon buildup. However, after the xenon concentration reaches a peak, boration may be required to maintain the reactor subcritical as the xenon decays out.

Hot Shutdown and Cold Shutdown

Before initiating a cold shutdown, the Reactor Coolant System hydrogen concentration is reduced by reduction of the volume control tank overpressure and venting the gases to the waste gas vent header.

During the plant cooldown, charging is provided to makeup for coolant contraction. During the initial phase of the cooldown, the makeup is usually provided from the boric acid tanks. Utilizing the boric acid tanks requires less boration volume than the RWST. The operators can continue using the boric acid tanks if additional volume is available, or shift suction of the charging pumps to the refueling water storage tank. If the boric acid tanks are used, boric acid can be charged until the reactor coolant system reaches the desired cold shutdown concentration. The cooldown can be completed by using blended makeup at the cold shutdown concentration.

Contraction of the coolant during cooldown results in increased charging flow to maintain normal pressurizer water level. This results in a decreasing volume control tank level and makeup to maintain the inventory.

After the Residual Heat Removal System is placed in service and the reactor coolant pumps are shut down, further cooling of the pressurizer liquid is accomplished by the auxiliary spray line. Coincident with plant cooldown, a portion of the reactor coolant flow may be diverted from the Residual Heat Removal System to the CVCS for cleanup. Demineralization of ionic radioactive impurities and stripping of fission gases reduce the reactor coolant activity level sufficiently to permit personnel access for refueling or maintenance operations.

9.3.4.3 Safety Evaluation

9.3.4.3.1 Reactivity Control

Any time that the plant is at power, the quantity of boric acid retained and ready for injection always exceeds that quantity required for the normal cold shutdown assuming that the control assembly of greatest worth is in its fully withdrawn position. This quantity always exceeds the quantity of boric acid required to bring the reactor to hot shutdown and to compensate for subsequent xenon decay. An adequate quantity of boric acid is also available in the refueling water storage tank to achieve cold shutdown.

When the reactor is subcritical; i.e., during cold shutdown, hot shutdown, or hot standby, fuel movement during refueling (as described in Section 4.2) and during approach to criticality, the neutron source multiplication is continuously monitored and indicated. Any appreciable increase in the neutron source multiplication, including that caused by the maximum physical boron dilution rate, is slow enough to give ample time to start a corrective action to stop boron dilution and begin boration to prevent the core from becoming critical. The rate of boration via the normal charging line, with a single boric acid transfer pump operating, is sufficient to take the reactor from full power operation to 1 percent shutdown in the hot condition, with no rods inserted, in approximately 90 minutes. In an additional 100 minutes, enough boric acid can be

injected to compensate for xenon decay, although xenon decay below the full power equilibrium operating level will not begin until approximately 25 hours after shutdown. Additional boric acid is employed if it is desired to bring the reactor to cold shutdown conditions.

Two separate and independent flow paths are available for reactor coolant boration; i.e., the charging line and the reactor coolant pump seal injection. A single failure does not result in the inability to borate the RCS.

If the normal charging line is not available, charging to the RCS is continued via reactor coolant pump seal injection at the rate of 20 gpm (5gpm per reactor coolant pump), approximately 370 minutes are required to add enough boric acid solution to counteract xenon decay, although xenon decay below the full power equilibrium operating level will not begin until approximately 25 hours after the reactor is shut down.

As backup to the normal boric acid supply, the operator can align the refueling water storage tank outlet to the suction of the charging pumps.

The Technical Requirement Manual requires that at least one flow path is available for boron injection when in Modes 4, 5, and 6. The Technical Requirement Manual requires redundant boration capability when in Modes 1, 2, and 3. The capability of such injection is adequate to ensure shutdown margin can be maintained after xenon decay and cooldown. An upper limit to the boric acid tank boron concentration, and a lower limit for ambient temperature ensure that solution solubility is maintained.

The Technical Requirements Manual permits one charging pump and associated flow path to be nonfunctional during power operation for a specified time period, provided that the opposite charging pump and associated flow path is functional. Out of service action times and specific actions are described in the Technical Requirements Manual.

9.3.4.3.2 Reactor Coolant Purification

The Chemical and Volume Control System (CVCS) is capable of reducing the concentration of ionic isotopes in the purification stream as required in the design basis. This is accomplished by passing the letdown flow through the mixed bed demineralizers which remove ionic isotopes, except those of cesium, molybdenum and yttrium, with a minimum decontamination factor of 10. Through occasional use of the cation bed demineralizer, the concentration of cesium can be maintained below 1.0 ☒Ci/cc, assuming one percent of the rated core thermal power is being produced by fuel with defective cladding. The cation bed demineralizer is capable of passing the normal letdown flow, through only a portion of this capacity is normally utilized. Each mixed bed demineralizer is capable of processing the maximum letdown flow rate. If the normally operating mixed bed demineralizer's resin has become exhausted, the second demineralizer can be placed in service. Each demineralizer is designed, however, to operate for one core cycle with one percent defective fuel.

9.3.4.3.3 Seal Water Injection

Flow to the reactor coolant pump seals is assured by redundant charging pumps capable of supplying the normal charging line flow plus the nominal seal water flow.

9.3.4.3.4 Leakage Provisions

Chemical and Volume Control System components, valves and piping which see radioactive service are designed to limit leakage to the atmosphere. Leakage to the atmosphere is limited through:

1. Welding of all piping joints and connections except where flanged connections are provided to facilitate maintenance and hydrostatic testing,

2. Extensive use of leakoffs to collect leakage, and

3. Use of diaphragm valves where conditions permit.

The volume control tank in the CVCS provides an inferential measurement of leakage from the CVCS as well as the Reactor Coolant System. Low level in the volume control tank actuates makeup automatically or alarms for manual makeup alignment. The amount of leakage can be inferred from the amount of makeup added by the reactor makeup control system. In the event of pipe breaks outside the containment, the CVCS can be isolated from the RCS.

9.3.4.3.5 Ability to Meet the Safeguards Function

A failure analysis of the portion of the CVCS which is used as part of the Emergency Core Cooling System is included as part of the ECCS Failure analysis presented in Section 6.3.

9.3.4.4 Tests and Inspections

As part of plant operation, periodic tests, surveillance inspections and instrument calibrations are made to monitor equipment condition and performance. Most components are in use regularly; therefore, assurance of the availability and performance of the systems and equipment is provided by control room and/or local indication.

Technical Specifications have been established for appropriate CVCS components.

9.3.4.5 Instrumentation Application

Process control instrumentation is provided to acquire data concerning key parameters about the Chemical and Volume Control System. Instrumentation furnishes input signals for monitoring and/or alarming purposes.

The instrumentation supplies input signals for control purposes. Some specific control functions are:

1. Letdown flow is diverted to the volume control tank upon high temperature indication upstream of the mixed bed demineralizers.

2. Pressure downstream of the letdown orifices is controlled to prevent flashing of the letdown liquid.

3. Charging flow rate is controlled during charging pump operation.

4. Water level is controlled in the volume control tank.

5. Temperature of the boric acid solution in the batching tank is maintained.

6. Reactor makeup is controlled.

A simplified flow and instrument drawing is provided in Figures 9.3.4-1, 9.3.4-2, 9.3.4-3, and 9.3.4-4. Pump logic is provided in Figures 9.3.4-5 and 9.3.4-6.

9.3.5 Auxiliary Charging System

9.3.5.1 Design Bases

The Auxiliary Charging System (ACS) is designed to provide makeup to the Reactor Coolant System (RCS) when the plant is operating in the "flood mode." For definition of "flood mode" see Appendix 2.4A. This system is an essential part of the equipment used in flood protection provisions. This system is also designated as the Flood-Mode Boration Makeup System.

The ACS includes the following equipment:

1. Four full-capacity auxiliary charging pumps (two per unit)

2. Auxiliary makeup tank

3. Filter

4. Demineralizer

5. Two auxiliary charging booster pumps

Each auxiliary charging pump (ACP) and each auxiliary charging booster pump have capacities several times greater than the maximum leakage loss from the primary system. Leakage loss is based on No. 2 and No. 3 seal leakage with No. 1 seal injection and return lines isolated and an RCS pressure of 500 lb/in^2g (maximum during "flood mode"), plus the remainder of recoverable and nonrecoverable leakage, based on the average annual rates for normal power operation (at full RCS pressure).

The auxiliary makeup tank (AMT) has a capacity sufficient to provide a minimum of 24 hours makeup based on the above leakage loss. Makeup is prepared in a batch process.

A filter and demineralizer are provided for cleanup of makeup water.

9.3.5.2 System Design Description

The ACS is shown on Figure 9.3.6-1. The initial supply of auxiliary makeup water is from the demineralized water tanks. The majority of leakage, from RCS pump seals, etc., is collected in the reactor coolant drain tank (RCDT) and can be pumped by the RCDT pumps to the AMT. This recoverable leakage is the main preferred source of makeup water. Additional makeup water is supplied from other preferred sources: (1) accumulator tanks via the RCDT pumps, (2) pressurizer relief tank via the RCDT pumps, and (3) demineralized water tanks.

The above preferred sources of makeup water are backed up by the fire protection system which can supply river water to the AMT. To prevent inadvertent injection of raw water into the primary system, this source is connected, via fire hose, only if it is needed.

Auxiliary makeup water is borated to the extent necessary to maintain refueling shutdown concentration in the RCS. Hydrazine and lithium hydroxide are added to makeup water as required.

The primary system can be sampled periodically and analyzed for boron concentration. Sample outlets are provided that are accessible in the flood mode. The makeup water is pumped from the auxiliary makeup tank to the primary system as demanded by pressurizer level.

9.3.5.3 Design Evaluation

The ACS includes both essential and preferred components. Essential components are designed to standards required of engineered safety features. Preferred components are not designed as engineered safety features, but are high quality commercial components.

The ACP and AMT are essential components.

Sufficient separation and redundancy of components and circuits are provided so that no single failure can jeopardize the operation. All components are capable of being supplied with emergency power.

Seismic qualification of the ACS is not required since the coincidence occurrence of a flood exceeding plant grade and an earthquake is a low probability event (see Appendix 2.4A).

9.3.5.4 Tests and Inspection

All components of the ACS are accessible for inspection. Insofar as practicable, the design provides capability to demonstrate the state of readiness.

9.3.5.5 Instrument Application

Manual control is employed to the maximum extent practicable. ACS motors and I&C are classified as essential.

Completely manual operation will be used to transfer water to the AMT. Levels in the AMT can be visually checked since the tank has a 1 day supply under worst case conditions. The redundant pressurizer level loops in the RCS serve as indications of the low pressurizer level necessary for the activation of the ACP.

9.4 HEATING, VENTILATING, AND AIR-CONDITIONING

The Sequoyah Nuclear Plant heating, ventilating, and air-conditioning systems are designed to maintain the proper temperatures within the plant in all weather situations. To assure this capability, outside weather conditions for weather extremes in the plant area are used to size this equipment. These design bases climatic conditions are as follows:

Winter median of annual extremes, °F dry bulb	11
Winter design temperature, °F dry bulb	15
Winter relative humidity, maximum, percent	100
Coincident wind velocity	Light
Summer design dry bulb, °F	97
Summer design wet bulb, °F	78

In December through February, 99 percent of hourly readings have been equal to or above the winter design temperature. During the months of June through September, 99 percent of hourly readings have been equal to or below the summer design dry bulb temperature, and 99 percent have been equal to or below the summer design wet bulb temperature.

9.4.1 Control Building

9.4.1.1 Design Bases

The Control Building heating, ventilating, air-conditioning, and air cleanup systems are designed to maintain the temperature and humidity conditions throughout the building for the protection, operation, and maintenance and testing of plant controls; and for the safe, uninterrupted occupancy of the Main Control Room during an accident and the subsequent recovery period.

The Control Building air-conditioned spaces are maintained at approximately 75°F and 50 percent relative humidity for the protection of instruments and for the comfort and safety of the operators. These conditions are continuously maintained during normal and accident operation, except for evacuation of the main control room or in case of a fire.

During normal plant operation fresh air flow is induced to replace that which is being mechanically exhausted.

The Control Building outside air intakes are provided with radiation monitors and high temperature detectors that annunciate in the Main Control Room.

Isolation of the main control room occurs automatically upon the actuation of a safety injection signal from either unit or upon indication of high radiation or high temperature in the outside air supply stream to the building or manually by the operator from the MCR. Manual action by the operator, in lieu of the automatic control room isolation (CRI), is credited for CRI based on detection of smoke.

The following occur on a CRI signal:

1. The control room emergency air cleanup fans will operate to recirculate a portion of the control room air-conditioning system return air through the cleanup trains composed of HEPA filters and charcoal adsorbers.

2. The control room emergency pressurizing air supply fans will operate to supply a stream of outside air to the control room air-conditioning system to keep the control room pressurized to a positive 1/8-inch or greater w.g. relative to outside atmosphere and a slightly positive pressure relative to its surroundings, and also, to maintain a slightly positive pressure in other rooms in the habitability zone relative to adjoining spaces, minimizing the in-leakage of unprocessed or contaminated air. This fresh air is routed through the emergency air cleanup trains.

3. Fresh air will continue to be drawn in through the make-up air ducts for the electrical board room air handling units for the lower floors.

4. The exhaust fan in the toilet and locker rooms will be stopped and double isolation dampers closed to prevent the inflow of unfiltered outside air to the control room.

5. The spreading room supply and exhaust fans will be stopped and the battery rooms exhaust fan will continue to run.

6. Double isolation dampers in the spreading room fan supply duct and a single isolation damper in the exhaust fan duct will close to prevent infiltration of outside air to the spreading room.

7. Redundant isolation dampers close to prevent inflow of unfiltered air into the control room and spreading room from the normal path of induced fresh air.

8. The Auxiliary Building shutdown board room pressurizing fans (EL. 734') will be stopped to prevent in-leakage of unfiltered air from adjacent spaces into the Control Room.

Main CRI may be accomplished manually at any time by the control room operators.

The following safety related control building air-conditioning and ventilating system components are each provided with two 100-percent capacity units. Each meets the single failure criterion, and automatic switchover is assured if one of the units fail.

1. Main Control Room and electrical board room air-conditioning systems, refrigerant compressors, air handling units, and piping.

2. Main Control Room emergency air cleanup supply fans and filter assemblies.

3. Main Control Room emergency pressurizing air supply fans.

Fresh air, for control room emergency pressurizing, is taken from the outdoors from either of two intakes. One is located near the south end of the building roof at elevation 752 and the other is tied into the fresh air intake on the roof at the north end of the building.

All air-conditioning equipment, essential ventilating equipment, isolation dampers, and ducts are designed to withstand the Safe Shutdown Earthquake (SSE).

All air-conditioning and essential ventilating equipment are protected from the effects of a design basis tornado (Section 3.3.2), by dual tornado isolation dampers, located at all external openings to the Control Building.

9.4.1.2 System Description

The Control Building heating, ventilating, air-conditioning, and air cleanup systems are shown in Figure 9.4.1-1 and consist of the following systems:

1. MCR air-conditioning system and electrical board rooms air-conditioning system.

2. Main Control Room emergency air cleanup system.

3. Main Control Room emergency pressurizing system.

4. Battery room ventilating system.

5. Miscellaneous ventilating systems.

The Main Control Room air-conditioning system equipment is located in the mechanical equipment room at elevation 732 and serves the main control room, technical support center, and other rooms on that elevation. The electrical board rooms air-conditioning system equipment is located in the mechanical equipment room at the north end of elevation 669, and serves the battery rooms, battery board rooms, communications rooms, and other rooms on elevation 669, and the computer and auxiliary instrument rooms at elevation 685.

Each of the above two air-conditioning systems is provided with two parallel 100 percent capacity refrigerant condensing units, and two parallel 100-percent capacity air handling (fan-coil) units. The refrigerant condensing units in each equipment room are separated by a concrete partition. Each air-conditioning system is provided with an assemblage of air supply and return ducts, dampers, heaters, grilles, and controls.

Conditioned air is supplied by either one of the control room system air handling units to the main control room, the relay room, technical support center, and several small rooms at the elevation 732 floor. During normal operation fresh air flow is induced by the mechanical equipment room's negative pressure to replace that mechanically exhausted to the outdoors or supplied to the spreading room.

Conditioned air is supplied by either set of electrical board rooms air handling units to the air-conditioned rooms at the elevation 669 and elevation 685 floors. Fresh air flow is induced to replace that mechanically exhausted to the outdoors.

All air, fresh and recirculated, is filtered by passing through one of two-100 percent capacity filter banks provided for each air-conditioning system, one per air handling unit. This arrangement provides for one filter bank per air-conditioning system to be in continuous service while the other bank is on standby and available for servicing. Fresh air for the Control Building is passively taken from the outdoors through a penthouse located on the roof at the north end of the building. The air flow is induced by the exhaust fans located within the Control Building.

The control room air-conditioning system and the electrical board room air-conditioning system are each served by two separate full-capacity air cooling assemblies. Each assembly consists of

a helical screw-type refrigerant compressor with water-cooled condenser which is connected to a horizontal upblast type air handling unit containing direct-expansion air cooling coils and fans.

During normal operation, air exhausted to the outdoors by the building exhaust fans is replaced by a continuous stream of fresh air which is induced by the elevation 732 mechanical equipment's room negative pressure and the suction of the elevation 669 electrical board room's air handling unit.

During accident conditions, double isolation dampers automatically close to prevent the supply of fresh air to the main control room and spreading room floors. Induced air flow to the rooms of the lower floors are provided to replace the air exhausted from the battery rooms to maintain these rooms at a negative pressure relative to the Main Control Room.

The Main Control Room emergency air cleanup system is located within the mechanical equipment room at elevation 732. This system is provided with two parallel 100-percent capacity emergency air cleanup fans, and two parallel 100-percent capacity air cleanup filter / fan assemblies. Each air cleanup filter assembly consists of a bank of HEPA filters followed by a bank of charcoal adsorbers enclosed within a housing. Each housing is provided with static pressure differential indicators, thermometers, connections for in-place testing of filters and adsorbers, and access doors for filter and adsorber maintenance.

This system automatically operates upon a safety injection signal, a high radiation signal in the fresh air supply, or high temperature in the fresh air supply. Manual action by the operator, in lieu of the automatic control room isolation (CRI), is credited for CRI based on detection of smoke. This system can also be manually started from the Main Control Room at any time. Controls are provided to permit the control room operators to shut down either one of the redundant emergency air cleanup/pressurizing systems to keep it as a backup. The backup system automatically starts in the event the operating system fails. The same controls for operating one of the air cleanup units also operates the corresponding emergency pressurizing fan.

During air cleanup system operation, a portion of the control room air-conditioning system return air is continuously routed through one or both of the HEPA filter-charcoal adsorber trains and then to the system return air plenum. The cleaned air is then recirculated to the Main Control Room by the air-conditioning system.

The Main Control Room emergency air cleanup fans are the vane-axial type, each rated for 4000 cfm against 5.0-inch water gauge static pressure and are each direct driven by a 10-hp motor. These fans are redundant ESF equipment and are connected to separate divisions of the Emergency Power (EP) System.

The Control Building emergency air pressurizing supply fans are the centrifugal type, each having a capacity of 1000 cfm when used in conjunction with an air cleanup unit fan and are each driven by an approximate 0.25-hp motor. These redundant fans are ESF equipment and are connected to separate divisions of the EP System.

The fresh or pressurizing air is taken from either of two air intakes, one on the Control Building roof at elevation 752 near the south end of the building and the other is tied into the fresh air

intake at the north end of the building. Each emergency pressurizing fan is duct connected to both intakes. Each emergency pressurizing supply fan discharges to the control room air-conditioning system return air at a point upstream of the air cleanup filter assembly trains.

The Main Control Room is pressurized with filtered outdoor air during operation of the control room emergency air cleanup system. The maintenance of at least 1/8-inch w.g. positive pressure in the main control room relative to outside atmosphere and a slightly positive pressure relative to its surroundings and also, maintenance of a slightly positive pressure in other rooms in the habitability zone relative to adjoining spaces minimizes the in-leakage of unprocessed air.

The battery rooms ventilation system consists of three 100 percent capacity exhaust fans, with two on standby, discharging battery room air to the outdoors. Two fans are located on the elevation 669 floor near the north end of the building and one located on the elevation 706 floor near the south end of the spreading room. During control room isolation, a continuous stream of fresh air is drawn in through the electrical board room's air handling unit to replace that exhausted from each battery room.

The battery room exhaust fans are the centrifugal type, each rated 2000 cfm against 1.5 inch water gauge static pressure and are each direct driven by 1.5 hp motor.

The battery rooms ventilation system is required to operate at all times, except during the design basis flood, and are under administrative operational control. These three fans are ESF equipment and are connected to the EP System. The fans will be disconnected from the Class 1E power system before they are flooded.

The spreading room is ventilated by one of two spreading room exhaust fans located at the south end of the spreading room at elevation 706. These 100 percent capacity fans each exhaust to the outdoors. One spreading room supply fan, located in the mechanical equipment room at elevation 732, supplies air to the spreading room.

The spreading room supply fan is a centrifugal type, rated for 3200 cfm against 1.25 inch water gauge static pressure and is belt driven by a 1.5 hp motor. The spreading room exhaust fans are the centrifugal type, each rated for 2500 cfm against a 1.0 inch water gauge static pressure and are each belt driven by a 1.5 hp motor. These fans are not connected to the EP System. During control room isolation the spreading room supply and exhaust fan are cut off and isolation dampers close to prevent leakage of unfiltered air into the control room.

The mechanical equipment room at elevation 732 is normally ventilated by the passage of air-conditioning system return air to the system air handling unit and to the spreading room supply fan. During an accident, a portion of the control room air-conditioning system return air is routed through the mechanical equipment room to the system air handling unit and to the air cleanup fans.

The mechanical equipment room at elevation 669 is ventilated at all times by routing a portion of the electrical board rooms air-conditioning system supply and return air through the room to the air-conditioning return air duct.

The toilet, kitchen, and locker rooms at elevation 732 are ventilated by exhausting a portion of the control room air-conditioning system return air through the rooms. The toilet and locker

rooms exhaust fan is located in the elevation 732 mechanical equipment room and discharges to the outdoors.

The toilet and locker rooms exhaust fan is a centrifugal type, rated for 1200 cfm against 1.0 inch water gauge static pressure and belt driven by a 0.75 hp motor. This fan is not connected to the EP System. During control room isolation the toilet and locker rooms exhaust fan is shutdown and double isolation dampers close to prevent leakage of unfiltered air into the control room.

9.4.1.3 Safety Evaluation

The Control Building air-conditioning systems are redundant ESF, and each full-capacity compressors and air handling units is served from separate trains of the EP System and from coordinated separate loops of the Essential Raw Cooling Water (ERCW) System.

All Main Control Room equipment will operate normally within the rated temperature range as described in Section 3.11. At temperatures above 104°F, failure rates for this control room equipment may tend to rise somewhat and some instrumentation inaccuracies may arise. The full-capacity air-conditioning system redundancy discussed above, however, reduces the probability of overtemperature operations to acceptably small values. Loss of ventilation problems are discussed further in Section 3.11.3.

The Control Building tornado dampers protect the building environment from depressurization during a tornado. Indications in the MCR and elevation 732 mechanical equipment room will confirm that the dampers have closed. Tornado dampers located in areas exposed to freezing weather conditions can be monitored to ensure their closing; however, a tornado occurring during freezing weather conditions is unlikely. Motive power to the tornado dampers is normally de-energized to prevent spurious isolation of flowpaths needed for emergency pressurizing system operation.

The air cleanup equipment installed to purify air supplied to the main control room during emergencies was designed in accordance with accepted ESF design practices. As a result, good general agreement with Regulatory Guide 1.52 standards for air cleanup equipment is achieved. Details on this compliance are given in Table 9.4.1-1.

Each of the Control Building emergency air cleanup filter trains consists of a bank of four HEPA filter cells rated at 99.97 percent efficiency based on DOP test and designed for use in temperatures up to 250°F and a relative humidity of 90 percent. These filters are mounted in series with a bank of 12 carbon adsorber modules rated at 95 percent efficiency for removal of elemental iodine and 95 percent efficiency for removal of methyl iodide. Each HEPA filter cell is rated for an initial resistance of 1.0 inch water gauge when clean and should be replaced with new filter cell upon an increase in combined resistance of the HEPA and charcoal absorber banks to 3.0 inches. Static differential pressure gauges are provided to indicate filter band differential pressure.

For discussions on radioactivity dose levels and detection of airborne contaminants, refer to Section 6.4, Section 12.2.4, and Section 15.5.3.

9.4.1.4 Tests and Inspection

The Control Building emergency air cleanup and pressurizing air supply systems are periodically inspected and tested in accordance with plant Technical Specifications.

HEPA filters are tested in place initially and periodically with DOP. The charcoal adsorbers are tested initially and periodically with Freon. Charcoal surveillance specimens are periodically evaluated to assure iodine adsorptivity. These tests are performed in accordance with plant Technical Specifications.

The air-conditioning system filter cells shall have their filtering media replaced upon a resistance buildup to 1 inch water gauge static pressure differential.

9.4.2 Auxiliary Building

9.4.2.1 Design Bases

The Auxiliary Building ventilating systems serve all areas of the Auxiliary Building including the radwaste areas and the fuel handling area. Separate subsystems are utilized for the environmental control of the shutdown board rooms, auxiliary board rooms, and other miscellaneous rooms and laboratories. The ventilating systems also incorporate individual cubicle coolers to provide supplementary cooling to specific safety feature equipment.

The Auxiliary Building ventilating systems are designed to maintain acceptable environmental conditions for personnel access, operation, inspection, maintenance, testing and protection of mechanical and electrical equipment, and controls and to limit the release of radioactivity to the environment during all weather conditions. These building environmental controls systems maintain the building temperatures with limits (Section 3.11). For outdoor design conditions, see Section 9.4.

The Auxiliary Building is considered divided into five separately controlled and isolated types of areas as follows:

1. The fuel-handling area at elevation 734; the penetration rooms at elevation 734 and elevation 759; and the fuel, waste and cask handling areas at elevation 706 and elevation 669, and the unit 1 ESF pump rooms.

2. The General Building and penetration room areas at elevation 653, elevation 669, elevation 690, elevation 714, and Unit 2 ESF pump rooms.

3. The shutdown board, auxiliary control, and battery board rooms at elevation 734, and auxiliary board room and battery rooms at elevation 749.

4. The shutdown board transformer rooms at elevation 749.

5. The Reactor Building steam valve rooms.

To control airborne activity, the ventilation air is supplied to clean areas, then routed to areas of progressively greater contamination potential. Areas of the building which are subject to

radioactive contamination are maintained at a slight negative pressure to limit out-leakage. In addition, the system has the capability of isolating the contaminated areas from the outdoors. During non-accident operation, air is discharged into the Auxiliary Building exhaust stack which is located atop the Auxiliary Building, and extends above the roof.

The Auxiliary Building Gas Treatment (ABGT) System is discussed in Section 6.2.3.

9.4.2.2 System Description

The Auxiliary Building ventilation systems are shown on Figures 9.4.2-1 through 9.4.2-5.

The Auxiliary Building ventilation and cooling systems consist of the following subsystems:

1. Building air supply and exhaust system (general ventilation).

2. Building cooling system (chilled water).

3. Safety feature equipment coolers.

4. Shutdown board room air-conditioning system.

5. Auxiliary board room air-conditioning system.

6. Shutdown transformer room ventilation system.

7. Miscellaneous ventilation and air-conditioning systems.

9.4.2.2.1 Auxiliary Building Air Supply and Exhaust Systems (General Ventilation)

This system is non safety related except as necessary for Auxiliary Building Isolation and ABGTS operation (see section 6.2.3). The supply system filters 100 percent of outdoor air through a bank of filters for each of two mechanical equipment rooms located at opposite ends of the building at elevation 714. The filters have a nominal efficiency of 85 percent based on the NBS atmospheric dust spot test.

During heating season, hot water can be supplied to heating/cooling air intake coils to temper the incoming air.

During cooling season, chilled water can be supplied to heating/cooling air intake coils to increase cooling capacity of ventilation air. During moderate ambient temperatures, unconditioned air is supplied.

The air supply system utilizes four 50 percent capacity supply fans with two located in each of the two mechanical equipment rooms at elevation 714. During normal operation, one fan in each equipment room is in operation with the other fan in the standby mode.

Fan inlet dampers can be manually operated to reduce the volume of supply air such as during low outdoor temperature conditions to conserve heat. Supply air is ducted to various clean or

accessible areas of the Auxiliary Building and fuel handling areas from where it flows to areas of progressively greater contamination potential before being exhausted through a duct system by the building exhaust fans.

The building supply fans are belt-driven centrifugal type located downstream of the heating/cooling coils. Each fan is rated at 100,000 cfm at 5.75 inch water gauge static pressure. Each fan is driven by a nominal 150 hp motor. These fans are not ESF equipment and are not energized from emergency power.

The general exhaust from the Auxiliary Building is provided by four exhaust fans each rated at 50 percent of system capacity. These fans are controlled in blocks of two; during normal operations two fans are in operation and the remaining fans are in the standby mode. These fans are located on the roof of the Auxiliary Building and discharge into the Auxiliary Building exhaust vent.

Air utilized to ventilate the fuel handling area, waste packaging area, unit 1 ESF pump rooms, and cask shipping area is exhausted by the fuel handling area exhaust fans. An exhaust duct system from the waste packaging area and cask loading area is connected to a duct system around the periphery of the spent fuel pit and fuel transfer canal.

Thus, exhaust air from the fuel handling area passes across the spent fuel pit forming an air curtain across the pool. Two 100 percent capacity fuel handling area exhaust fans are provided. Pre-filters and HEPA filters are installed in the filter plenum room located on elevation 749 for Fan A prior to fan discharge. Fan B has no filter plenum or filters installed. Both fans discharge to the Auxiliary Building exhaust stack. During normal operation either fan may be used, however, during an outage or periods when maintenance is being performed in the transfer canal it is preferable that Fan A be used since it provides the only filtered exhaust path.

An inlet damper, furnished with each Auxiliary Building exhaust and fuel handling area exhaust fan, is used to regulate the volume of air exhausted as required to maintain 1/4 inch water gauge negative pressure within the building. These dampers are automatically operated by static pressure controllers.

Upon smoke detection within the Auxiliary Building general air supply ducts, the Auxiliary Building general supply and exhaust fans and the fuel handling exhaust fans are automatically stopped.

During periods of high radiation detected in the Auxiliary Building exhaust vent monitor or fuel handling area radiation monitor, upon initiation of a containment isolation signal or a high temperature signal from the Auxiliary Building air intakes, the Auxiliary Building supply and exhaust fans and the fuel handling exhaust fans are automatically stopped. Low leakage dampers located in the ducts which penetrate the Auxiliary Building are closed. An isolation barrier is thus formed between the building and the outdoor environment, and the ABGT System is placed in service (see Section 6.2.3).

The Auxiliary Building exhaust fans are belt-driven centrifugal type rated at 84,000 cfm each at 6 inch water gauge static pressure. Each fan is driven by a nominal 125-hp motor.

The fuel handling exhaust fans are belt-driven centrifugal type rated at 60,000 cfm at 7 inch water gauge static pressure. Each fan is driven by a nominal 100 hp motor. These fans can be energized by emergency power since they are required to operate under certain conditions when normal power is unavailable.

9.4.2.2.2 Building Cooling System (Chilled Water)

The purpose of the non safety related auxiliary building cooling system is to supplement the general ventilation system and to maintain a more comfortable temperature in Auxiliary Building general spaces at conditions other than design maximum.

The building cooling system consists of two 100 percent capacity packaged water chillers, two 100 percent capacity primary loop circulating pumps, two 100 percent capacity secondary loop circulating pumps, six fan-coil type air handling units, and associated piping, duct work and controls.

Primary and secondary chilled water circulating loops are designed for mixing supply and return water to obtain a variable coil inlet temperature, mainly 47°F to 72°F, to minimize unnecessary latent heat removal. The primary loop pump provides circulation of water through the water chiller, whereas the secondary loop pump circulates chilled water to air intake heating/cooling coils and also to the six air handling units located in various areas where ventilation air alone is not sufficient to maintain the 104°F maximum space temperature.

The chilled water system is designed for manual startup with automatic mixing of primary and secondary loop flows by means of thermostatically controlled three-way control valves. Flow to heating/cooling coils and to air handling units is individually controlled at each terminal unit by three-way modulating control valves. The seasonal change over from heating to cooling or from cooling to heating is done by the manual operation of system valves.

During outages the chilled water system may be used to temporarily cool the lower containment area by providing the medium to cool the normally supplied cooling water i.e., the Essential Raw Cooling Water (ERCW) to the lower compartment coolers via a temporary heat exchanger.

9.4.2.2.3 Safety Feature Equipment Coolers

Cubicles or areas containing engineered safety feature equipment are ventilated by the non safety related auxiliary building ventilation exhaust system during normal plant operation or when the equipment is not required to operate. Safety related air cooling units, located in each cubicle or area, will automatically start to provide necessary cooling, depending on its specific logic, whenever an ABI occurs or the safety feature equipment is operated or when the room temperature exceeds the thermostat setpoint. Each of these coolers is designed to maintain the room temperature within the required limits (see Section 3.11). The pump room coolers 1 thru 4 listed below are interlocked to operate with the equipment they serve. A thermostat, located near the return airflow to each cooler, allows the cooler to remain in operation until the low limit temperature set point is reached. The cooling water control valve and fan are interlocked to operate together except for the RHR and CCP pump room cooler control valves which are failed open.

Air cooling units are provided for the following equipment and areas:

1. RHR pumps.

2. Safety injection pumps.

3. Containment spray pumps.

4. Centrifugal charging pumps.

5. Deleted.

6. Unit 1 auxiliary feedwater and component cooling water pumps.

7. Unit 2 auxiliary feedwater and boric acid transfer pumps.

8. Component cooling water booster and spent fuel pit pumps.

9. Pipe chases.

10. Elevation 669 penetration rooms.

11. Elevation 690 penetration rooms.

12. Elevation 714 penetration rooms.

13. Emergency gas treatment filters.

The above pumps 1 through 4 are each located in a separate room with a single cooler, and each room (containing pump and cooler) is provided with another opposite train room and cooler for 100 percent redundancy. Pumps and equipment 6 through 13 are each provided with two 100-percent redundant coolers.

The air flow paths for each of the coolers is shown in Figure 9.4.2-3. The ERCW is discussed in Section 9.2.

9.4.2.2.4 <u>Shutdown Board Room Air-Conditioning System</u>

The shutdown board rooms are located on elevation 734 of the Auxiliary Building. The boards in either unit can provide the service necessary for the safe shutdown of both plant units following an accident in either unit.

Environmental control for the auxiliary control room is maintained by the safety related shutdown board room air-conditioning system. Each of the four shutdown board room air-handling units is arranged so that any one of the four units can provide the necessary cooling required by the auxiliary control room. A duct heater, provided in the supply duct to the room, provides heating and/or humidity control as required to maintain the design ambient conditions. Each shutdown board room air-conditioning system is connected to coordinated emergency power and water supply source trains.

The pressurizing fans pressurize the shutdown board rooms and auxiliary control room with filtered air to prevent infiltration of contaminated plant air from adjacent areas except during Control Room Isolation.

9.4.2.2.5 <u>Auxiliary Board Rooms Air-Conditioning Systems</u>

The Auxiliary Board Rooms, located at floor elevation 749 are separated into four sub-areas corresponding to the unit and train emergency power supply. Four separate safety related air-conditioning systems are provided. One in each of the four plant sub-areas. Following an accident, the train A or train B boards have the capability for the safe shutdown of the unit.

The attendant air-conditioning equipment for each sub-area, sized to remove 100 percent of heat produced by electrical equipment in that subarea, are therefore redundant. The four Auxiliary Board Room Air-conditioning units normally cool the four sub-areas (Train A and B areas of Units 1 and 2) individually. A connecting duct ties together the Train A air-conditioning discharge headers from both Units 1 and 2. A similar connecting duct ties together the Train B air-conditioning discharge headers from both Units 1 and 2. These connecting ducts have normally closed isolating dampers and fire dampers to provide for unit separation. If an air-conditioning unit is unavailable, the connecting duct can be used to support the cooling of the two connected sub-areas. This is done manually by isolation damper re-alignment and by adjusting the throttled position of a damper installed at each header discharge point for the required flow. Thus, the four sub-areas can be cooled by as few as two air-conditioning units.

The train A air-conditioning equipment is located within the elevation 749 mechanical equipment room. The train B air-conditioning equipment is located on the 763 roof above within a housing for protection from outdoor environmental hazards.

Each board room air-conditioning system contains a refrigerant compressor, air-cooled condenser, a fan-coil air handling unit with direct-expansion cooling coil(s), two 100 percent pressurizing air supply fans, air supply distribution system, and control and safety devices.

Two 100 percent capacity safety related roof ventilator exhaust fans located on the roof of each of the four separate battery rooms on elevation 749 provide continuous ventilation to prevent the possible accumulation of dangerous hydrogen gas.

The two 100 percent capacity safety related pressurizing air supply fans per air- conditioning system serve a twofold purpose. One is to replace a portion of air-conditioning system air exhausted through the battery room and the other is to pressurize the board room to prevent infiltration of contaminated plant air from adjacent areas. The mixture of this makeup air and board room return air is conditioned upon passing through the air handling unit.

One pressurizing air supply fan and one battery room exhaust fan in each individual air-conditioning system are connected to train A power with the other fan pair connected to train B power. Control system interlocks provide simultaneous operation of the pressurizing air supply fan and battery room exhaust fan. The availability of this fan combination on either power train ensures continuous ventilation in each battery room regardless of operability of the direct-expansion air-conditioning equipment. In the event of air-conditioning system failure, pressurizing fan air is drawn through the normal board room supply ducts by the battery room exhaust fan.

Condensing unit cooling air for the train A air-conditioning system of each plant unit is routed from intakes located on the roof, elevation 763, through the condenser and discharged through a roof-mounted exhaust housing. The train B system condenser cooling air is drawn through an intake on the side of the equipment housing on the roof and is discharged through an exhaust opening atop the equipment housing.

Dampers capable of withstanding pressure differentials between areas of the elevation 749 board rooms and mechanical equipment rooms and the outside environment under tornado conditions are located in the intake and exhaust connections for each of the train A air-cooled condensers.

Each battery room exhaust fan has a damper capable of withstanding pressure differentials imposed by tornado conditions. The dampers are mounted below the fans at elevation 763. Small ventilation holes are provided in damper frame between exhaust fan and tornado damper to allow continuous venting of hydrogen gas even when the damper is closed. Each of these dampers is remote manual operating and will be closed upon tornado alert.

For additional tornado protection, the train B air handling unit intake and discharge ducts, located in the rooftop housing, are capable of withstanding a minimum pressure differential of 0.5 lb/in^2 with the higher pressure being inside the duct.

9.4.2.2.6 Shutdown Transformer Room Ventilating Systems

The shutdown transformers, located on elevation 749, are divided into two sub-areas with seven transformers in each sub-area. These sub-areas are further divided into two enclosed areas with train A emergency power available to one transformer grouping and train B emergency power for the other.

Outside air enters each sub-area through air intake structures located on the Auxiliary Building roof. Each safety related roof-mounted ventilator type exhaust fan is energized by thermostatic control according to room temperature rise. Activation of a single ventilation fan will in turn open dampers in both air intake structures. Upon continued increase in room temperature, the remaining exhaust fans are energized in staged series sequence until all available fans are in operation.

Individual fans may be manually stopped if room temperature is below setpoint. Manually stopping the fans shall not interfere with automatic fan start upon future increasing room temperature.

The transformer room motor-operated air intake dampers have the capability of being remote manually powered to the open position without regard to thermostatic control following tornado alert.

This ventilation system is designed to maintain the temperature in the transformer rooms within the range from 15°F minimum and 97°F for which the equipment is environmentally qualified.

9.4.2.2.7 Miscellaneous Ventilation and Air-Conditioning Systems

The control rod drive equipment room has two 100 percent capacity non safety related air-conditioning units located within each room per plant unit that are cooled by Raw Cooling Water. During normal operation, one air-conditioning unit in each room is in operation with one on standby. Each unit is automatically controlled by a self-contained thermostat. Electric unit heaters are located in each room to maintain the room at 60°F, during heating season.

The instrument shop air-conditioning unit is non-safety related and utilizes 100 percent makeup air thus preventing the recirculation of any possible contaminant. The hot instrument shop ventilation is provided by a lab hood exhaust fan which discharges to the General Building Exhaust Duct System.

The sample room is ventilated by five non-safety related lab hoods with exhaust fans. Three fans are located on unit 1 side and two fans are located on unit 2 side. Air enters the sample room through doors with transfer grilles and back draft dampers. Each hood is provided with a separate exhaust fan and HEPA filter assembly. A differential pressure gauge is used to indicate the need for filter replacement. Each hood exhaust fan discharges into the Auxiliary Building General Exhaust System.

The turbine-driven auxiliary feedwater pump rooms are normally ventilated by the Auxiliary Building air exhaust system. Each room is provided with two roof ventilator type exhaust fans located on the roof. One of these two fans per room is quality related and designed to operate on 115 volt, 60 Hz alternating current emergency power while the other is safety related and designed

for 115 volt direct current station vital battery power. Both fans per room are thermostatically controlled to automatically operate upon room temperature rise. The direct current powered fan will also automatically run upon pump start and is designed to circulate a sufficient quantity of building air through their rooms to limit the maximum temperature (see Section 3.11).

The waste gas analyzer room is located in the sample room on unit 2. Air enters the waste gas analyzer room through a door with a transfer grille and a backdraft damper. Air is exhausted into the suction of both sample room exhaust fans on unit 2 and filtered through the sample room hood exhaust HEPA filter before being discharged into the Auxiliary Building General Exhaust Duct System.

The Reactor Building steam valve vault rooms each have an independent ventilation system consisting of two non safety related roof mounted exhaust fans. Each exhaust fan starts independently in response to temperature setpoints on individual thermostats. The fans draw outside ventilation air for room cooling through wall opening(s) near the floor. Space temperature control is maintained by inlet vanes which modulate airflow in response to a pneumatic temperature controller.

9.4.2.3 Safety Evaluation

The Auxiliary Building supply inlets are located near ground level on each side of the building. The inlet area is of sufficient size to limit the incoming air stream velocity to approximately 500 fpm. The building air supply filters are rated 85 percent efficiency based on NBS atmospheric dust spot test.

Auxiliary Building fuel handling areas, Reactor Building penetration rooms and other spaces located below elevation 734 are continuously maintained at a slight negative pressure relative to outdoors to minimize out-leakage. During normal operations, these spaces are exhausted to the outdoors. During accident conditions, the ABGT System operates to exhaust a reduced quantity of air from the Auxiliary Building Secondary Containment Enclosure through HEPA filters and charcoal adsorbers before release to the environs.

Each ABGTS filter bank is provided with a static pressure differential indicating gauge. ABGTS HEPA filter cells are rated for an initial resistance of approximately 1.0-inch water gauge when clean and should be replaced upon an increase in combined resistance of the HEPA and charcoal adsorber banks to 3.0 inches.

To guarantee proper operation of steam relief valves during plant operation, the steam valve room exhaust air dampers modulate in response to a pneumatic temperature controller to ensure that room ambient temperatures do not fall below 80°F during the heating season. In the event extreme outside winter time conditions result in room temperatures falling below 80°F, the fans are automatically shut down.

9.4.2.4 Inspection and Testing Requirements

The Auxiliary Building Environment Control Systems and ABGTS are accessible for periodic inspection and tested initially and periodically.

ABGTS HEPA filter and charcoal absorber cells are tested in place initially and periodically in accordance with Tech. Specs.

9.4.3 Radwaste Area

9.4.3.1 Design Bases

The Auxiliary Building ventilating systems serve all of the radwaste areas which are physically located within the Auxiliary Building at elevation 706, 690, 669, and 653. These areas are continuously ventilated, and the exhaust air is released to the atmosphere.

The Auxiliary Building is continuously maintained at a slight negative pressure relative to the environment to minimize exfiltration of air. A radiation-monitoring system is provided to detect and annunciate high activity in the auxiliary building exhaust and provides for Auxiliary Building Isolation.

9.4.3.2 System Description

The Auxiliary Building radwaste area ventilating systems are shown on Figure 9.4.2-1, 9.4.2-4, and 9.4.2-5

Filtered and heated or cooled (if necessary) fresh air is mechanically supplied to the general occupied or accessible areas of each floor by the Auxiliary Building main air supply system. Air is mechanically exhausted from each radwaste equipment room and directly from individual radwaste tanks, sumps, and equipment by the Auxiliary Building Main Exhaust System. All exhaust air is routed through duct to the building exhaust stack.

9.4.3.3 Safety Evaluation

Refer to Auxiliary Building FSAR Section 9.4.2.3.

9.4.3.4 Test and Inspection Requirements

Refer to Auxiliary Building FSAR Section 9.4.2.4.

9.4.4 Turbine Building

9.4.4.1 Design Bases

The Turbine Building Heating, Cooling, and Ventilating Systems are designed to maintain an acceptable building environment for the protection of plant equipment and controls; for the comfort and safety of operating personnel; and to allow personnel access for the operation, inspection, maintenance, and testing of mechanical and electrical equipment. These systems are non-safety related.

9.4.4.2 Ventilation

The building can be considered to contain four large rooms: elevation 732.0 turbine room, elevation 706.0 spaces, elevation 685.0 spaces, and elevation 662.5 spaces. Because elevation

732.0 floor is predominantly concrete and thus isolated from the remaining floors below, the Turbine Building ventilation is provided by two separate systems. One system serves elevation 732.0 spaces, and the other system provides ventilation for the spaces on elevation 706.0 and elevation 685.0, with no direct ventilation provision for spaces on elevation 662.5.

Basically, both ventilation systems operate on the basis of mechanically supplying a continuous flow of outside air to spaces being ventilated, and exhausting the building air to outdoors.

Each supply and exhaust fan, except the lube oil purification exhaust fan, is provided with a motor operated damper designed to automatically close when fan is stopped to prevent air backflow.

Outside air is distributed to areas of heat concentration either by duct distribution systems, or is induced, by the negative pressure caused by operation of roof exhaust fans, through strategically located air intake openings.

9.4.4.2.1 Elevation 732.0 Ventilation

Ventilation system for elevation 732.0 consists of two mechanical air supply systems, one on the east side and the other on the west, free-air- intake openings on the north and south walls, and exhaust fans on the elevation 797.0 roof. Total air exhausted is approximately 570,000 cfm, whereas only approximately 206,000 cfm is mechanically supplied through supply ducts. The remaining air is drawn through the north and south free-air-intake openings by the negative pressure created by the operation of exhaust fans. Two centrifugal, belt-driven, two-speed supply fans located in the elevation 773.0 fan rooms, deliver air to the east side of the elevation 732.0 room through two separate duct systems. Two centrifugal, belt-driven, two-speed supply fans, located in elevation 732.0 fan room, supply air to the west side of the elevation 732.0 room through two separate duct systems.

Ten centrifugal belt-driven roof ventilator fans and ten roof ventilator fans together exhaust a total of approximately 570,000 cfm building air.

During cold weather, all intake and exhaust openings can be closed off by motor-operated dampers to conserve heat. The building may also be kept under a slight positive pressure to prevent infiltration of cold air by keeping the east elevation 685 floor supply fans running at half speed. Hot water heating coils installed in the ducts are designed to heat the incoming outside air to 60 degrees F.

9.4.4.2.2 Elevation 706.0 & Elevation 685.0 Ventilation

Elevation 706.0 and elevation 685.0 ventilation system consists of two mechanical air supply systems, one on the east side and the other on the west, and exhaust fans on the roof; elevation 732.0. A total of approximately 412,000 cfm is supplied and exhausted.

Four centrifugal, belt-driven, two-speed supply fans, located in elevation 773.0 fan room, deliver equal quantities of air to the east side of elevation 706.0 and elevation 685.0 rooms through four independent duct systems. Four centrifugal, belt-driven, two-speed supply fans, located in the elevation 732.0 fan rooms, deliver equal quantities of air to the middle of elevation 706.0

and elevation 685.0 rooms through four independent duct systems. Thirty-six propeller fans, installed in pairs in exhaust housings on the roof, elevation 732.0 exhaust air from the two floors below.

During cold weather, all supply and exhaust systems can be closed off by motor operated dampers to conserve heat. The two supply fans serving east elevation 685.0 floor may be operated at half speed since two hot water heating coils located in the supply duct connected to each of these fans are designed to heat the incoming air. With no exhaust fan running, the operation of these two supply fans will pressurize the entire Turbine Building to prevent infiltration of cold outside air.

9.4.4.2.3 Miscellaneous Ventilating Systems

The lubricating oil purification room at elevation 685 is ventilated by a centrifugal fan mounted on the room roof which discharges to the outdoors by means of a duct routed to a basement exhaust housing.

The lubricating oil dispensing room at elevation 706 is ventilated by a wall-exhauster type fan, and approximately 300 cfm is exhausted through the room.

The condenser vacuum exhaust bypass system, located on elevation 732.0, can be used to filter noncondensibles from the main condenser in order to minimize the releasing of radioactive particles and gases to the atmosphere. It consists of HEPA and charcoal filters (optional) in series. Refer to Section 10.4.2.

9.4.4.2.4 Coolers

To supplement the turbine building ventilation systems during peak cooling load conditions, fan-coil type raw water cooled cooling units have been installed. Each cooling unit consists of a centrifugal fan and its motor, and a finned tube type water coil through which raw cooling water is circulated and over which air is passed and cooled. Space coolers are located on floors elevation 706.0, elevation 685.0, and elevation 662.5. A thermostat, located near the return airflow to each cooler, controls a solenoid valve on the raw cooling water supply line to coil, and the cooler fan. Solenoid valve and fan on each cooler are interlocked to operate together.

Pumps and fans of the coolers assigned to them are interlocked to run simultaneously. Raw cooling water to each cooling coil can be turned off and on manually to conserve water during off times. These coolers are not controlled thermostatically.

9.4.4.2.5 Building Heating System

The Turbine Building is heated by thermostatically controlled unit and hot water space heaters strategically located throughout the building.

A portion of the fresh air supply to the elevation 685 floor is heated by thermostatically controlled duct-mounted heating coils.

The heating system is a medium-temperature hot water, closed, forced- water loop. The system consists of an assemblage of two 100-percent capacity water circulating pumps, two 70-percent

capacity steam to water heat exchangers, tanks, heating coils, space and unit heaters, nitrogen pressurization, demineralized water makeup, chemical treatment, controls, and supply and return water distribution piping. Steam is normally taken from the turbogenerator cold reheat cycle during operation of either unit, or is taken from the plant auxiliary boiler during plant shutdown or when both units are operating at low power.

The heating system heat exchangers, pumps, and tanks are located at elevation 706 along the east end of unit 2.

The Auxiliary Building air preheating portion of this heating system consists of a secondary forced-water loop system for each plant unit containing pump and 3-way temperature controlling valve. The valve is thermostatically controlled to supply outdoor air heated to approximately 60°F.

9.4.4.3 Safety Evaluation

The Turbine Building Ventilating and Heating Systems are designed to assure their reliable operation during normal plant operation and are not safety-related. The free air intake dampers, located along the north and south walls of the elevation 732.0 turbine room are designed to open if a power failure occurs. There is no safety-related equipment located in their immediate vicinity. If they become frozen open during winter, they may be manually deiced and closed.

9.4.4.4 Inspection and Testing Requirements

The Turbine Building Environment Control Systems are accessible for periodic inspection and tested initially and periodically as necessary.

9.4.5 Diesel Generator Building

9.4.5.1 Design Bases

The Diesel Generator Building Ventilating Systems are designed to maintain an acceptable building environment for the protection of the diesel generators, electrical boards and equipment, and for the safety of operating personnel.

Each diesel generator unit room is separately ventilated to limit the room maximum ambient temperature to 120°F when the entering air is 97°F and the diesel generator is operating.

The electrical board rooms are ventilated to limit the room ambient temperature to 104°F when the entering air is 97°F.

9.4.5.2 System Description

The Diesel Generator Building Heating and Ventilating Systems are shown on Figures 9.4.5-1.

Two diesel generator room exhaust fans and one electrical board room exhaust fan are located in the fan room at elevation 740.5 for each of the four diesel generator units. These centrifugal type exhaust fans discharge to the outdoors. One generator

and electrical panel ventilation fan is provided within each diesel room at the air supply opening to the room to deliver cooling air to the generator air intake and to the interior of the generator's electrical control panel. The original battery hood exhaust fans have been isolated from the system and abandoned in place.

Each of the diesel generator room fans is connected to its respective diesel generator engineered safety power supply. One exhaust fan will automatically start upon diesel generator start. The generator and electrical panel ventilation fan will run when the diesel is running. Approximately 40,000 cfm of fresh air is routed through each diesel generator room when one exhaust fan is operating.

Each diesel generator unit is provided with a fan designed to exhaust approximately 3500 cfm of air from the elevation 740.5 electrical board room. A roof mounted air intake admits outdoor air to each electrical board room. Other building exhaust fans provide ventilation for the lubricating oil storage room, fuel oil transfer room, CO_2 storage room, toilet room, radiation shelter room, and muffler rooms.

The oil and storage rooms are normally ventilated at all times while the electrical board rooms and muffler rooms are ventilated as required to remove heat during warm weather. However, the CO_2 and lube oil storage room, diesel generator rooms and electrical board rooms exhaust fans are stopped during a CO_2 initiation.

Each exhaust fan and the corridor air intake vent is provided with motor-operated shutoff dampers designed to close tight when the fan is not running.

A backdraft damper is installed in the duct between the air intake room 1A-A and the CO_2 storage room in order to prevent CO_2 backflow into the diesel generator air intake room in the event of a CO_2 system rupture.

Thermostatically controlled electric unit heaters are located within the diesel generator rooms, equipment access corridor, storage rooms, radiation shelter room, and electrical board rooms. These heaters are designed to maintain the rooms at not less than 50°F when 15°F outdoors.

Thermostats in each air exhaust room are designed to stop all operating diesel generator room fans upon a drop in room exhaust air temperature to below 68°F if the diesels are not running. The thermostats will automatically start the exhaust fans upon room temperature rise to 90°F. The thermostats will also start the standby exhaust fan, during diesel operation, when the room exhaust air temperature exceeds 90°F.

In the case of a tornado event the Diesel Generator Room Air Intake Dampers are opened by manual action as noted in section 3.3.2.2. For damper control see Figure 8.3.1-14.

9.4.5.3 Safety Evaluation

The Diesel Generator Ventilating Systems are required to operate for maintenance of plant safety in the event of natural disasters or plant accidents. The diesel units are redundant to each other and the diesel generator room main exhaust fans for each diesel unit are provided in pairs for reliability.

In the diesel generator building, the diesel generator room exhaust fans, electrical board room exhaust fans, and the generator and electrical panel ventilation

fans are designed to quality assurance and seismic category I requirements. (With the exception of the CO_2/fire protection electrical control interlocks). All these fans are connected to ESF power.

9.4.5.4 Test and Inspections

The Diesel Generator Building Ventilating and Heating Systems are accessible for periodic inspection and tested initially and periodically.

9.4.6 Condensate Demineralizer Building Environmental Control System

9.4.6.1 Design Basis

The Condensate Demineralizer Building (CDB) Environmental Control System (ECS) is a non-safety related system designed to supply an acceptable ventilation air flow to the CDB continuously and to supply increased air flow for heat removal as necessary. All cooling needs within the building are accomplished with ventilation air flow.

Heat is supplied by duct and space electric heaters when required. The duct heaters are interlocked with supply fans to prevent their operation upon fan failure. The heaters are designed to maintain the building at 50°F or higher except in the condensate polisher rooms where freeze protection is the design basis.

Supply and exhaust ductwork is designed in accordance with the SMACNA Low Pressure Duct Standard.

Air flow is from areas of lower radioactivity potential to areas of greater radioactivity potential. There is no requirement for exhaust monitoring or filtration.

9.4.6.2 System Description

Air is supplied to the building through air intakes located on floor elevation 706. An air intake is located in the north wall and auxiliary air intakes are located in the south and west walls. Air supplied through the air intake in the north wall and the auxiliary air intake in the south wall is ducted to the required release points throughout the building. Air supplied through the auxiliary air intake in the west wall is blown directly into the valve gallery.

Air is exhausted through two roof exhaust fans located on elevation 729 over the valve gallery. An additional roof exhaust, located on elevation 729, is connected by ductwork to tank rooms and the hall on elevation 685, and to the high crud filter room, condensate polishers rooms, and cation and anion tank rooms on elevation 706.

The CDB ECS uses two speed fans only. Main CDB control panel controls set the fans to automatic operation, high or low speed operation, or the off position. In the automatic mode of operation outdoor air temperature controls fan speed. When a fan is started its respective outdoor damper is opened. All air intake and exhaust dampers are spring loaded to fail closed.

Duct and space electric heaters operate to keep the building temperatures above 50°F. At low outside air temperature, the air intake and exhaust fans can operate at half speed and

approximately one third of the air flow can be recirculated building air. When the outside air temperature is higher, both the intake air fan and the exhaust fan can begin full speed operation.

9.4.6.3 Safety Evaluation

No nuclear safety-related systems or components are located in the Condensate Demineralizer Building. The CDB ECS is not safety related. Therefore, a single failure within the ECS will not affect nuclear safety.

9.4.6.4 Inspection and Testing Requirements

Satisfactory operation of the CDB ECS will demonstrate the system capability.

9.4.7 Reactor Building Purge Ventilating System

9.4.7.1 Design Bases

The Reactor Building Purge Ventilating (RBPV) System is designed to maintain the environment in the primary and secondary containment within acceptable limits for equipment operation and for personnel access during inspection, testing, maintenance, and refueling operations, and to limit the release of radioactivity to the environment.

The design bases include the provisions to:

1. Supply fresh air for breathing and contamination control when the primary or annulus secondary containment is or will be occupied.
2. Exhaust primary or annulus secondary containment air to the outdoors whenever the purge air supply system is operated.
3. Cleanup containment exhaust by routing the air through HEPA-charcoal filter trains before release to the atmosphere.
4. Provide a reduced quantity of ventilating air to permit occupancy of the instrument room during reactor operation. The provisions for 1., 2., and 3. above will apply.
5. Ensure an unimpeded closure of the containment isolation valves installed in the system penetrations on a Containment Vent Isolation (CVI) Signal.

9.4.7.2 System Description

The RBPV System is shown schematically in Figure 9.4.7-1. One complete and independent RBP System is provided for each unit.

The RBPV System provides for mechanical ventilation of the primary containment, the instrument room located within the containment, and the annulus secondary containment located between the Containment and Shield Building. The system is designed to supply fresh air for breathing, and contamination control to allow personnel access for maintenance and refueling operations. The exhaust air is filtered to limit the release of radioactivity to the environment.

The RBPV, in conjunction with the annulus vacuum control system, can be used to maintain containment pressure within acceptable limits during normal plant operations. RBPV valves are available to vent excess lower containment air directly into the annulus where the annulus vacuum control system will discharge the effluent through the auxiliary building exhaust vent. The effluent in this path is monitored for radiation in accordance with the ODCM. Containment venting is terminated in the event of a Phase A containment isolation signal or may be manually terminated following the detection of high radiation during the venting process.

During power operation, cooling of the Reactor Building upper compartment, lower compartment, and control rod drive mechanisms is accomplished by the air cooling systems discussed in Section 9.4.8. The annulus is normally maintained at a negative pressure by the annulus vacuum control subsystem of the EGT System as discussed in Section 6.2.3.

The containment upper and/or lower compartments are purged with fresh air, if needed, by the RBPV System before occupancy. The annulus can be purged with fresh air during reactor shutdown or at times when the annulus vacuum control system of the EGT System is shutdown. The instrument room is purged with fresh air during operation of the RBPV System or can be separately purged by the instrument room purge subsystem. Limitation on purge path alignments and duration of RBPV operation is stated in Technical Specifications.

Each purge system consists of two 50 percent capacity air supply fans, two 50 percent capacity air exhaust fans, two 50 percent capacity cleanup filter trains, instrument room supply fan, instrument room exhaust fan, air supply distribution system, air exhaust collection system, containment isolation valves, and system airflow control valves.

The purge air supply fans are located in the penetration room at elevation 714. Filtered fresh air, heated when required, is taken from the Auxiliary Building Air Supply Systems located in the mechanical equipment rooms at elevation 714 and is discussed in Section 9.4.2. These fans are designed to supply a total of approximately 28,000 cfm.

The purge air exhaust fans and air cleanup filter trains are located within the penetration room at elevation 690. The cleaned air is discharged to the outdoors by means of the Shield Building exhaust vent located in the annulus space of the Reactor Building and extending through the roof of the Reactor Building. These fans are designed to exhaust a total of approximately 28,000 cfm.

The purge air supply and exhaust fans are centrifugal type, each rated at 14,000 cfm. These fans do not receive emergency power.

The supply fans, exhaust fans, and air cleanup filter assemblies for each unit are connected and controlled in two 50 percent capacity trains. The controls are designed to have simultaneous starting and stopping of the matching supply and exhaust equipment. The controls are also designed to give an automatic shutdown and isolation upon receipt of containment ventilation isolation signal. Upon failure of a fan, system redundancy will provide 50 percent capacity.

Each air cleanup filter plenum contains a bank of prefilters, a bank of HEPA filters, and a bank of charcoal adsorbers. Each plenum is provided with static pressure differential indicators, thermometers, connection for inplace testing of filters and absorbers, and access doors for filter and adsorber maintenance.

The system air supply and exhaust ducts are routed through the secondary containment to several primary containment penetrations. Two air supply locations are provided for each of the upper and lower compartments and one for the instrument room. Several air pickup points are located to exhaust air from the lower compartment and instrument room and to provide an air sweep across the surface at the refueling canal.

Annulus purging air is taken from system ducts which is routed through the annulus. These air supply and exhaust duct openings are located approximately 180° apart for maximum ventilation.

The primary containment penetrations for the ventilation supply and exhaust subsystems are designed to primary containment requirements. These are discussed in detail in Section 6.2.4, Containment Isolation Systems.

Each purge system containment penetration is provided with both inboard and outboard air-operated isolation butterfly valves designed for minimum leakage in their closed position. A similar type of valve is mounted in each purge supply and exhaust air opening for the annulus, and in each of the systems main supply and exhaust duct located exterior to the Shield Building. Each of the above butterfly valves is designed to fail closed and to be normally closed during purge system shutdown.

The containment purge penetrations are safety-related in that they must not jeopardize the integrity of the containment boundary. These penetrations are designed to withstand (with essentially zero leakage) the forces produced by a Loss-of-Coolant Accident (LOCA), or a Main Steam Line Break (MSLB). The penetrations are provided with an isolation mechanism which is activated by the initiation of the Containment Ventilation Isolation Signal. The isolation mechanism has 100 percent redundancy in both equipment and power sources. The system also isolates upon detection of high radiation in the purge exhaust.

Screens are provided inboard of the inboard containment isolation valve on both supply and exhaust to prevent foreign material from restricting isolation valve closure. They are provided on purge line penetrations X-4, X-5, X-10A, X-10B, X-11, and X-80, and consist of 10 gauge steel wire on 2 mesh back by reinforcing bars. The screens are quality group C and Seismic Category I. These screens are approximately one valve diameter away from the valve pivot. Purge line penetrations X-6, X-7, X-9, X-9B do not have debris screens because their physical location precludes the need for protection from accident blowdown debris in order to ensure proper valve closure.

To permit personnel access to the instrument room during reactor operation or during purge system shutdown, the room can be purged by the instrument room purge subsystem fans (approximately 800-900 CFM). These subsystem supply and exhaust fans are located alongside the main system supply and exhaust fans and will use the main system ducts and filter train. Valves are manually positioned to allow only the instrument room to be ventilated.

The instrument room purge air supply and exhaust fans are centrifugal type.

9.4.7.3 Safety Evaluation

Portions of the containment purge system are engineered safety features. All supply and exhaust penetration isolation valves and piping between these valves have a Nuclear Safety Class designation in accordance with ANS Safety Class 2A. Refer to Section 6.2.4. Other portions of the exhaust system are designated ANS Safety Class 2B.

The RBPV fans and filters are not engineered safety features and credit for LOCA mitigation is not claimed. Containment Ventilation Isolation signals automatically shuts down the fans and

includes interlocking dampers and backdraft dampers where provided, and closes the containment purge penetration butterfly valves and annulus secondary containment butterfly valves, thereby isolating the containment purge systems. The purge exhaust paths to the shield building exhaust stack also have isolation valves that are manually controlled. Each purge system butterfly valve, including those provided for containment penetration isolation, is designed for fail-safe closing. Those used for containment penetration isolation fail close within 4 seconds. Valve travel stops were installed on the containment isolation valves to prevent the valves from opening greater than 50 degrees to assure adequate closure time is achievable to mitigate the consequences of design basis accidents (Reference 9.4.11-1). Temporary removal of the valve travel stops is permitted in Mode 5 and in Mode 6, when reactor core alterations and nuclear fuel movement are not being implemented, to accelerate the containment purging process to support outage activities. Removal of the valve travel stops may require the alteration of the normal control and logic functions to purge containment with the valves in an open position greater than 50 degrees. Valve travel stops shall be re-installed and valve travel verified for select plant operations in accordance with Technical Specifications.

The purge containment isolation valve locations and descriptions are given in Table 9.4.7-1. Each valve is provided with air cylinder valve operator, control air solenoid valve, and valve position indicating limit switches. Butterfly valves are provided outside the shield wall for annulus secondary containment isolation as needed. The Reactor Building purge fans, filters, and duct work located beyond the isolation valves are not required for post accident (MSLB, LOCA) mitigation; except where their integrity is required to ensure annulus secondary containment and ABSCE boundaries. Possible missiles generated by this system will not damage any ESF equipment.

The RBPV System will isolate in the event radioisotopes are released from the nuclear fuel rod assembly during a fuel handling accident inside containment. The accident analysis addressed in FSAR Section 15.5.6 takes no credit for the cleanup operation of the Containment Purge Exhaust System to mitigate the accident. Rather, the system is assumed to be isolated on a CVI by the purge line radiation monitors and the associated containment isolation valves on high radiation in the exhaust air stream. No fuel handling or movement inside primary containment will be allowed unless the purge line radiation monitors and the purge line containment isolation valves are operable or containment purge is isolated. The containment purge system will also be isolated upon the actuation of a CVI signal whenever the primary containment is being purged during normal operation. This radiation monitor is discussed in Chapter 11.

The air cleanup equipment installed in the exhaust side of the system was designed in accordance with accepted engineered safety feature design practices. As a result, good general agreement with Regulatory Guide 1.140 standards for air cleanup equipment is achieved.

The system butterfly valves and exhaust fans were purchased to Seismic Category I requirements. System supply fans were not purchased to Seismic Category I requirements. Filter train cleanup units consist of prefilters, HEPA filters, charcoal absorbers, and are qualified to Seismic Category I requirements. All of the above equipment, except for supply fans, was purchased in compliance with Quality Assurance Procedures.

All supply and exhaust penetration isolation valves, annulus duct, exhaust system duct, fans, and filter trains are supported to Seismic Category I requirements, and all supply system duct (excluding annulus duct), fans, and filter trains are supported to Seismic Category I(L) requirements. All ducts connecting to the Shield Building exhaust vent extending to the outside are designed and constructed to withstand the tornado pressure decrease of 3 lb/in^2 in three seconds.

An analysis was performed to determine the offsite radiological consequences of a LOCA during a containment purge operation and before completion of containment isolation. Additional details are provided in Section 6.2. The dose is considered as the summation of (a) the dose resulting from direct release to the environment during containment purge and before complete containment isolation and (b) the dose resulting from the release of radioactivity by various pathways after containment isolation. The results of this analysis is presented in Table 15.5.3-4. As indicated in this table the dose due to the accident does not exceed those guidelines specified in Regulatory Guide 1.4.

9.4.7.4 Inspection and Testing Requirements

The Reactor Building purge ventilation system is accessible for periodic inspections and tested initially and periodically. HEPA filter cells are subjected to periodic tests with DOP in accordance with approved plant procedures. Carbon adsorbers are subjected to periodic tests with freon in accordance with approved plant procedures. Purge system containment penetration isolation valves are in service tested per ASME Section XI and leak tested per 10 CFR 50, Appendix J.

9.4.8 Containment Air Cooling System

9.4.8.1 Design Bases

The Containment Air Cooling Systems are designed to maintain an acceptable temperature within the Reactor Building upper and lower compartments, reactor well, control rod drive mechanism (CRDM) shroud, and instrument room for the protection of equipment and controls during normal reactor operation and normal shutdown. The instrument room is mechanically cooled to permit personnel access during normal reactor operation.

The Lower Compartment Air Cooling System, together with operation of the CRDM Air Cooling System, is designed to supply air at a maximum temperature of 90°F to maintain an average air temperature less than 125°F in various lower compartment spaces during normal reactor operation. Four 33.34 percent capacity fan-coil assemblies are available. When river temperatures are high, four assemblies may be needed to maintain acceptable average air temperature in the lower containment. Operating history data indicate slightly greater than 120°F average temperatures have occurred less than 1% of the time.

During normal reactor operation, the CRDM Air Cooling System is designed to operate in conjunction with the Lower Compartment Air Cooling System to maintain the CRDM internals within their design temperatures (see Section 4.2.3.2.2).

The CRDM Air Cooling System consists of four 50 percent capacity fan-coil assemblies combined into two 50 percent capacity subsystems. Of these four fan-coil assemblies, one for each subsystem is normally operated for a total of two, and one for each system normally remains on standby for a total of two. Air drawn through the CRDM shroud is cooled by the active fan-coil assemblies and discharged into the lower compartment.

Upon the requirement for additional cooling in the lower compartment, an arrangement of dampers will allow either or both standby CRDM fan-coil assemblies to recirculate, and cool an additional portion of the lower compartment air.

The Upper Compartment Air Cooling System is designed to recirculate the upper compartment air and to maintain the average upper compartment temperature between 85°F and 105°F during normal reactor operation. This temperature range is consistent with the containment analysis input assumptions for the bulk air mass. Four fan-coil assemblies are installed on Unit 2 and two fan-coil assemblies are installed on Unit 1.

The Reactor Building instrument room is cooled during normal reactor operation or shutdown by either of two 100 percent capacity air-conditioning systems. Each system consists of a fan-coil unit located within the instrument room, a water-chilling condensing unit and chilled water pump located in the Auxiliary Building, and the connecting chilled water piping including containment penetration valves.

The heat sink for each lower compartment, upper compartment, and CRDM air cooling fan-coil assemblies, and for each Instrument Room Air Cooling System condensing unit is the ERCW System.

The lower compartments and CRDM air cooling fan-coil assemblies are energized from the Emergency Power System. Two of the four lower compartment coolers are required to operate for non-LOCA post-HELBs inside containment when the RCS is maintained at hot standby conditions.

9.4.8.2 <u>System Description</u>

The Containment Air Cooling Systems are shown in Figure 9.4.7-1. It consists of four subsystems as follows:

1. Lower compartment air cooling.
2. CRDM air cooling.
3. Upper compartment air cooling.
4. Reactor Building instrument room air cooling.

9.4.8.2.1 <u>Lower Compartment Air Cooling System</u>

The four safety related lower compartment air cooling fan-coil assemblies are located in two annular concrete chambers around the periphery of the lower compartment at floor elevation 693. Each fan-coil assembly consists of plenum, eight air cooling coils, vane-axial fan, instruments, and controls. Each fan-coil assembly is designed to cool approximately 65,000 cfm of 120°F air to 90°F or lower when supplied with 200 gal/min of 84.5°F water from the plant ERCW System. A cooling water throttling valve for each assembly can be automatically controlled by a temperature controller. Manual control is also available. The ERCW System is described in Section 9.2.2. Coolers are designed to utilize 87°F ERCW water for design basis accident (main steam line break).

Lower compartment air passes directly to each active fan-coil assembly where it is cooled and supplied through a common duct distribution system to the lower compartment spaces. The system is designed for three of the four fan-coil assemblies to operate together, with a total design flow rate of 165,000 cfm during normal operation. During periods of high river temperature, all four fans may be needed to maintain adequate cooling. The cooled air is supplied directly to each steam-generator compartment, pressurizer compartment, regenerative and excess letdown heat exchanger room, main lower compartment space, and to the space below the reactor vessel. In addition, two units are required to supply a minimum flow rate of 100,000 cfm for post-accident recovery periods.

During outages, the Auxiliary Building General Building Ventilation Chilled Water System may be used to temporarily cool the lower containment area by providing the medium to cool the normally supplied cooling water i.e., the Essential Raw Cooling Water (ERCW) to the lower compartment coolers via a temporary heat exchanger.

9.4.8.2.2 Control Rod Drive Mechanisms Air Cooling System

The four control rod drive mechanisms air cooling fan-coil assemblies are located in the main lower compartment space at floor elevation 679.78. Each assembly consists of plenum, two air cooling coils, vane-axial fan, assembly isolating air-operated damper, instruments, and controls. Each fan-coil assembly is designed to cool approximately 31,250 cfm air to 120°F or lower when supplied with 84 gal/min of 84.5°F water from the plant ERCW System. Normally, a cooling water throttling valve for each assembly is automatically controlled by a temperature indicating controller which utilizes an input from a thermocouple in the cooler. The ERCW System is described in Section 9.2.2. Cooling water flow can also be controlled manually with operator temperature monitoring.

The four CRDM air cooling fan-coil assemblies are divided into two pairs with either one of each pair, for a total of two, designed to operate together to exhaust a total of approximately 62,500 cfm of air from the CRDM shroud during normal reactor operation. The air is cooled by the fan-coil assemblies and is discharged to the lower compartment spaces. An estimated 3,080,000 Btu/hr of cooling capacity is provided.

9.4.8.2.3 Upper Compartment Air Cooling System

A portion of the upper compartment air is recirculated and cooled as needed by four upper compartment fan-coil assemblies (Unit 2) and two upper compartment fan-coil assemblies (Unit 1). One fan coil assembly operates as needed with one (or more for Unit 2) on standby during normal reactor operation. The fan-coil assemblies are located within the upper compartment on top of the steam generator enclosures at elevation 778.69. Each fan-coil assembly consists of plenum, three air cooling coils, vane-axial fan, instruments, and controls. Each fan-coil assembly is designed to cool 16,000 cfm of 110°F air to 98°F or lower when supplied with more than 20 gal/min of 84.5°F water from the plant ERCW System. Roughly 190,000 BTU/hr cooling capacity is provided by each fan-coil assembly. A cooling water throttling valve for each assembly is either automatically controlled by a temperature indicating controller which utilizes an input from the thermocouple mounted in the return air supply to control the containment air temperature or operated in manual and adjusted as necessary. Upper containment air temperatures during normal operations are maintained within the limits specified in the Technical Specifications. The ERCW System is described in Section 9.2.2.

9.4.8.2.4 Reactor Building Instrument Room Air Cooling System

The non safety related Instrument Room Air Cooling System consists of two 100-percent capacity air-conditioning systems. Each system consists of a semi-hermetic packaged water chilling unit and chilled water pump located in the Auxiliary Building penetration room at elevation 669, a fan-coil unit with air supply duct located in the Reactor Building instrument room, connecting chilled water piping with double containment penetration isolation valves (see Section 6.2.4), and all necessary and customary control and indicating devices.

Each water chilling unit is rated at 10.4 tons of refrigeration. The fan-coil unit is designed to recirculate not less than 6200 cfm of air.

9.4.8.2.5 Controls and Instrumentation

Operation of each fan-coil unit (lower compartment, upper compartment, CRDM, and instrument room) is indicated in the main control room. Air flow switches are mounted in the fan-coil unit discharge and/or suction to provide annunciation in the main control room upon loss of air flow and with exception of the CRDM Air Cooling System, start the redundant fan coil unit, when

operated in the automatic mode. The CRDM Air Cooling System Units are manually started. Thermocouples measuring air temperatures for lower and upper compartments, CRDM Air Cooling System, and Instrument Room can be monitored to evaluate system performances.

9.4.8.3 Safety Evaluation

The Lower Compartment Coolers of the Containment Air Cooling System are ESF and provide the safety function of maintaining the air below a specified temperature following a High Energy Line Break (HELB), except for a LOCA. The temperature in lower containment will be maintained under the Environmental Qualification temperature profiles. These coolers are supplied cooling water by separate trains of ERCW water. The Lower Compartment Air Cooling System is designed in accordance with ANS Safety Class 2B.

The Upper Compartment Coolers of the Containment Air Cooling System are not ESF but are necessary to establish and maintain the upper compartment air bulk temperature within the design temperature range prior to an accident. Technical Specification 3.6.5 establishes an average upper compartment temperature of 85°F to 105°F during normal reactor operation. This temperature range is consistent with the containment analysis input assumptions for the upper compartment's bulk air mass.

The remaining Containment Air Cooling Systems are not required for maintenance of plant safety in the event of an accident and are not part of the engineered safety systems. However, the reactor containment penetration isolation valves for the Instrument Room Air-Conditioned Chilled Water System and the ERCW supply to the upper and lower compartment coolers have a Nuclear Safety Class designation in accordance with ANS Safety Class 2A.

The capability of assuring containment ambient temperature levels are discussed in Section 3.11.

To prevent damage to adjacent safety-related equipment necessary for the plant safe shutdown in case of a nuclear accident, all air cooling assemblies, instrument room fan-coil units, water-cooled condenser portion of the instrument room water chillers, ductwork and duct supports, and chilled water piping and pipe supports are designed and installed to seismic requirements.

9.4.8.4 Test and Inspection Requirements

Air cooling assemblies and their temperature controlling devices, located within containment, are initially tested before reactor operation and are generally accessible for inspection only during unit shutdown. Instrument room fan-coil units, control devices, and containment isolation chilled water valves are accessible for periodic inspection. Water chilling equipment, pumps, and all essential electrical starting and switchover controls located in the Auxiliary Building are accessible for periodic inspection.

Instrument room chilled water containment isolation in-service testing and inspection requirements are in accordance with ASME Section XI and 10 CFR 50 Appendix J.

9.4.9 Condensate Demineralizer Waste Evaporator Building Environmental Control System

The building is not used and the supply and exhaust connections to the Auxiliary Building are isolated. CDWE building and equipment are excluded from the design basis of the plant. Therefore, environmental control for CDWE building is not required.

9.4.10 Postaccident Sampling Ventilation System

9.4.10.1 Design Basis

The postaccident sampling facility environmental control system (PASFECS) provides heating, cooling, and ventilation during normal plant operations and training activities. In addition, heating, ventilation, and control of airborne radiological contamination is provided during postaccident acquisition and testing of samples. This is accomplished through pressurization of the areas by the ventilation system which induces air from areas of lesser to areas of greater contamination potential. The system maintains temperatures within a range of 50°F to 104°F. The PASFECS has redundant isolation capability in all ductwork which interfaces with the Auxiliary Building Gas Treatment System (ABGTS) or penetrates the Auxiliary Building Secondary Containment Enclosure (ABSCE).

9.4.10.2 System Description

The PASFECS is shown on Figures: 9.4.10-1. The PASFECS consists of a ventilation subsystem (PASFVS), a heating and cooling subsystem (PASFHCS), and a radiological gas treatment subsystem (PASFGTS).

9.4.10.2.1 PASFVS

During normal plant operation, ventilation air is supplied to the facility via the Unit 2 Auxiliary Building general ventilation system and an auxiliary supply fan. Exhaust air is ducted directly to the fuel handling area exhaust fans.

During postaccident sampling operations, the normal supply and exhaust systems are isolated and ventilation air is taken directly from the outside at a point on the roof of the unit 1 additional equipment building. Both the unit 1 and unit 2 systems share this common intake. A supply fan provides air to the sampling side of the facility in response to a differential pressure controller. Air is drawn from both the sample and valve gallery areas and through a gas treatment system by an exhaust fan and routed to the exhaust duct downstream of the ABGTS air cleanup unit. The sampling area is maintained at a positive pressure $\geq$ 0.12 inch WG with respect to atmosphere while the valve gallery is kept at a negative pressure of $\leq$ 0.25 inch WG with respect to the sample side.

9.4.10.2.2 PASFHCS

In the normal mode of operation, supply air taken from the unit 2 Auxiliary Building general ventilation system has already been tempered and no additional heating or cooling is required.

In the postaccident mode, incoming air is preheated in response to a duct mounted temperature switch. No cooling is provided in this mode. However, the ventilation system will maintain the facility below 104°F with 97°F outside conditions.

9.4.10.2.3 PASFGTS

The radiological gas treatment subsystem consists of one HEPA/charcoal-type air cleanup unit located just upstream of the exhaust fan. Air supplied to the facility during postaccident sampling operations is processed through the air cleanup unit prior to being discharged to the atmosphere.

9.4.10.3 Safety Evaluation

The PASFECS is not a nuclear safety related system; however, the isolation valves and duct which interface with the ABGTS and ABSCE are designed to Category 1 standards. These valves are also backed by Class 1E power. All remaining portions of the system are designed to Category 1(L) requirements.

9.4.10.4 Inspection and Testing Requirements

The Post Accident Sampling Facility Ventilation Subsystem will be periodically inspected and tested.

Air cleanup units are designed and tested per the requirements of NRC Regulatory Guide 1.140. The charcoal filters are tested in accordance with ASTM D-3803-1989. Preoperational tests provided data for the initial balance of the system and verification of design flow rates.

NOTES:

1. The postulated DBA for the main control room air cleanup units is the DBA LOCA.

2. Compliance with this section is not required because this system was fabricated well before the publication of the Regulatory Guide.

3. Each redundant air cleanup subsystem contains a HEPA filter bank and a carbon adsorber bank.

4. No pressure surges of any significance to this system are envisioned during the postulated DBA identified in note 1.

5. Air flow sensors utilized to sense low flow through the operating air cleanup unit and switch to the backup unit annunciate the low flow indication in the main control room. Differential pressure sensors for the HEPA and adsorber banks are located on the air cleanup unit

TABLE 9.4.1-1 (Sheet 2)

REGULATORY GUIDE 1.52 (Rev. 2) SECTION APPLICABILITY
FOR THE MAIN CONTROL ROOM AIR CLEANUP SUBSYSTEM

housings in the mechanical equipment room located next to the main control room. This mechanical equipment room is readily accessible to main control room personnel.

6. The amount of radioactive material collected by the filter and adsorber banks in the DBA LOCA will not be sufficient to create a serious radiation hazard. Furthermore, adequate capacity for air cleanup is provided to protect the control room personnel for the full 30-day duration of the postulated emergency. Therefore, there will be no need for a filter or adsorber bank replacement during the emergency.

7. No enhancement in safety is foreseen by utilizing low leakage ducting in this system. Leakage from commercial grade ducting within the main control room cannot jeopardize safety because all supply and exhaust air will be clean. No safety hazard due to small duct leakage outside the enclosed space containing the main control room is envisioned either because in emergencies essentially all air in-leakage into ducting with air below atmospheric will be cleaned up in its passage through the air cleanup unit and all external ducting having air at a positive pressure will not entrain contaminants that will be subsequently introduced into the main control room (the leakage from ducting having a positive air pressure will be from the duct to the outside).

8. No equipment of this kind is utilized in the system.

9. The small quantities of outside air brought inside will not contain sufficient moisture to cause the mixture of recirculated air and outside air to have a humidity level sufficiently high to degrade the adsorber bank performance.

10. The amount of radioactive material collected during the entire 30 day emergency due to the postulated DBA is too small to raise the adsorber bank temperature near the carbon ignition temperature.

11. Compliance with this section is not a licensing requirement.

12. This system does not contain heaters and the technical specifications require periodic operation.

13. The requirements of section C.5.d are met except that ANSI N510-1975 sections 8 and 9 are not performed as prerequisites to section 12. See notes 2 and 11.

14. Dampers do not meet the requirements of ANSI N509-1976. However, butterfly valves which do meet ANSI N509-1976 are installed as required to assure tight shut off and system integrity. See Note 7.

15. Compliance with this section is not required since charcoal filter testing is performed in accordance with ASTM D3803-1989, “Standard Test Method for Nuclear-Grade Activated Carbon,” in order to provide assurance for complying with the current licensing basis, per NRC Generic letter 99-02, “Laboratory Testing of Nuclear-Grade Activated Charcoal.”

9.5 OTHER AUXILIARY SYSTEMS

9.5.1 Fire Protection System

9.5.1.1 Design Basis

The Fire Protection System and fire protection features are described in the Fire Protection Report (FPR). The FPR is a separate document that is revised and updated periodically similar to this FSAR (e.g., 10 CFR 50.59 process). The FPR should be referred to for a detail description of the Fire Protection Program.

9.5.2 Plant Communications System

9.5.2.1 Design Bases

The design basis for interplant and/or offsite communications is to provide dependable systems to ensure reliable service during normal plant operation and emergency conditions.

The primary interplant communications systems are fiber optics, commercial telephone service, emergency notification system, health physics network, and radios.

The design basis for the intraplant communications is to provide sufficient equipment of various types such that the plant has adequate communications to start up, continue safe operation, or safely shutdown.

The primary intraplant communications systems are the EPBX telephone equipment, sound powered telephones, closed circuit television, evacuation alarm, loud speaker paging, general fire or medical emergency alarm, radios, and Wi-Fi System (with VoIP Telephones).

9.5.2.2 General Description

9.5.2.2.1 Intraplant Communications

The following paragraphs describe the basic functions of the intraplant communications systems.

Telephone System

Electronic Private Branch Exchange (EPBX) - A EPBX is installed to provide primary 2-way communications throughout the Sequoyah Nuclear Plant as well as access to offsite circuits. The EPBX is equipped with a minimum of the following provisions:

1. 2-Way telephone conversation
2. Fire and Medical Emergency Alarm
3. Loud Speaker Paging
4. Executive override
5. Single digit access to the EPBX telephone switchboard (dial 0)
6. Dial access to offsite locations
7. Automatic Alternate Routing
8. Direct inward dial from local central office
9. Direct outward dial to local central office

10. 2-Way trunks to Chattanooga
11. 2-Way trunks to Chattanooga Central Emergency Control Center

The EPBX is powered from a 48V DC source. This source consists of a telephone battery charger, a spare battery charger, a regulating power board, and a battery. The telephone battery charger is fed from a non-1E source with an alternate feed from a train A diesel-backed board. The spare battery charger is fed from a train A diesel-backed board with an alternate feed from a train B diesel-backed board. Should both chargers fail, the battery is sized to carry the load.

<u>Sound-Powered Telephone Systems</u>

1. <u>Plant Operation Systems</u> - The primary purpose of these systems is to provide communications for maintenance and operations personnel. The following 6 separate systems are provided for each of the two units, a total of 12 systems for use with portable sound-powered headsets. Signaling capabilities are not provided.

   SP1 - Sound-powered jack system for turbine control, generator, and auxiliary power system

   SP2 - Sound-powered jack system for feedwater, steam and condensate system

   SP3 - Sound-powered jack system for reactor control system

   SP4 - Sound-powered jack system for reactor coolant and auxiliary steam system

   SP5 - Sound-powered jack system for engineered safeguards system and auxiliary system

   SP6 - Sound-powered jack system for refueling system

2. <u>Backup Control Center System</u> - The primary purpose of this sound powered system is to provide communications between the auxiliary control room and other stations which must be manned to shutdown the reactors if the main control room is abandoned. This system consists of two completely redundant subsystems. Each subsystem is wired directly and independently of all other communications systems. Wiring routes avoid the spreading room, unit control rooms, and auxiliary instrument rooms. Sound-powered telephones with signaling capabilities, portable head-chest sets, and jacks are provided in the diesel generator buildings, the 480V ac shutdown board rooms, the 6.9kV ac shutdown board rooms and the auxiliary control room.

3. <u>Health Physics System</u> - The primary purpose of this sound powered telephone system is to provide an alternate communications link between the health physics office and the main control room. A direct circuit is provided between a magneto-equipped telephone in the health physics satellite laboratory and the main control room.

4. <u>Diesel Building to Main Control Room</u> - The primary purpose of this sound powered telephone system is to provide an alternate communications link between the diesel generator building and main control room. A direct circuit is provided between a telephone in the radiation shelter room in the diesel generator building and a telephone in the main control room at the diesel generator control panel. Both telephones have signaling capabilities.

Closed-Circuit Television Reactor Containment and Control Room - Two portable cameras can be provided for remotely viewing refueling operations. Permanent wiring for the cameras is terminated in plug receptacles on the refueling floor and lower compartment of each unit and at the common spent fuel pit area. A monitor and video switcher can be provided in the electrical control room. This system can be used by operations but is also useful in providing training information.

Evacuation Alarm System

Plant-wide siren coverage is provided for signaling assembly and accountability to the plant personnel. These sirens are operated in two modes, undulating and monotone.

There are two completely separate power supplies and control stations provided for the system and also redundant automatic timers. The timers may be manually bypassed in case both fail.

The motor-driven sirens and strobelights operate in groups using separate contactors, each of which have two diesel-backed 120V ac power supplies (except for the ERCW pumping station and the Office and Power Stores building) and two redundant actuating relays.

Paging System

Paging speakers are installed in the auxiliary, reactor, turbine, and control buildings. Paging handsets are provided in both unit control and the auxiliary control room. In addition to the paging handset locations, this equipment may be accessed from any EPBX telephone. The speaker-amplifiers are fed in parallel from an alternating current lighting source.

Fire and Medical Emergency Alarm

This system is used to sound the general fire alarm or medical emergency. The system is activated by way of the EPBX, as well as from the control room.

Inplant Radio System - The primary purpose of this system is to provide voice communications throughout the plant for plant personnel. This system consists of UHF/VHF radios, UHF/VHF signal, and portable radios. All systems use the Distributed Antenna system.

Wi-Fi System - The primary purpose of the Wi-Fi System is to provide wireless internet access in the power block. The Wi-Fi system in conjunction with wireless VoIP telephones will provide redundant communications for performing Appendix R Operator Manual Actions in the event a fire disables the primary Inplant Radio System. The system consists of a main distribution cabinet located in the Spreading Room, with end switch cabinets and access points located throughout the plant power block.

9.5.2.2.2 Interplant Communications

The following paragraphs describe the basic functions of the interplant communication system.

Optical Ground Wire (OPGW) Circuit

The OPGW circuit enters through the plant switchyard. The fiber optic terminal equipment is located in the Node 2 Building. This circuit terminates at remote TVA locations which are staffed continuously. The OPGW circuit is cross-connected to the telephone switch to permit rerouting

in the event of a failure. Access is provided at the electrical operators desk in the main control room. Power is supplied from the 48-volt UPS communications power system in the Node 2 Building.

Telephone System

1. Commercial Telephone Service - Public telephone service is provided to all EPBX telephones with proper class of service, to pay telephones, and to dedicated data circuits.

2. Emergency Telecommunications System - This system consists of communication links that are considered by the NRC to be essential in the event of a serious emergency at a nuclear plant reactor site. Dedicated telephone lines that are independent of the local public telephone switching network provide the required functions which are as follows. The Emergency Notification System (ENS) is used primarily to provide initial notification to the NRC of a problem as well as ongoing information on plant systems, status, and parameters.

   The Health Physics Network (HPN) is used primarily to report to the NRC on radiological and meteorological conditions, as well as assessment of trends and protective measures taken on-site and off-site. Several other links are furnished which are primarily used for internal NRC discussions but may also be used for discussions between the NRC and plant management at the site.

Onsite Paging System - The primary purpose of this system is to provide daily and emergency paging of plant personnel. This system, which is accessible from the EPBX, is controlled from offsite.

Transmission Power Supply (TPS) Radio - The primary purpose of this system is to provide communications for engineers and control room personnel. This system is capable of contacting local mobile units and other TVA power generating facilities.

Nuclear Security Service (NSS) Radio - The primary purpose of this system is to provide effective communications between all onsite NSS officers. This system consists of two VHF channels and portable radios for NSS officers. The NSS officers also have access to the UHF channels.

Radiological Communication Radio (RCR) - The primary purpose of this system is to provide a communications link between health physics personnel and mobile monitoring vehicles. This system consists of two offsite repeaters, various remote control units and portable radios. Onsite remote control units are located in the Technical Support Center, the Radiological Control lab, and the main control room.

Sheriff's Radio - The primary purpose of this system is to provide communications between NSS officers and the Hamilton County sheriff. This system consists of one base station and remote control units.

9.5.2.3 Evaluation

The following evaluation is intended to establish adequacy and redundancy of the plant communications systems design.

The fiber optic circuits enter the plant via different paths and they are redundant to each other. The fiber optic circuit enters the plant via an overhead static wire located in the 161 KV switchyard. The fiber optic and the radio frequency equipment each have an automatic standby mode energized and ready to operate. The power for the fiber optic is fed from a 48 volt battery-battery charger system in the Node 2 communication building. This battery is capable of operating Node 2 communications.

The public telephone lines are routed through the EPBX powered by 48 volt DC (battery backed). However, in the event of EPBX system failure, certain public lines will be available for use.

The Emergency Telecommunications System consists of dedicated telephone lines that are independent of the local public telephone switching network. This prevents failure of the system due to congestion of the local public switching networks during an emergency. Backup power for this system is provided by SQN.

The TPS Radio is located in the hallway outside of the Technical Support Center on elevation 732 of the Control Building. The complete loss of the Communications Room (elevation 669 of the Control Building) would not cause the loss of this link.

The NSS VHF radio is not located either with the TPS VHF radio or in the communications room. It is located in the Auxiliary building. The NSS radio to the local sheriff's office is located in the turbine building. It is not probable that these radios and the TPS radio will be out of service simultaneously.

A fiber optic cable connection from the cell site to a VHF remote interface unit (RIU) on elevation 732' in the turbine building extends the communications capabilities to inplant buildings. The RIU allows the existing UHF/VHF Radio System communications to operate using the inplant Distributed Antenna System. The Wi-Fi VoIP Telephone equipment is located in a separate fire zone and is available as a communication tool during various postulated events for a loss of the UHF/VHF system.

The Wi-Fi system main distribution cabinet is located in the Spreading Room and physically separated from the Inplant Radio System. In the event that a fire disables the primary Inplant Radio system cabinets, the Wi-Fi will be available for emergency communications. Power supplies for Inplant Radio System and the Wi-Fi system are also physically separated; ensuring that no single fire in a given plant fire area can disable the power feed to both the primary Inplant Radio System and the redundant Wi-Fi system simultaneously.

Refer to Table 9.5.2-1 for availability of interplant communications during various postulated conditions.

The EPBX is designed so that individual component failures within the EPBX do not interrupt service. However, such failures are annunciated so that repairs can be made promptly. The switching equipment for this system is located in the communications room which is in a Seismic Class I building and in the telecommunication node 2 building located outside the protected area. These two locations can work independently of each other. The EPBX is designed to provide continuous service in times of emergency.

The paging equipment is dispersed in the control building and powerhouse areas. Single or multiple open circuits or amplifier failure in individual units will not prevent the remaining equipment from functioning. The failure of the equipment will not impair the use of the paging equipment from the local paging stations located in the control room, or the auxiliary control room.

The sound-powered telephone systems are completely independent of power, each other, and all other systems provided. As long as a complete metallic path exists between instruments, communications can be maintained since the instruments supplied with these systems are very rugged and will successfully withstand high shocks, negligence and abuse. If permanently installed wires are rendered unusable for any reason, a temporary pair of wires can be used with the sound-powered instruments.

The design of the evacuation alarm system is such that it will not likely be inoperative for the following reasons:

1. Two independent widely separated operating centers are provided.

2. Duplicate timers located in widely separated bays are furnished with provision for manual override in case both fail. Each timer is powered by a separate alternating current source.

3. Duplicate actuating relays are provided in each remote control unit.

4. Independent contactors are provided, each controlling a group of sirens. Failure of one contactor will not affect the others.

5. Two sources of diesel-backed alternating current power are provided for most control units with provisions for annunciation upon failure of each source.

6. Power failure to the timers and to the remote control unit actuating relays is annunciated.

Refer to Table 9.5.2-1 for availability of intraplant communications during various postulated conditions.

9.5.2.4 Inspection and Tests

Two communications systems were covered by preoperational test (TVA-11):

1. The sound-powered telephone systems provided for the backup control center, health physics office, and diesel building shielded room.

2. The evacuation alarm system.

All systems were also carefully installed and checked for proper operation initially by construction forces. Maintenance is performed on an as needed basis and includes such items as checking for proper switch operation, checking for proper operating levels, visual inspection, etc.

The most comprehensive testing, however, results from the heavy daily usage of the equipment and the subsequent reports by the users. Power failures in the systems are annunciated.

9.5.3 Lighting Systems

9.5.3.1 Design Bases

There are three basic lighting systems in the plant (see section 9.5.3.3 for the Diesel Generator building lighting) designated as follows: normal, standby, and emergency. These systems are

designed in accordance with the recommendations of the Illuminating Engineering Society, National Electrical Code, and good engineering practice to provide the required illumination necessary for safe conduct of plant operations and under normal conditions to make the plant personnel as comfortable as possible.

The normal system is designed to economically provide the amount and quality of illumination to meet normal plant operations and maintenance requirements.

The standby system, on loss of the normal lighting system, provides the minimum illumination level necessary to support the safe shutdown of the reactor and the evacuation of personnel from the plant if the need should occur. It forms an integral part of the normal lighting requirements but is fed from an entirely independent source.

The emergency lighting system, fed from independent direct current (DC) voltage sources, provides immediately the minimum illumination level in areas vital to the safe shutdown of the reactor when the other lighting systems are unavailable.

9.5.3.2 Description of the Plant Lighting Systems

All plant lighting systems have the following features in common: adequate capacity and rating for the operation of all loads connected to the systems, independent wiring and power supply, overcurrent protection for conductor and equipment using nonadjustable circuit breakers, and copper conductors with 600 Volt insulation run in metal raceways (except flex conduit utilized for some low voltage lighting).

The insulated cable used inside the primary containment area is resistant to nuclear radiation and chemical environmental conditions in this area.

The plant lighting system consists of three basic schemes, the first of which is the normal lighting. This system is for general lighting of the plant; the major power supply is through normal and alternate feeders from the 6.9 kV common boards A and B to 3-phase, 120/208 Volt AC transformers feeding lighting boards distributed throughout the main plant. Other lighting boards in the service building, office building, gatehouse, etc., are fed from various 480 Volt boards through 3-phase 120/208 Volt AC transformer. These lighting boards feed the normal lighting cabinets, designated by the prefix LC. In the power board rooms and control rooms, alternate rows of fixtures or alternate fixtures are fed from different lighting boards to prevent total blackout in a particular area in case of failure of one of the other lighting boards or cabinets.

The second system is the standby lighting which forms a part of the normal lighting requirements and is energized at all times. This system is fed from 480 Volt shutdown boards 1A2-A, 2A2-A, 1B1-B, and 2B1-B to 3-phase 120/208 Volt AC transformers to each standby lighting cabinet, designated by the prefix LS. The shutdown boards have a normal and alternate ac power supply and in event of their failure are fed from the diesel generators. The cable feeders to the standby cabinets located in the Category 1 structure are routed in redundant raceways and the fixtures are dispersed among the normal lighting fixtures.

The third lighting system is referred to as the emergency system. The feeder to this system is electrically held in the off-position until a power failure occurs on the AC systems. Then the emergency lighting cabinets, designated by the prefix LD, are automatically energized from the

125-Volt DC vital battery boards. This system is an essential supporting auxiliary system for the ESF, and the cable feeders to the LD cabinets are routed on the redundant ESF cable tray system or in conduit. The fixtures are dispersed among the normal and standby fixtures with alternate emergency fixtures being fed from redundant power trained LD cabinets.

In addition, eight-hour battery-powered emergency lighting system is provided as described in the Fire Protection Report (see Section 9.5.1).

9.5.3.3 Diesel Generator Building Lighting System

The diesel generator building lighting cabinets are fed through 480-208/ 120 Volt 3-phase local lighting transformers, which in turn are fed from the diesel 480 Volt auxiliary boards respectively. Each of these auxiliary boards has dual feeders from the 480 Volt shutdown boards, and ultimately the diesel generators if normal power is not available. Each diesel generator unit has a lighting cabinet which supplies approximately one-half of the lighting for that unit, with the remaining half being supplied from the lighting cabinet of the adjacent like-trained unit.

9.5.3.4 Functions of the Lighting System

The normal system is designed to provide the amount and quality of illumination to meet normal plant operations, maintenance, and evacuation requirements.

The standby system provides low level lighting in the vital areas, less critical areas, and exit points for support of the safe shutdown of the reactor and evacuation of personnel.

The emergency lighting in the vital areas is adequate for the safe shutdown of the reactor and the evacuation of personnel.

9.5.3.5 Inspection and Testing Requirements

Following the complete installation of a lighting system in the protected area, it shall be inspected and tested. The maintenance and relamping of the normal and standby lighting system shall be according to routine plant operating procedures.

The 125 Volt emergency lighting system shall be tested periodically by tripping the holding coil circuit fed from the LS standby cabinet, thus closing the feeder circuit to the LD emergency cabinet. All emergency lamps of this system shall be inspected and replacements made where necessary. A written record of dates and results of these tests shall be maintained by plant personnel responsible for these tests.

9.5.4 Diesel Generator Fuel Oil System

9.5.4.1 Design Bases

That portion of the Diesel Generator Fuel Oil System within the Diesel Generator Building is designed to Class I seismic requirements, and is designed to be impervious to the effects of tornadoes, hurricanes, floods, rain, snow, or ice as defined in Chapter 3 of this document.

The system has storage and transfer capacity to supply No. 2 diesel fuel to all four diesel generator sets operating at full load for a period not less than 7 days, with the ability to replenish the supply from offsite sources during that time.

The design code requirements for the system are as follows:

1. Diesel Generator Building fuel oil storage tanks - Code for Unfired Pressure Vessels, ASME Section VIII, Division I.

2. Piping, valves, pumps, and associated equipment - Power Piping Code, ANSI B31.1-1967. The system is designed with the ability to meet single failure criterion.

9.5.4.2 Description

The flow diagram of the Diesel Generator Fuel Oil System is shown in Figure 9.5.4-1.

The Diesel Generator Fuel Oil System consists of four embedded storage tank assemblies, one for each diesel generator unit, and associated pumps, valves, and piping. The tanks are embedded in the Diesel Generator Building substructure with a capacity of approximately 68,000 gallons of fuel for each Diesel Generator (DG) unit.

Two engine-mounted, motor-driven, 15 gal/min pumps are provided for each DG unit to transfer fuel from the embedded storage tank assemblies to the two 550 gallon engine-mounted day tanks per DG unit. Each of these pumps is capable of supplying fuel to both day tanks. Two sets of level switches are provided for each day tank. The level switches are arranged so that each pump serves as the primary pump for its respective day tank, and the backup pump for the other day tank. In the configuration, both tanks are filled by either pump.

A 200 gal/min transfer pump located in the fuel oil transfer pump room of the Diesel Generator Building has been provided to accomplish the following functions:

1. Transfer oil from any embedded diesel oil storage tank to any other.

2. Transfer oil from any embedded diesel oil storage tank to either of two 70,000 gallon yard fuel oil storage tanks.

3. Reject oil from the embedded diesel oil storage tank through a reject connection in the yard.

A 200 gal/min transfer pump located adjacent to the yard fuel oil storage tanks is provided to accomplish the following functions:

1. Transfer oil from a tank truck to either of two yard fuel oil storage tanks.

2. Transfer oil from either yard fuel oil tank to the other.

3. Transfer oil from either yard fuel oil tank to any one of the four Diesel Generator Building embedded fuel oil storage tank assemblies.

4. Reject oil from either yard fuel oil tank through a reject connection in the yard.

The diesel building storage tanks may be filled directly from a tank truck at fill connections located outside the Diesel Generator Building.

Level switches are provided on the diesel building storage tanks to accomplish the following functions:

1. Provide local level indication.

2. Annunciate an alarm in the main control room when the fuel level drops below a 7 day supply.

3. Provide an interlock with the 200 gal/min transfer pumps at the yard storage tanks and in the fuel oil transfer pump room of the diesel building to shutoff the pumps automatically on a high level.

4. Annunciate an alarm in the main control room on a high level above the pump shutoff setting.

The 200 gal/min transfer pumps provide a capacity ratio to the total fuel consumption of all generators of approximately 10:1.

9.5.4.3 Safety Evaluation

With a 68,000 gallon capacity of diesel fuel in each fuel tank assembly, and each assembly embedded in the concrete substructure of a Class I seismic building and separated by 18 inches of concrete, the diesel generating units will be assured of having at least a 7 day fuel supply in the event any of the aforementioned environmental conditions prevail.

Additional fuel oil can be procured and delivered to the site by tank truck to refill the embedded Diesel Generator Building storage tanks through the Class I seismic fill connections provided immediately outside the building, in the event the 70,000 gallon yard storage tanks or the transfer pipeline between the yard storage tanks and the Diesel Generator Building are damaged or destroyed by an earthquake or tornado, and additional oil is needed after 7 days.

A 0.125 corrosion allowance has been provided in the design of the wall thickness for the Diesel Generator Building embedded fuel oil storage tanks. The fuel oil piping and fittings within the Diesel Generator Building have more than ample corrosion allowance, having been designed per the Power Piping Code, ANSI B31.1-1967, and expected to operate at a pressure considerably below the maximum allowable for size and schedule pipe fittings used.

9.5.4.4 Inspection and Testing Requirements

Provisions have been made for the removal of water and/or sludge buildup from the bottoms of the Diesel Generator Building fuel oil storage tanks, and the engine-mounted day tanks due to condensation. A periodic inspection program is utilized for the detection and removal of the buildup.

A program has been established to inspect incoming fuel oil supplies to assure the specified grade and quality of fuel is being delivered.

Finally, a program will be initiated to sample and inspect the fuel stored in the Diesel Generator Building embedded tanks for deterioration and algae growth and to introduce proper additives to inhibit the deterioration and/or growth of algae or, if necessary, dispose of the fuel and replace it with fresh fuel.

9.5.5 Diesel Generator Cooling Water System

A closed circuit jacket cooling water system is furnished for each engine (Figure 9.5.5-1). Each system includes pumps, heat exchanger, expansion tank, and all accessories required for a cooling loop. Thermostatically controlled jacket water immersion heaters are provided for each engine to maintain the jacket water temperature within a specified range while the DGs are in standby mode to reduce the thermal stresses and assure faster starting and load acceptance capability. Jacket water flows through the lube oil cooler by thermosyphon action. The engine cooling water (closed loop) is circulated through the shell side of the heat exchanger by two engine-shaft-driven pumps. An electric-motor-driven lube oil circulation pump is also provided for each engine to circulate the lube oil through the lube oil cooler which is warmed or cooled by the jacket water and returned to the engine sump. The lube oil circulation pump runs continuously when the engine is not running.

Each diesel generator set is provided with two closed circuit engine cooling water loops, one for each engine. The heat sink for the engine cooling water loop is provided by the Essential Raw Cooling Water System (ERCW) which flows through the tube side of the heat exchanger. Minimum ERCW design flow to each emergency diesel generator heat exchanger is at least 400 gpm (including 5 percent measurement uncertainties and including reference to Tubular Exchanger Manufacturers association for fouling factor of 0.0020 Hr-degree Fahrenheit-foot squared per Btu) (Reference 1). The DG sets and cooling water system satisfies the single failure criteria.

9.5.6 Diesel Generator Starting System

Each diesel engine is equipped with an independent pneumatic starting system complete with valves, piping, controls, etc. (as shown in Figure 9.5.6-1). Four (2 sets of 2 each) starting air motors are provided for each diesel engine. Two electric-motor-driven air compressors are provided for each diesel generator set. Two accumulators are provided for each diesel engine. Each accumulator set is sized for an air storage capacity sufficient to start the engine five times without recharging. Each set of accumulators is equipped with shutoff valves, pressure gauges, safety valves, and low-pressure alarm contacts for use on the 125 Volt direct current circuit.

Redundant equipment is provided for each set such as air compressors, accumulators, starting air motors, and accessories so that a failure of a component will not jeopardize the design starting capacity of the system.

9.5.7 Diesel Generator Lubrication System

The Engine Lubricating Oil System (ELOS) prelubes the engine, supplies oil under pressure to the various moving parts of the engine as well as supplying oil for the cooling of the pistons. Since the operating pressure range is determined by such things as manufacturing tolerances, oil temperature, oil dilution, wear, and engine speed, specific operating pressures will vary. However, an overpressure relief is provided. An AC and DC soak back oil pumps are provided to lubricate/cool the turbochargers.

The lubricating oil pumps are positive displacement type and mounted externally for accessibility. The scavenging, main, and piston cooling oil pumps are shaft-driven from the diesel engines.

The ELOS provides for filtering and cooling the oil. The filters are cartridge type with automatic bypass. The oil is maintained within a specified temperature range via the lubricating oil cooler by the Closed Circuit Cooling Water System (refer to Section 9.5.5, Diesel Generator Cooling Water System).

The lubricating oil is maintained at a predetermined temperature by heating when the engine is not operating to ensure rapid starting.

An individual lubricating oil system is provided for each diesel generator engine. A failure in one lubricating oil system will not jeopardize the operation of the other diesel engines.

Each engine crankcase sump contains ample lubricating oil for 7 days of full load operation without requiring replenishment. Additional oil is stored within the Diesel Generator Building to replenish the engines for longer periods of operation and to "top-off" the engines after their periodic exercising operations. Additional oil can also be procured from off the site for extremely long periods of operation.

9.5.8 Hydrogen System

9.5.8.1 Design Bases

The design bases for the hydrogen system are as follows: 1) to provide hydrogen to the main electric generators for cooling; and 2) to provide a cover gas on the volume control tank to maintain the hydrogen concentration in the design range.

9.5.8.2 System Description

Hydrogen is supplied from the hydrogen transport trailers located in the hydrogen trailer port. The hydrogen is reduced in pressure at the trailer port and is fed through two headers to the secondary control stations located near the turbine and auxiliary buildings. At the secondary control stations, the hydrogen is further reduced in pressure before being supplied to the generators and volume control tanks.

9.5.8.3 Design Evaluation

In the event of a sudden increase in flow of hydrogen into the Auxiliary Building, a flow element installed in the hydrogen piping will detect the increase and automatically close two control valves, one located in the secondary control cabinet and the other located in a cabinet adjacent to the Auxiliary Building wall. The ventilation system is designed to pull air through the volume control tank rooms and through the passageways where the header runs. Because of this air flow a major hydrogen leak would produce a maximum H_2 concentration less than 1% which is far below the 4% safe concentration for H_2 in air.

9.5.8.4 Tests and Inspections

Periodic pressure tests and inspections are performed to detect minor leaks.

9.5.8.5 Instrumentation Application

The main instruments in this system are pressure gages and the control valves which control the pressure and flow.

Flow Diagrams

The flow diagram for this system is shown in Figure 11.3.2-2.

9.5.9 Nitrogen System

9.5.9.1 Design Bases

The bases for the nitrogen system is the need for a cover gas and also for the degasification purging of the volume control tank and other components. It maybe used to dilute stored waste gas if the H_2 and O_2 ratio approach the explosive limit in the waste gas decay tanks.

9.5.9.2 System Description

The nitrogen supply system is a shared system and is divided into two sections; a low pressure section and a high pressure section. The high pressure section is for pressurization of the accumulators and inerting of the steam generators. The large quantities of nitrogen gas required are supplied from a tank truck using the truck fill connections located in the wall at the railroad area of waste packaging or from a liquid nitrogen system located outside the auxiliary building. There are separate lines to Unit 1 and to Unit 2 with cross-connections between them. For makeup, high pressure gas is taken from the dual 24-bottle section provided for the low pressure section.

The low pressure section is used to purge the vapor space of various components to reduce the hydrogen concentration or to replace fluid that has been removed. This system consists of a dual bank of 24 bottles each, connected to a manifold with an automatic controller. When the operating header is exhausted, its discharge pressure will fall below a set point and an alarm will alert the operator. The second bank will come into service automatically to ensure a continuous supply of gas. The operator will then reset the pressure to 100 psig and see that the exhausted bottles are refilled.

9.5.9.3 System Evaluation

Since the nitrogen system is not an engineered safety feature, accident conditions are not considered. The nitrogen system is TVA safety class G by virtue of its location in the auxiliary building.

9.5.9.4 Instrumentation Application

The instruments for this system are shown on the flow diagram, in Figure 11.3.2-2.

9.5.10 Postaccident Sampling Program and Facility

The program will ensure the capability to obtain and analyze reactor coolant, radioactive iodines and particulates in plant gaseous effluents, and containment atmosphere samples under accident conditions. The program shall include the following:

(i) Training of personnel,
(ii) Procedures for sampling and analysis,
(iii) Provisions for maintenance of sampling and analysis equipment.

9.5.10.1 Design Basis

The postaccident sampling facility (PASF) is designed to safely obtain, transfer, analyze, and dispose of, as necessary, samples of reactor coolant, containment sump water, and the containment atmosphere samples. Each reactor unit has its own respective PASF that will obtain the necessary samples following a loss of coolant accident (LOCA).

As committed in Technical Specification Change 01-11, the following commitments must be addressed in the design change for eliminating PASS from the plant.

1. TVA will develop contingency plans for obtaining and analyzing highly radioactive samples of reactor coolant, containment sump, and containment atmosphere. The contingency plans will be contained in technical procedures and implemented in accordance with the License amendment.

2. The capability for classifying fuel damage events at the Alert level threshold will be established at radioactivity levels of greater than or equal to 300 μCi/gm dose equivalent iodine. This capability will be described in emergency plan implementing procedures.

3. TVA will establish the capability to monitor radioactive iodines that have been released to offsite environs. This capability will be described in chemistry and radiation protection implementing procedures.

9.5.10.2 Facilities

The major components of the postaccident sampling system (PAS) are discussed in the following sections.

9.5.10.2.1 Reactor Coolant and Containment Sump Sampling System

Each unit has a reactor coolant sampling system equipped with a closed cooling water heat exchanger to cool the sample as it is acquired by the liquid sampling panel (LSP). Samples are taken from the reactor coolant hot legs and from the containment sump, when the RHR system is in the recirculation mode of operation. The PASF is equipped with the necessary calibration reagents, with dilution water, and with flush water lines. Waste sample streams are discharged to the PASF Collector Drain Tank which is drained into the tritiated drain collector tank or the containment sump.

9.5.10.2.2 Containment Air Sampling System

Acquisition of the containment air samples is performed by the Radiological and Chemical Technology (RCT) particulate, iodine, and gas separation system and the Security Equipment Corporation (SEC) shielded syringe, jointly.

These samples are subsequently transported to an onsite facility for isotopic analysis. Hydrogen levels in the containment atmosphere are determined by the containment hydrogen monitors.

9.5.10.2.3 Sampling and Analysis Capabilities

Samples acquired in the PASF can be transported to an onsite laboratory where analyses not performed in the PASF can be completed. Provisions are established for offsite analysis support. The postaccident sampling and analysis capabilities are shown in Table 9.5.10-1.

9.5.10.3 Design Evaluation

The design life of all major components, equipment, and instrumentation is 40 years. Items designed for postaccident service will be designed to remain functional in the expected postaccident environment.

9.5.10.4 Tests and Inspections

The equipment located in the PASF will be tested and inspected to verify equipment operability and availability.

10.0 STEAM AND POWER CONVERSION SYSTEM

10.1 SUMMARY DESCRIPTION

The Steam and Power Conversion System is designed to convert the heat produced in the reactor to electrical energy through conversion of a portion of the energy contained in the steam supplied from the steam generators, to condense the turbine exhaust steam into water, and to return the water to the steam generator as heated feedwater.

The major components of the Steam and Power Conversion System are: turbine-generator, main condenser, vacuum pumps, turbine seal system, turbine bypass system, hotwell pumps, condensate booster pumps, main feed pumps, main feed pump turbines (MFPT), feedwater heaters, heater drain pumps, condensate demineralizer system, and condensate storage system. Component arrangement is shown in Figure 10.1-1. The heat rejected in the main condenser is removed by the circulating water system.

The saturated steam produced by the steam generators is expanded through the high pressure turbine and then exhausted to the moisture separator/ reheaters. The moisture separator section removes the moisture from the steam and the two stage reheaters superheat the steam before it enters the low pressure turbines. The steam then expands through the low pressure turbines and exhausts into the main condenser where it is condensed and deaerated and then returned to the cycle as condensate.

The first stage reheater is supplied with steam from the No. 1 extraction point; the condensed steam is cascaded to the No. 2 heater. The second stage reheater is supplied with main steam; the condensed steam cascades to the highest pressure (No. 1) heater.

Condensate is withdrawn from the condenser hotwells by motor-driven hotwell pumps. The pumps discharge into a common header which can carry the condensate through the full flow condensate demineralizers to the demineralized condensate pumps. Normally a percentage (typically 10-30 percent) of the condensate is polished and the remainder of the condensate flow bypasses the condensate demineralizers. These pumps discharge into a common header which carries the condensate through the gland steam condenser (partial flow), the main feed pump condensers, and then through three parallel strings of low-pressure heaters. Each string of low pressure heaters consists of three stages, Nos. 5 through 7, with No. 5 the highest pressure. After passing through the low pressure heaters, the condensate discharges into a common header which carries it to the condensate booster pumps. These pumps discharge to a common header which divides back into three parallel strings of intermediate-pressure heaters, each string consisting of three stages (Nos. 2 through 4) of extraction feedwater heaters. The condensate from the intermediate pressure heater strings is then routed to the main feed pumps. These pumps discharge to a common header which divides and passes through three parallel strings of single-stage high-pressure heaters and returns to a common line before dividing into four streams to the four steam generators. SG blowdown heat exchangers also receive condensate flow for cooling the blowdown.

Heat for the feedwater heating cycle is supplied by the moisture separator reheater drains and by steam from the turbine extraction points. A summary description of the important components and design parameters of the Steam and Power Conversion System is contained in Table 10.1-1. Heat balances for the steam and power conversion cycle are shown in Figures 10.1-2 and 10.1-3.

TABLE 10.1-1 (Sheet 1)

SUMMARY OF IMPORTANT COMPONENT DESIGN PARAMETERS

VERTICAL STEAM GENERATORS

Design data for the steam generators are provided in Table 5.5.2-1.

Operating Conditions at 100 Percent Load (Best Estimate)

	Unit 1	Unit 2
Steam flow rate	3.78×10^6 lb/h	3.79×10^6 lb/h
Steam temperature	530.3° F	530.3° F
Steam pressure	887 lb/in^{2}a	887 lb/in^{2}a
Steam quality	99.9 percent	99.9 percent

TURBOGENERATOR

Manufacturer - Westinghouse Electric Corporation
Turbogenerator nameplate rating - 1,183,192 kW

Turbine type -	Horizontal, reaction, tandem-compound, 2-stage reheat, extraction, condensing, 1800-r/min single shaft - 1 high-pressure and 3 low-pressure turbines with 6-flow exhaust and 44 inches last-stage buckets
Generator type and maximum nameplate rating -	One direct connected, hydrogen cooled rotor, water-cooled stator, 1,356,000 kVA, 0.9 power factor, 75 lb/in^{2}g hydrogen, 3 ph, 60 Hz, 24,000 V, 33,625 A, 0.6 scr, Y-connected
Exciter type and capacity -	One shaft-driven, brushless - 5500 kW, 525 V, 1800 r/min

Heat Rate*

Guaranteed performance based on extraction for feedwater heating, including all losses in the unit, also exciter and rheostat losses, rated throttle steam conditions, and 2.0 inches of Hg absolute exhaust pressure with zero makeup:

kW	Btu/kWh
1,183,192	9,871

* This information is provided for historical purposes only. This was the guaranteed tubogenerator performance based on the original plant design conditions.

Moisture Separator and Reheaters

Type -	Moisture removal separator and 2-stage reheater (both high pressure and low pressure are one pass shell and four pass U-tube reheaters).
Manufacturer -	Westinghouse Electric Corporation (moisture removal separator and reheater shell), South Western Engineering Co. (high- and low-pressure tube bundles). TEi, MSR Internal and External Modifications (Unit 2 only).
Tube Data -	High pressure - 484 U-tubes, 3/4 inch O.D., .040 inch wall thickness, SA-268 TPXM-8 (439), 27 fins/inch effective surface area of 20,005.9 square ft.

TABLE 10.1-1 (Sheet 2)

SUMMARY OF IMPORTANT COMPONENT DESIGN PARAMETERS

Low pressure - 447 U-tubes, 3/4 outside diameter, .049 inch wall thickness, SA-268 TPXM-8 (439), 27 fins/inch, effective surface area of 18,476.6 square ft.

Size - 46 ft., 1-1/8 inch length
10 ft., 9 inches diameter

Main Feedwater Pump Turbine

Number - (1 Turbine per pump) - 2
Manufacturer - Westinghouse Electric Corporation
Type and speed - EMM-25AN, multistage, dual inlet, 6000 r/min
Throttle pressure - Low-pressure steam, 160 lb/in^{2}a, high-pressure steam, 1060 lb/in^{2}a
Throttle temperature - Low-pressure steam, 494°F, high-pressure steam, 546°F
Back pressure - 5 inches of Hg absolute
Number of stages - 8
Extraction points - None
Rated horsepower - 11,700

Main Feedwater Pumps

Number - 2
Manufacturer - Borg-Warner Corporation, Byron Jackson Pump Division
Type - DVSR, single stage, double suction, double volute, centrifugal
Size - 14 x 14 x 17C
Design point - 20,000 gal/min, 1680-feet head
Service conditions - Pump suitable for continuous service to deliver up to 28,300 gal/min at 399.3°F against a total head of approximately 1405 feet at 6150 r/min, while operating under a minimum net positive suction head of 250 feet

Condensate Booster Pumps

Number - 3
Manufacturer - Borg-Warner Corporation, Byron Jackson Pump Division
Type - DVDSR, single stage, double suction, double volute, centrifugal
Size - 14 x 14 x 15H
Design point - 9000 gal/min, 680-feet head
Motor manufacturer - Hitachi, LTD
Motor design - 1750 hp, 3570 r/min, 6600 V, 3 ph, 60 Hz, horizontal, constant speed

No. 3 Heater Drain Pumps

Number - 3
Manufacturer - Borg-Warner Corporation, Byron Jackson Pump division
Type - DSJH, single stage, double suction, double volute, centrifugal
Size - 8 x 10 x 18H
Design point - 3600 gal/min, 1200-feet head
Motor manufacturer - Hitachi, LTD
Motor design - 1250 hp, 3570 r/min, 6600 V, 3 ph, 60 Hz, horizontal, constant speed

TABLE 10.1-1 (Sheet 3)

SUMMARY OF IMPORTANT COMPONENT DESIGN PARAMETERS

No. 7 Heater Drain Pumps

Number - 2
Manufacturer - Borg-Warner Corporation, Byron Jackson Pump Division
Type - DSJH, single stage, double suction, double volute, centrifugal
Size - 8 x 10 x 15L
Design point: 2300 gal/min, 830 feet

Motor manufacturer - Hitachi, LTD
Motor design: 700 hp, 3545 r/min, 6600 V, 3 ph, 60 Hz, horizontal, constant speed

Demineralized Condensate Pumps

Number - 3
Manufacturer - Ingersoll-Rand Company
Type of pump - AA, single stage, end suction, centrifugal
Size - 10 x 18
Design point - 6700 gal/min, 150-feet head
Motor manufacturer - Westinghouse Electric Corporation
Motor design - 350 hp, 1770 r/min, 460 V, 3 ph, 60 Hz, horizontal, constant speed

Condensate Hotwell Pumps

Number - 3
Manufacturer - Borg-Warner Corporation, Byron Jackson Pump Division
Type of pump - VMT, four stages, single suction, vertical process
Size - 28KXH
Design point - 6700 gal/min, 600-feet head
Motor manufacturer - Hitachi, LTD
Motor design - 1250 hp, 1180 r/min, 6600 V, 3 ph, 60 Hz, vertical, constant speed

Condenser

Number - 1
Manufacturer - Ingersoll-Rand Company
Type - Horizontal, triple shell, single pass, surface, deaerating
Total surface area, 757,952 ft^2

Tube data -	77,592 tubes, 49 feet, 9 inches effective length, 3/4 inch outside diameter, No. 24 BWG, B338 Gr2 Titanium (No. 22 BWG tubes used in impingement zone)
Tube sheets -	Base material: Carbon steel; cladding material: Titanium
Waterboxes -	Divided, two inlets (72 inches diameter) and two outlets (72 inches diameter) bottom connections per shell

TABLE 10.1-1 (Sheet 4)

SUMMARY OF IMPORTANT COMPONENT DESIGN PARAMETERS

Hotwell data - Deaerating type, storage capacity of hotwells at normal operating level, 32,992 gal
Circulating water quantity, gal/min - 530,600
Cleanliness, percent - 95
Duty, 10^9 Btu/hr - 7.829

Design pressures: Shell, lb/in^{2}g - 20
Hotwell, lb/in^{2}g - 20
Waterboxes, lb/in^{2}g - 25

Air Removal Equipment

Number - 3
Manufacturer - Nash Engineering Company
Size - AT-2004E
Type - Mechanical, 2-stage liquid ring pump
Design point - Suction pressure inch of Hg absolute - 1.0, rated capacity each - 15 SCFM
Motor manufacturer - General Electric Company
Motor design - 115 hp, 500 r/min, 460 V, 3 ph, 60 Hz, horizontal, constant speed

FEEDWATER HEATERS

Number - 21 (seven stages divided into three streams)
Type - Closed, horizontal, U-tube
Nos. 1 and 2 Heater Tubes: 304SS (Heater Manufacturer: YUBA)
Nos. 3 and 4 Heater Tubes: 304SS (Heater Manufacturer: Foster Wheeler)
Nos. 5, 6, and 7 Heater Tubes: SA-688-304 SS (Heater Manufacturer: Southwestern Engineering Company)

CONDENSATE CLEANUP SYSTEM

Number - Twelve service vessels (two batteries of service vessels; one battery per plant generating unit; six service vessels per battery). One regeneration subsystem (common to two plant generating units).
Manufacturer - L & A Water Treatment Division, Chromalloy American Corporation
Type - Deep bed (externally regenerated mixed-bed ion exchange process)
Size - 9 feet, 6 inches diameter condensate demineralizer service vessels
Design conditions - Capacity per unit battery - 17,000 gal/min (at full condensate flow)
Capacity per service vessel - 3400 gal/min (five service vessels in service, one standby)
Pressure - 300 lb/in^{2}g
Temperature - 140° F

TABLE 10.1-1 (Sheet 5)

SUMMARY OF IMPORTANT COMPONENT DESIGN PARAMETERS

SAFETY VALVES

Number - 5 per steam generator
Minimum Required Rated Capacity, - 3,917,000 lb/hr for each set of five safety valves (based on original maximum calculated turbine steam flow)
Nozzle Size - 16 sq. inches
Set Pressure - See Technical Specification 3.7.1, Table 3.7.1-2 for the steam generator safety valve setpoints.

Atmospheric Relief Valves

Number - 1 per steam generator
Minimum capacity, (Flood Mode) - 60,000 lb/hr @ 90 psig inlet pressure
Minimum capacity, (RHR cut-in) - 101,000 lb/hr @ 110 psig inlet pressure
Maximum capacity - 890,000 lb. hr @ 1085 psig inlet pressure
Outlet pressure - 0 psig

Turbine Bypass Valves

Number of valves - 12
Flow per valve, lb/h - 522,000
Main steam pressure at valve inlet (for above flow), lb/in^{2}g - 782
Maximum flow per valve at 1085 lb/in^{2}g inlet pressure, lb/h - 890,000
Time to open (full stroke), seconds - 3
Full stroke modulation, seconds - 20
Failure position - Closed

10.2 TURBINE GENERATOR

10.2.1 Design Basis

The purpose of the turbine generator is to use steam supplied by the PWR System in the conversion of thermal energy to electrical energy, and to provide extraction steam for feedwater heating. The turbine generator together with its associated systems and their control characteristics are integrated with the features of the reactor and its associated systems to obtain an efficient and safe energy conversion and power generation unit.

The turbine receives steam from the four steam generators and converts the thermal energy to electric energy. The Unit 1 heat balance indicates that the generator produces 1,221,000 kW when the turbine passes 14,420,210 lb/h of steam at throttle conditions of 861.9 lb/in^{2}a, 0.21 percent moisture, and at back pressure of 2.0 inches of Hg absolute (Figure 10.1-2). The Unit 2 heat balance indicates the generator produces 1,213,800 kW when the turbine passes 14,421,200 lb/hr of steam at throttle conditions of 860.3 lb/in^{2}a, 0.21 percent moisture, and at a back pressure of 2.0 inches of Hg absolute (Figure 10.1-3). Under emergency conditions the Turbine Protection System provides the necessary protection for the turbine-generator equipment.

It is intended that the units will be utilized primarily as base loaded units.

The functional limitation on the turbine imposed by the Nuclear Steam Supply System (NSSS) is that the NSSS accepts step load changes of ± 10 percent and ramp load changes of ± 5 percent per minute over the range of 15 percent to 100 percent. Manual control is required below 15 percent load.

10.2.2 Description

The turbine generator unit consists of the following components: turbine, generator, exciter, controls, and required support subsystems. (The turbine is a tandem compound double-stage reheat unit with 44-inch last-stage blades.) It consists of double-flow high-pressure turbine and three double-flow low-pressure turbines with extraction nozzles arranged for seven stages of feedwater heating. Exhaust steam from the high-pressure unit passes through six moisture separator/reheaters before entering the low-pressure turbines. The moisture separator/reheaters are shell and tube-type heat exchangers containing a section of chevron vanes for moisture separation. The chevron-type vanes alter the steam velocity to reduce the moisture content of the steam through centrifugal separation of the moisture particles.

Heating steam enters the high- and low-pressure reheater U-tube bundles to provide two stages of reheat for the steam flowing from the chevron section.

The generator is a direct-connected, hydrogen-cooled, 3 phase, 60 Hz, 24,000 V, 1800 rev/min synchronous generator. The generator has a nameplate rating of 1,356,200 KVA at 0.9 power factor (PF) with 75 psig hydrogen pressure. The generator has a short circuit ratio of 0.60, designed with conductor cooling of the armature winding, and conductor coolant is demineralized water. The excitation system is rated at

5,500 kW and 525 V, and uses shaft-mounted solid-state electronic control devices for the establishment of generator field current. The devices are mounted internally in the exciter shaft so as to eliminate the necessity for sliprings.

The turbine utilizes a Westinghouse (Unit 2) or Siemens (Unit 1) designed Electrohydraulic Control (EHC) System for control of both speed and load. The EHC System, composed of solid-state electronic devices coupled through suitable electrohydraulic transducers to a high-pressure hydraulic fluid system, provides control of the main stop, governing, intercept, and reheat stop valves of the turbine. Emergency speed protection is provided by an electrical overspeed governor, backed up by mechanical (Unit 2 only) and electrical overspeed trip mechanisms.

The reactor controls enable the nuclear steam supply system to follow plant (turbogenerator) load changes automatically, including the acceptance of step load increases or decreases of 10 percent and ramp increases or decreases of 5 percent per minute within the load range of 15 percent of 100 percent without reactor trip or steam dump. The difference between the highest measured average reactor coolant loop temperature and the programmed reference temperature (based on turbine impulse chamber pressure) which is processed through a lead-lag compensation unit, contained within the DCS, constitutes the primary control signal for the reactor control system. An additional control input signal to the reactor is derived from the reactor power versus turbine load mismatch signal. These signals provide input to the rod control system to control the reactor coolant temperature by regulation of the control rod bank position.

The turbine generator is also protected by the Turbine Protection System which will automatically trip the turbine on evidence of low condenser vacuum, abnormal thrust bearing wear, or low bearing oil pressure. The turbine can be tripped manually if subjected to excessive shaft vibration. The turbine trip system is also equipped with solenoid-operated trip devices, which provide means to initiate direct tripping of the turbine upon receipt of appropriate electrical signals. The turbine will also be tripped manually on detection of high temperature or pressure differences between condenser shells, high back pressure on the main condenser, high journal or thrust bearing metal temperature, high bearing oil discharge temperatures, and high differential expansion. When a turbine trip is initiated, the extraction system nonreturn valves are tripped closed either by means of a pilot dump valve connected to the turbine trip system, on electrical trip signal generated by the turbine trip, or by both of these means. Turbine governor functions and turbine control are discussed under Control Systems Not Required for Safety, Section 7.7. For overpressure protection of the turbine exhaust hoods and the condenser, four rupture diaphragms which rupture at approximately 5 lb/in^2g are provided on each turbine exhaust hood. Additional protective devices include exhaust hood high temperature alarm.

Any influence of the turbine controls on the RC System is controlled by the RC System. Analyses of the most severe of these influences are given in Chapter 15.

10.2.3 Turbine Missiles

An evaluation of the turbine missile threat to essential safety-related equipment and structures at the Sequoyah Nuclear Plant is provided. The potential turbine missile sources and turbine missile characteristics are identified. Following this is a statement defining the turbine missile protection criterion adopted for Sequoyah. Essential safety-related equipment and structures of the plant are identified. An evaluation of the turbine missile hazard to these essential safety-related equipment and structures is then provided.

10.2.3.1 Potential Missile Sources and Missile Characteristics

The missile containing ability of Westinghouse steam turbines was evaluated by Westinghouse by performing various tests and analyses.

Some of these tests involved spinning alloy steel discs to failure within various carbon steel housings. The discs were notched to ensure failure in a given number of segments at the desired speed. Test results were correlated with various parameters descriptive of the missile momentum and energy and the geometry of the missile and housing.

The housings were of varying geometry but mainly were axisymmetric and concentric with the rotation axis of the disc. They ranged in complexity from a circular cylinder to containments which approximated actual turbine construction.

From these tests, logical criteria were evolved for predicting the missile containing ability of various turbine structures. In addition, the tests also served to determine the mode of failure which certain structural shapes common to turbine construction undergo when impacted by a missile. This is important since the mode of failure has a great influence on the amount of energy absorbed by the housing.

In 1979, a Westinghouse test program was initiated to develop guidelines for evaluating nonsymmetric impacts. Earlier tests had concentrated primarily on symmetric impacts whereas most disc collisions with the typical cylinder structure were of a nonsymmetrical type. Also in 1979, stress corrosion cracking was found in the keyway areas of several discs on low-pressure rotors being refurbished by Westinghouse. Consequently, in 1980 and 1981, Westinghouse reevaluated their turbine missile energies and probability analyses and developed a revised methodology to include the above failure mechanisms, the effects of an ultrasonic low-pressure turbine disc inspection and other miscellaneous changes resulting from the reevaluation. The results of Westinghouse's latest analyses are included in this section. These latest analyses were considered in conjunction with the original FSAR hazard analyses and the missile energies are such that no appreciable change in the strike probabilities will occur. Consequently, the original FSAR hazard analyses are still valid. References 3 and 4 present the methods used by Westinghouse to address their revised analysis for turbine missiles in 1981. This reflects upgrade to address stress corrosion cracking of rotor discs.

Criteria Considered in Selecting Number of Disc Segments

Disc fractures into 90°, 120°, and 180° segments were considered. Calculations show that the 90° fragments pose the greatest threat as external missiles.

A 120° segment has an initial translational kinetic energy greater than that of a 90° segment; however, it also has a greater rim periphery resulting in greater energy loss while penetrating the turbine casing.

This results in nearly equal kinetic energy of 90° and 120° segments leaving the turbine casing. However, since the 90° segments have the smaller impact areas they represent a more critical missile.

The initial translational kinetic energy of a half disc is equal to that of a quarter disc. Because of kinematic considerations, a half disc segment will always impact with the rotor after fracture. The 180° segment, due to its larger size, will subject the stationary parts to greater deformation. As a result the 180° segment will leave the turbine casing with lower energy than the 90° segment.

For the purpose of evaluating the missile containing ability of the turbine structure against the 90° segments, the shrunk on discs have been postulated to fail in four quarters.

<u>Energy Considerations</u>

Before failure, a disc has a total energy which is purely rotational of 1/2 (Iw^2), where I is the mass moment of inertia of the disc about its axis of rotation and w is the angular velocity of the turbine at the postulated failure speed. After failure the mass center of each fragment translates at a velocity of w_r, r being the distance from the rotation axis of the disc to the mass center of the fragment. In addition the fragment rotates about its center of mass with an angular velocity of w. The initial rotational energy of the disc is partitioned into both the translational and rotational kinetic energy of the fragments.

Test results and analytical considerations indicate that the translational kinetic energy of a fragment is of much greater importance than the rotational kinetic energy in predicting the ability of the fragment to penetrate the turbine casing. Rotational kinetic energy tends to be dissipated as a result of blade crashing and friction forces developed between the fragment surface and stationary parts.

These principles apply to fragments which would be generated by failure of either the high-pressure turbine rotor or the low pressure turbine discs.

<u>High-Pressure Turbine</u>

High-Pressure Turbine Construction and Design

The high-pressure turbine element is of a double-flow design, thus it is inherently thrust balanced. Steam from the four control valves enters at the center of the turbine element through four inlet pipes, two in the base and two in the cover. These pipes feed four double-flow nozzle chambers flexibly connected to the turbine casing. The steam leaving the nozzle chambers passes through inlet flow guide rings and flows through the reaction blading. The reaction blading is mounted in the blade rings which in turn are mounted in the turbine casing.

The high-pressure turbine rotor is made of NiCrMoV alloy steel. The specified minimum mechanical properties are as follows:

Tensile Strength, lb/in^2, min.	100,000
Yield Strength, lb/in^2, min. (0.2% offset)	80,000
Elongation in 2 inches, percent, min.	18
Reduction of Area, percent, min.	55
Impact Strength, Charpy V-Notch, ft-lb (min. at room temperature)	60
50% Fracture Appearance Transition Temperature °F, max.	0

Material Properties

Due to the very large margin between the high pressure, spindle-bursting speed and the maximum speed at which the steam can drive the unit with all the admission valves fully open and because the probability of failure due to fatigue or stress corrosion cracking is so small it is insignificant, the probability of spindle failure is practically zero. Therefore, no missile will be developed during turbine runaway.

The main body of the rotor (bladed) weighs approximately 132,500 lb. The approximate values of the transverse centerline diameter, the maximum diameter, and the main body length are 36, 67.3, and 138.5 inches, respectively.

The blade rings are made of stainless steel castings and the casing cover and base is made of carbon steel castings. The specified minimum mechanical properties are as follows:

Tensile Strength, lb/in^2, min.	100,000
Yield Strength, lb/in^2, min. (0.2 percent, min. for Unit 1)	80,000
Elongation in 2 inches, percent, min.	15
Reduction of Area, percent min.	40

The bend test specimen is required to be capable of being bent cold through an angle of 90° and around a pin 1 inch in diameter without cracking on the outside of the bent portion.

The approximate weights of the four blade rings, the casing cover, and the casing base are 65,000, 115,000, and 115,000 lbs, respectively.

The casing cover and base are tied together by means of more than 100 studs. The stud material is an alloy steel having the following mechanical properties:

	2-1/2 Inches and less	Over 2-1/2 to 4 inches	3.625 inches	Over 4 to 7 inches
Bolt Length, in		28 to 59	72.5	
Tensile Strength, lb/in^2, min.	125,000	115,000	135,000	110,000
Yield Strength, lb/in^2, min. (0.2% offset)	105,000	95,000	110,000	85,000
Elongation in 2 inches, percent, min.	16	16	14	16
Reduction of Area, percent, min.	50	50	32	45
Cross-sectional Area, in^2 (total for outer cylinder, approximate)		620	660	
Free-length Volume, in^3 (total for outer cylinder, approximate)		31,500	34,000	

The studs have lengths ranging from 28 to 59 inches and diameters ranging from 2.50 inches to 3.5 inches. The total stud cross-sectional area is approximately 620 in^2 and the total stud free-length volume is approximately 31,500 in^3.

Effects on High-Pressure Element of Turbine-Generator Unit Over-Speeding

The maximum speed at which the unit may run is 190 percent of rated speed. (Note that this is slightly more than the burst speed of 186 percent of rated speed used in the analysis.) At this

speed the highest stressed low-pressure turbine disc will fracture. Upon failure these low-pressure disc fragments will damage the turbine to the extent that additional overspeed will not be possible.

The minimum bursting speed of the high-pressure rotor, based minimum specified mechanical properties of the rotor material, is 270 percent of rated speed. The actual bursting speed is closer to 300 percent of rated speed.

Hence, the actual margin between the bursting speed and the maximum running speed is of the order of 110 percent of nominal. No failure of the high-pressure rotor is anticipated as a consequence of a unit runaway; and therefore, no missiles are expected to be generated.

Furthermore, Reference 6 reports that in addition to no expected missiles due to turbine overspeed, no high-pressure rotor missiles are expected to be generated for High Cycle or Low Cycle Fatigue. The purpose of this paper is to discuss technical reasons that nuclear HP rotors of integral construction do not need to be considered when assessing missile generation probability of nuclear turbines. This supports Guideline b (used to represent conditions at the Sequoyah Nuclear Plant) in Section 10.2.3.4, which states “the only source for missiles will be low-pressure turbines.”

<u>Low-Pressure Turbine</u>

Low-Pressure Turbine Construction and Design

The double-flow low-pressure turbine incorporates high efficiency blading, diffuser type exhaust and liberal exhaust hood design. The low-pressure turbine cylinder is fabricated from steel plate to provide uniform wall thickness thus reducing thermal distortion to a minimum. The entire outer casing is subjected to low temperature exhaust steam.

The temperature drop of the steam from its inlet to its exhaust from the last rotating blades is taken across three walls: an inner cylinder No. 1, a thermal shield, and an inner cylinder No. 2. This precludes a large temperature drop across any one wall, except the thermal shield which is not a structural element, thereby virtually eliminating thermal distortion. The fabricated inner cylinder No. 2, is supported by the outer casing at the horizontal centerline and is fixed transversely at the top and bottom and axially at the centerline of the steam inlets, thus allowing freedom of expansion independent of the outer casing. Inner cylinder No. 1 is, in turn, supported by inner cylinder No. 2, at the horizontal centerline and fixed transversely at the top and bottom and axially at the centerline of the steam inlets, thus allowing freedom of expansion independent of inner cylinder No. 2. Inner cylinder No. 1 is surrounded by the thermal shield. The steam leaving the last row of blades flows into the diffuser where the velocity energy is converted to pressure energy.

<u>Material Properties</u>

The outer cylinder and the two inner cylinders are fabricated mainly of ASTM 515-GR65 material. The minimum specified properties are as follows:

Tensile Strength, lb/in^2, min.	65,000
Yield Strength, lb/in^2, min.	35,000
Elongation in 8 inches, percent min.	19
Elongation in 2 inches, percent min.	23

The low-pressure rotors are made of NiCrMoV alloy steel. The specified minimum mechanical properties are as follows:

Tensile Strength, lb/in^2, min.	115,000
Yield Strength, lb/in^2, min. (0.2% offset)	100,000

Elongation in 2 inches, percent, min.	16
Reduction of Area, percent, min.	40
Impact Strength, Charpy V-Notch, ft-lb (min. at room temperature)	40
50% Fracture Appearance Transition Temperature, °F, max.	80

The shrunk-on discs are made of NiCrMoV alloy steel. There are ten discs shrunk on the shaft with five in each steam flow path. These discs experience different degrees of stress when in operation. Disc No. 2, starting from the transverse centerline, experiences the highest stress, while disc No. 5 experiences the lowest. The minimum specified mechanical properties for the discs are shown in Table 10.2.3-1. The actual specified mechanical properties for the discs, which are proprietary, were submitted to the NRC for Sequoyah Unit 1 by L. M. Mills' letter dated August 1, 1980 to A. Schwencer.

Effects on Low-Pressure Element of Turbine-Generator Unit Overspeeding

The bursting speed of each of the shrunk-on discs is calculated under the assumption that the disc will fail when the average tangential stress equals the maximum temperature corrected tensile strength of the disc material. (No disc cracks are assumed. The effects of stress corrosion cracking on the low-pressure elements are discussed later in this section.) Disc No. 2 is the most highly stressed disc with a calculated failure speed of 190 percent of rated speed. Upon failure of disc No. 2 (or any other disc), further acceleration of the unit is assumed to halt because of extensive internal damage to the turbine.

For the purpose of analysis, all discs were assumed to fail at 186 percent of rated speed which corresponds to the destructive overspeed provided by Westinghouse in their original analysis. As previously stated, using the original destructive overspeed has not invalidated the hazard analysis.

Calculated initial translational velocity and initial translational kinetic energies of disc quadrants leaving the turbine rotor based on disc fractures at 190 percent rated speed are as follows:

Disc No.	Weight (lb)	Velocity c.g. (ft/s)	Kinetic Energy (10^6ft-lb)
1	2700	1096	50.4
2	2965	1143	60.2
3	2775	1071	49.4
4	3210	1072	57.3
5	3710	927	49.5

Summary of Individual Disc Results at Destructive Overspeed (190 Percent of Rated Speed) - Based on Westinghouse's Reanalysis

Disc No. 1

Disc No. 1 is assumed to fail at 190 percent of rated speed. At this speed the kinetic energy of a disc quadrant is 50.4 x 10^6 ft-lb. The initial collision of the quadrant of disc No. 1 is with the

concentric blade ring. Secondary collisions with inner cylinder No. 1, inner cylinder No. 2, and the outer cylinder also occur. As a result, four external missiles are generated by the failure of disc No. 1. One missile, the disc quadrant, has an energy of 0.52 x 10^6 ft-lb. The other missiles, blade ring and cylinder fragments, have energies of 0.66 x 10^6 ft-lb, 0.43 x 10^6 ft-lb, and 0.37 x 10^6 ft-lb respectively.

Disc No. 2

Disc No. 2 is calculated to fail at 190 percent of rated speed. The initial kinetic energy of a quadrant of disc No. 2 is 60.2 x 10^6 ft-lb.

An initial collision occurs between the disc No. 2 quadrants and the concentric blade ring. Secondary collisions also occur between the disc and blade ring fragments and inner cylinders No. 1, No. 2, and the outer cylinder. As a result, three external missiles are generated. The largest missile, the disc fragment, has an energy of 8.82 x 10^6 ft-lb. The other missiles (blade ring and cylinder fragments), have energies of 8.61 x 10^6 ft-lb, and 0.47 x 10^6 ft-lb, respectively.

Disc No. 3

Disc No. 3 is assumed to fail at 190 percent of rated speed. A quadrant of disc No. 3 has an initial kinetic energy of 49.4 x 10^6 ft-lb. The center plane of disc No. 3 is located axially between two concentric blade rings. The result is that fragments of disc No. 3 do not enter into a square collision with either blade ring. Consequently, as tests indicate, there is a high probability that the disc fragments in following the path of least resistance, will merely wedge between the rings pushing them aside with relatively little loss in translational kinetic energy. There will be subsequent collisions with and perforations of inner cylinder No. 2, and the outer cylinder. The calculated ejection energy for a quadrant of disc No. 3, is 15.35 x 10^6 ft-lb. Two other external missile fragments are also generated with energies of 5.92 x 10^6 ft-lb and 6.08 x 10^6 ft-lb, respectively.

Disc No. 4

Disc No. 4 is assumed to fail at 190 percent of rated speed. The initial kinetic energy of a quadrant of disc No. 4 is 57.3 x 10^6 ft-lb. The initial collision occurs between fragments of disc No. 4 and the surrounding blade rings and supporting structure. Inner cylinder No. 2 is perforated, and subsequent collision with and perforation of the outer cylinder occurs. As a result, quadrants of disc No. 4 are ejected with a kinetic energy of 30.17 x 10^6 ft-lb. Two other external missile fragments are also generated with energies of 4.51 x 10^6 ft-lb and 5.70 x 10^6 ft-lb, respectively.

Disc No. 5

Disc No. 5 is assumed to fail at 190 percent of rated speed (blades are lost prior to reaching 190 percent of rated speed). A quadrant of disc No. 5 has a kinetic energy of 49.5 x 10^6 ft-lb. The initial collision occurs between the disc fragments and the diffuser ring and adjacent blade ring. As a result, disc No. 5 is ejected through the end section of the outer cylinder with a translational kinetic energy of 32.59 x 10^6 ft-lb. Two other external missile fragments are also generated with energies of 2.99 x 10^6 ft-lb and 2.54 x 10^6 ft-lb respectively.

Table 10.2.3-2 tabulates the exit missile properties for all discs at 186 percent of rated speed which was the failure speed originally calculated by Westinghouse. These data were used in the original hazards analysis. Table 10.2.3-3 tabulates the exit missile properties as calculated by Westinghouse during their reanalysis for all discs at 100 percent and 120 percent of rated speed, in addition to summarizing the information provided above for 190 percent of rated speed (destructive overspeed). The disc failures at 100 percent and 120 percent of rated speed would be similar to those described for the 190 percent speed except for considerably lower missile energies and different representative postulated fragments as indicated in Table 10.2.3-3. As previously noted, the slight increase in destructive overspeed does not invalidate the original hazards analysis.

Effects on Low-Pressure Element Due to Stress Corrosion Cracking

Prior to 1980, the Westinghouse missile probabilities and energies analyses were directed primarily at missile generation due to destructive overspeed. Fatigue of the rotating elements due to speed cycling was also considered as a missile generation mechanism in these earlier analyses. These earlier Westinghouse analyses indicated that the probabilities of missile generation due to fatigue and destructive overspeed were very low in comparison to the probability estimated by Bush. The Bush probability (1 x 10^{-4} missile producing disintegrations per turbine operating year) was chosen for the original Sequoyah missile hazard evaluation in order to provide a very liberal margin of safety.

When stress corrosion cracks were discovered in some of the Westinghouse low-pressure turbine rotor discs keyways and bores in late 1979 and early 1980, new Westinghouse analyses which were concerned primarily with the probabilities of low-pressure disc failure and missile generation due to stress corrosion cracking (SCC) were developed to reflect this newly discovered and relevant missile producing mechanism. The results of the missile energies portion of the new Westinghouse analyses are shown in Tables 10.2.3-3 and 10.2.3-4, and Figures 10.2.3-1 and 10.2.3-2. These new Westinghouse analyses also reevaluated the missile generation probabilities for fatigue of the rotating low-pressure turbine rotor discs. These new fatigue missile generation probabilities are six to seven orders of magnitude lower than the maximum allowable turbine missile generation probability and thus are insignificant. The probabilities of disc failure and missile generation due to destructive overspeed are not affected by these new analyses, and thus remain the same as stated in the earlier Westinghouse analyses. (Several orders of magnitude lower than the maximum allowable turbine missile generation probability.) The probability of missile generation due to SCC at design overspeed conditions (120 percent of rated speed) is two orders of magnitude lower than the probability of missile generation due to SCC at rated speed. Consequently, the probability of missile generation at Sequoyah (due to all failure mechanisms) is, for analysis purposes, approximately equal to the probability of missile generation due to SCC at rated speed. Thus, the following discussion will be mostly concerned with the probability of missile generation due to SCC at rated speed.

The probability of a missile generation from stress corrosion of a low-pressure turbine rotor disc is a function of the disc inspection interval, the disc critical crack size, the disc maximum crack growth rate, the maximum crack sizes present initially (if any), and the ability of the turbine's cylinders and casings to contain the ruptured disc and associated fragments. Initially, the disc characteristics and properties such as the location and size of any cracks, the material toughness, the tangential bore stress, the normal operating temperature of the disc, the disc

yield strength, and other similar parameters are known. With this given information and that in Table 10.2.3-3, and the methodologies used in the latest Westinghouse analyses, critical crack sizes, the maximum growth rates, and a matrix of missile generation probabilities verses inspection intervals (based on turbine operating time) can be calculated for each disc. Westinghouse methodologies used in their latest reanalyses are documented in Topical Report WSTG-1-NP "Procedures for Estimating the Probability of Steam Turbine Disc Rupture from Stress Corrosion Cracking", May 1981, and Topical Report WSTG-2-NP "Missile Energy Analysis Methods for Nuclear Steam Turbines," May 1981. As an alternate to the above probabilistic approach for turbine missile analysis and the effects of SCC, the NRC has developed a deterministic approach which utilizes fracture mechanics, material properties, turbine operating history, etc., to determine critical crack sizes, maximum crack growth rates, and other suitable information which are used to establish low pressure nuclear turbine rotor disc inspection intervals. This deterministic approach for low pressure turbine disc inspection intervals will be used for Sequoyah. Note that both of the above approaches will provide approximately the same level of protection (or risk) with regard to turbine disc missile generation.

Prior to exceeding 5 percent power on Sequoyah Unit 1, a preservice (baseline) ultrasonic (and visual) inspection of the low-pressure turbine discs (and rotors) was performed at the request of the NRC to verify that there were not any significant cracks in these components. No significant cracks were found. The test results for this inspection were reviewed and accepted by the NRC. No preservice inspection was required or necessary for Sequoyah Unit 2.

Also at the request of the NRC, an ultrasonic (and visual) inspection of the low-pressure turbine discs (and rotors) were performed prior to startup following the second refueling outage on Sequoyah Unit 1. The results of these inspections and new inspection intervals, were provided to the NRC for their review.

Missile Impact Areas and Dimensions

Figure 10.2.3-3 shows the overall width and projected impact areas of a disc quadrant. The following dimensions and areas for each of the five disc quadrants were used in the hazards analysis:

Disc No.	1	2	3	4	5
A_1, ft^2	4.9	4.2	2.0	2.4	3.0
A_2, ft^2	2.31	2.04	1.74	1.96	2.45
A_3, ft^2	3.7	3.4	3.3	3.6	4.1
W, ft	6.1	6.0	6.0	5.8	5.2
L, ft	2.6	2.7	2.8	2.7	2.3

A_1: Disc rim projected impact area

A_2: Disc end projected impact area

A_3: Disc hub projected impact area

W: Maximum dimension of disc quadrant
L: Radial dimension of disc quadrant

Figure 10.2.3-1 shows the overall width and projected impact areas of a disc quadrant from the latest Westinghouse analysis. The dimensions and areas for each of the five disc quadrants are as follows:

Disc No.	1	2	3	4	5
A_1, ft^2	4.94	4.28	2.03	2.45	3.10
A_2, ft^2	2.40	2.23	1.77	2.03	2.60
A_3, ft^2	3.33	3.09	3.09	3.33	4.00
A_4, ft^2	1.27	1.26	1.28	1.46	1.89
W, ft	6.08	6.08	6.08	5.88	5.32
L, ft	2.64	2.72	2.80	2.74	2.43

A_1: Disc rim projected impact area

A_2: Disc end projected impact area

A_3: Disc hub projected impact area

A_4: Disc end impact area

W: Maximum dimension of disc quadrant
L: Radial dimension of disc quadrant

Table 10.2.3-4 and Figure 10.2.3-2 show the overall dimensions and shapes of the blade ring and cylinder fragments. (This information was also provided with Westinghouse's latest analysis).

Ejection Angles of Disc Quadrants (and Missile Fragments)

Based on test results, we calculate the ejection angles for disc quadrants leaving the turbine casing are calculated to be as follows:

1. Disc Nos. 1, 2, 3, and 4; ± 5° measured from the vertical radial plane passing through the disc.

2. Disc No. 5; 5° to 25° measured from the vertical radial plane passing through the disc. The disc quadrant will eject only towards the adjacent coupling on the rotor shaft. However, for conservatism in the analysis, the end disc was assumed to be ejected with an equal probability from 0° to 25° measured from the vertical radial plane.

10.2.3.2 Turbine Missile Protection Criterion

The turbine missile protection criterion adopted for the Sequoyah Nuclear Plant is based upon the recommendations given in Reference 1 and NRC inspection criteria for low pressure turbine rotor discs. The interpretation made for Sequoyah is that the possibility of unacceptable damage to safety-related equipment and structures should not be significant. A significant threat is considered to be one having a probability of unacceptable damage to safety-related equipment and structures greater than 1×10^{-7} per turbine per year or 2×10^{-7} per 2-unit plant per year. (These probabilities should not change appreciably when the new NRC inspection criteria discussed in the "Effects on Low-Pressure Element Due to Stress Corrosion Cracking" portion of FSAR section 10.2.3.1 is utilized). Equipment and structures considered essential for the preservation of safety are those needed to bring the reactor to and keep it in a cold shutdown state and/or those needed to keep the site boundary accident dosages at/or below limits specified in 10 CFR 100.

10.2.3.3 Essential Safety-Related Equipment and Structures

Six equipment installations and structures were considered essential for the preservation of safety following a missile producing turbine disintegration. Included in this listing are:

a. Unit 1 reactor containment
b. Unit 2 reactor containment
c. Main control room
d. Spent fuel pit
e. Diesel generator building
f. Intake structure

The location of these items within the plant and their relationship to the potential turbine missile sources are shown in Figure 10.2.3-4.

10.2.3.4 Turbine Missile Hazard Evaluation

The expression used to evaluate the turbine missile hazard contains four probability components and a factor accounting for the scope of the source of missiles. This is written as:

$$Pr(E) = nPr(A)Pr(B)Pr(C)Pr(D)$$

Where: n = The number of turbine generator units at the plant. At the Sequoyah Nuclear Plant n = 2.

Pr(A) = The probability of event A occurring per turbine operating year. Event A is defined as a missile producing turbine disintegration (penetration of outer turbine casings).

Pr(B) = The probability of event B occurring per turbine disintegration (missile generation). Event B is the production of a particular type of missile. In these analyses, two types of missiles are considered center-disc missiles (disc Nos. 1, 2, 3, and 4) and end disc missiles (disc No. 5).

Pr(C) = The probability of event C occurring per turbine disintegration (missile generation) producing the particular type of missiles considered in event B. Event C is defined as a turbine missile strike upon any safety-related equipment or structure.

Pr(D) = The probability of event D occurring per turbine missile strike upon safety-related equipment or structure. Event D is defined as the impairment or destruction of the equipment or structure.

Pr(E) = The probability of event E occurring per turbine operating year. Event E is defined as the infliction of unacceptable damage from a turbine missile.

Several guidelines were employed to make this expression represent conditions at the Sequoyah Nuclear Plant. A listing of these includes:

a. The probability of missile generation (missile penetrates and leaves the outer turbine casing), Pr(A), will be 1×10^{-4}/yr. Such a probability rate, as stated in Reference 1, is a very conservative upper bound limit based on current experience of 70,000 turbine years under actual operating conditions.

b. The only source for missiles will be the low-pressure turbines. In this instance, there are three low-pressure turbines in each of the two turbine generator units. Consequently, there are just six different locations from which missiles could originate. The center of low-pressure turbine was assumed to be the point of origin for missiles.

c. Only one turbine disc from one low-pressure turbine will disintegrate in a turbine accident producing missiles.

d. In the event of a missile producing turbine disintegration, the probability of a center disc rupture is assumed to be 1.0 (thus Pr(B) = 1.0) and the probability of an end disc rupture is assumed to be 0.5 (therefore , Pr(B) = 0.5 in this instance). Such values were assumed to assure conservatism.

e. Quarter-disc missiles from each missile producing turbine disintegration event were assumed.

f. The turbine missile masses and turbine casing exit velocities assumed are those specified in Table 10.2.3-2 for 186 percent of rated speed. These may be compared with the masses and energies for 190 percent presented in Table 10.2.3-3 which were produced by the Westinghouse reanalysis and are due to different failure assumptions (see Effects on Low-Pressure Element of Turbine-Generator Unit Overspeeding). Note that the energies vary greatly among the two cases. However, since disc No. 2 is calculated to fail first during a destructive overspeed event, this disc is used to represent the properties of all center discs. With this consideration, it may be seen that the values assumed in the analysis (Table 10.2.3-2) are considerably higher than those recently reported by Westinghouse.

g. Center-disc missiles were assumed to be deflected ± 5° during the turbine casing penetration process.

h. End disc missiles were assumed to be deflected from 0° to 25° during the turbine casing penetration process. This is conservative with respect to the new Westinghouse analysis which calculated deflections in the 5° to 25° range. In addition, the energy assumed in the

analysis is lower than that reported in the Westinghouse analysis for end discs (see disc No. 5 in Tables 10.2.3-2 and 10.2.3-3). However this difference is offset by the deflection angle range and the significantly larger center disc missile energies used in the analysis. There are four center discs for each end disc.

i. All strikes upon equipment installations or structures essential for the preservation of safety were assumed to eliminate that particular safety function. Under such an interpretation, Pr(D) = 1.0. This is true for rated and overspeed conditions. For conditions at less than rated speed Pr(D) = 0.5.

Strike probabilities upon essential safety-related equipment and structures were calculated by the conservative methodology described in Reference 2. Both three- and two-dimensional analyses were conducted.

The three-dimensional analysis of the strike probability is an investigation to determine the probability that a missile will emerge from a turbine casing with a velocity vector directed toward the essential safety-related items. Three of the six safety-related items listed in Paragraph 10.2.3.3 were considered to be vulnerable to this kind of impact.

These were the main control room and the two reactor containment structures. The results obtained indicated that no missiles can emerge from any of the low-pressure turbines at sufficiently low trajectory elevation angles to strike these structures. Such findings indicate that there is no hazard to these three essential structures from missiles on their upward portion of their trajectory.

The two-dimensional analysis of the strike probability is an investigation to determine the probability of a turbine missile striking any of the essential safety-related items identified in Paragraph 10.2.3.3 during the downward part of the trajectory. In the analyses conducted, both center-disc and end-disc missiles were considered. The results indicated that missiles from low-pressure turbine, low-pressure 2A, constituted the greatest threat. A strike probability for center- disc missiles from low-pressure 2A was found to be 4.5×10^{-4} per turbine disintegration and a strike probability for end-disc missiles from this turbine was found to be 9.3×10^{-4} per turbine disintegration. Additional details on these strike probabilities are shown in Table 10.2.3-5.

A summary of the factors appearing in the unacceptable damage probability equation for the two kinds of missiles that could originate at turbine low-pressure 2A are as follows:

<u>Center-Disc Missiles</u>

n = 2 turbine generator sets/plant

Pr(A) = 1×10^{-4} missile producing disintegrations/turbine year
Pr(B) = 1.0 center-disc missiles/missile producing disintegration
Pr(C) = 4.5×10^{-4} strikes on safety-related items/center-disc missile
Pr(D) = 1.0 unacceptable disablements/missile strike

<u>End-Disc Missile</u>

n = 2 turbine generator sets/plant

Pr(A) = 1 x 10^{-4} missile producing disintegrations/turbine year
Pr(B) = 0.5 end disc missiles/missile producing disintegration
Pr(C) = 9.3 x 10^{-4} strikes on safety-related items/end disc missile
Pr(D) = 1.0 unacceptable disablements/missile strike

The product of the related factors show that the probability of unacceptable damage to essential safety-related equipment or structures is 9.0 x 10^{-8}/turbine year for center-disc missiles and 9.3 x 10^{-8}/turbine year for end-disc missiles. In each instance, these conservatively determined probabilities are below the acceptable risk threshold of 1 x 10^{-7}/turbine/year per unit specified in Reference 1. It is, therefore, concluded that the hazard from turbine missiles at the Sequoyah Nuclear Plant is not significant. It should be noted that a hazards probability reanalysis was not performed upon submittal of the Westinghouse SCC work, the changes in missile energies are such that no appreciable change in the strike probabilities will occur. Further, there is considerable conservatism in the assumptions used in the analysis, which are listed above.

10.2.4 Evaluation

The following operational transients can occur, caused by operation of turbine, generator, or distribution system protection equipment.

a. Turbine trip due to turbine abnormalities.
b. Turbine trip due to generator abnormalities.
c. Transients due to rapid load changes or system abnormalities.

The analysis of the consequences of the severest of these events with respect to reactor safety are discussed in Chapter 15, Accident Analysis.

There can be any number of component or system operational abnormalities that can be postulated to produce a turbogenerator load transient. However, since the effects of such abnormalities can be no worse than a turbine or generator trip, these occurrences are not formally listed.

Any noble gas activity in the secondary system as well as the particulate activity present due to moisture carryover from the steam generators enters the high-pressure turbine. The subsequent activity entering the low-pressure turbine is reduced due to the moisture separation that occurs between the exit of the high-pressure turbine and the entrance to the low-pressure turbines. Activity levels in the turbine are expected to be low and the shielding is provided by the piping, turbine casing, and other components. If any additional shielding is required in local areas, it will be provided so that unlimited access to the turbine area is possible. Details of the shielding design are discussed in Section 12.1.

Radiation protection measures for the Steam and Power Conversion System are based on a maximum total primary-to-secondary leakage of 1 gal/min and 1 percent failed fuel. On that basis, all components of the system are considered access areas with maximum dose rates to an individual of less than 1 mr/hr. Because of (1) the very low probability of operation with a large primary-to-secondary leakage rate, (2) the low equipment contact doses, and (3) the absence of

equipment with which could accumulate significant amounts of radioactive material, TVA does not consider the steam and power conversion system or the turbine building to be a significant source of operator exposure.

10.3 Main Steam Supply System

10.3.1 Design Bases

The Main Steam Supply System is designed to conduct steam from the steam generator outlets to the high-pressure turbine and to the condenser steam dump system. This system also supplies steam to the feedwater pump turbines, auxiliary feedwater pump turbines, main turbine second stage reheaters, and turbine seals.

The Main Steam Supply System includes self-actuating safety valves to provide emergency pressure relief for steam generators, and atmospheric relief valves to provide the means for plant cooldown by steam discharge to atmosphere if the turbine bypass system is not available.

The Main Steam Supply System is designed to TVA Class B requirements from the steam generator outlet out to and including the main steam line isolation valves and flued-anchors. A failure or malfunction of any of the TVA Class B portion of the system must not:

a. Reduce flow capability of the Auxiliary Feedwater System.
b. Render inoperative any engineered safeguard system.
c. Initiate a loss-of-coolant accident.
d. Cause failure of any other steam (or feedwater) line.
e. Result in the containment pressure exceeding design value.
f. Impair the containment integrity.
g. Allow uncontrolled blowdown of more than one steam generator.

The remainder of the Main Steam Supply System, all piping downstream of the main steam line isolation valves, is designed to the requirements of TVA Class H (ANSI B31.1) or TVA Class L.

The main steam flow restrictor limits steam flow, in event of a steam line break downstream of the flow restrictor, to safety analysis limits which is required to reduce the probability of fuel clad damage as discussed in Section 15.4.2.

10.3.2 System Design Description

10.3.2.1 System Design

The Main Steam Supply System is shown schematically on Figure 10.3.2-1. The steam flows from each of four steam generators through containment and the main steam line isolation valves in a 32-inch outside diameter pipe. Each steam supply includes a flow restrictor, which will act to limit the maximum flow and the resulting thrust force created by a steam line break. The replacement steam generators incorporated an integral flow limiter into the main steam nozzle.

The steam generator safety valves and atmospheric relief valves are located upstream of the main steam line isolation valves. There are five safety valves per steam generator with a minimum required rated capacity of 3,917,000 lb/h combined. The steam generator safety valves provide emergency pressure relief for the steam generators in the event that steam generation exceeds steam consumption. For safety valve settings refer to Technical Specification 3.7.1, Table 3.7.1-2.

There is one atmospheric relief valve per steam generator. These valves have a capacity as tabulated in Table 10.1-1.

These atmospheric relief valves provide the means for plant cooldown by steam discharge to the atmosphere if the condenser steam dump is not available. These valves will also provide a means of steam generator pressure control if condenser steam dump is not available and by so doing avoid unnecessary lifting of steam generator safety valves. Pressure setting of these valves is slightly less than the relief pressure of the safety valves.

The maximum actual capacity at a steam pressure of 1085 lb/in^{2}g of any single safety or atmospheric relief valve does not exceed a flow of 890,000 lb/h to limit steam release if any one valve is inadvertently stuck open.

Steam supply for the auxiliary feedwater pump turbines is provided by one connection each on two of the main steam lines upstream of the main steam line isolation valves. Connecting into two steam generator steam lines upstream of the main steam line isolation valve provides both redundancy and dependability of supply.

The main steam line isolation and main steam isolation bypass valves are provided to protect the plant during the following accident situations:

1. Break in the steam line from one steam generator inside containment or upstream of MSIV.
2. Break in the steam header downstream of the MSIVs.
3. Steam generator tube rupture.

The main steam line isolation valves are 32-inch globe Y type, straight through flow, air to open, spring to close These valves were modified to prevent reverse flow which has allowed elimination of the downstream check valve. These valves are capable of closing within the required ESF actuation time. In series with and downstream of the isolation valve is a check valve body (internals removed) which is part of the TVA Class B pressure boundary.

In parallel with the main steam isolation valve is a 2-inch globe type main steam isolation bypass valve which is used to provide steam for downstream pipe warming and to equalize the pressure across the main steam isolation valve (MSIV) prior to opening it during plant startup. The main steam isolation bypass valves are air to open, fail-close valves which are capable of closing within 10 seconds of receipt of the same isolation signals provided to the MSIVs.

For accident situation No. 1, the steam generator associated with the damaged line discharges completely into the containment or main steam valve room. The other steam generators would act to feed steam through the interconnecting header to reverse flow into the damaged line and then release into the containment or steam valve room. The closure times specified above for the isolation valves will limit containment pressure rise below design pressure. (See Section 6.2.)

For accident situation No. 2, the time requirements established in situation No. 1 are the limiting case and are satisfactory for requirements resulting from this situation.

For accident situation No. 3, this requirement is not limiting. A fast acting valve is not required. The isolation valves serve to limit the total amount of primary coolant leakage during the shutdown period by isolating the damaged steam generator after pressure is reduced below steam generator shell side design pressure.

The main steam lines downstream of the main steam line isolation valves are 36-inch outside diameter pipes. Four main steam turbine stop valves and turbine control valves are provided at the high pressure turbine inlet. The steam lines are cross-connected ahead of the turbine stop valves. The cross connections provide both an entrance to the Condenser Steam Dump System and a distribution manifold for the turbine stop valves. The turbine is described in Section 10.2, Turbine-Generator. The Turbine Bypass System is described in Section 10.4, Other Features of Steam and Power Conversion System. The Main Steam Supply System interface with the Auxiliary Feedwater and Blowdown Systems are described in the appropriate subsections in Section 10.4, Other Features of Steam and Power Conversion System.

Each steam line flow restrictor is installed in the steam outlet nozzle integral to each replacement steam generator. Steam reaches the 32-inch outside diameter stream outlet nozzle after passing through seven, 6-inch inside diameter flow limiter inserts. The nickel alloy 690 inserts are installed in parallel at the nozzle inlet.

10.3.2.2 Material Compatibility, Codes, and Standards

All (pressure containing) components in the Main Steam Supply System are carbon steel, except for the Unit 1 Main Steam Trap Drain Piping from the condensate pots to the condenser, which is stainless steel. Carbon steel components, damaged by erosion corrosion, may be replaced with Cr Mo Steel or other erosion resistant steel.

Applicable codes, standards, and design conditions (pressure and temperature) are shown in Table 10.3.2-1.

10.3.2.3 NRC Bulletin 88-02 Analysis

To address the issue of rapidly propagating fatigue cracks in steam generator (S/G) tubes as identified in NRC Bulletin 88-02, a thermal-hydraulic analysis of the S/G secondary side was performed by Westinghouse as detailed in WCAP-12289/12290. This analysis was performed at rated steam flow and at a pressure of 800 psia for conservatism. The result of the analysis was that one tube in Unit 1 and two tubes in Unit 2 were required to be removed from service. No other tubes were identified as susceptible. The Sequoyah units have therefore met the requirements of the bulletin, provided modifications are not made to increase the steam flow rate, to decrease the operating steam pressure below 800 psia, or to significantly affect the S/G secondary side recirculating flow (see Section 5.5.2.3.4).

A subsequent evaluation of the Model 51 S/G tubes was performed in support of the 1.3% power uprate program for Units 1 and 2 (Reference Westinghouse WCAP-15725, September, 2001). This evaluation concluded that a few additional tubes would become susceptible to high-cycle fatigue at the higher power if the operating steam pressure falls below approximately 800 psia. These tubes would need to be repaired if this occurs.

The materials for piping and valves in the TVA Class B portion of the system are impact tested to plus (+) 10°F as per Appendix I, ANSI B31.7, for pipe and fittings and as per Appendix E, Draft ASME Pump and Valve Code for Nuclear Power for valves. The test temperature of plus (+) 10°F is related to a minimum service temperature of plus (+) 70° (hydro test water temperature).

10.3.3 Design Evaluation

The portion of the Main Steam Supply System designed to TVA Class B requirements is Category I seismically qualified. The TVA Class B portion of the system is protected from missiles and pipe whip by restraints, physical separation, or barriers. Redundant electrical power and air supplies assure reliable system operation, and safe shutdown capability. Redundant steam supply connections are provided for the auxiliary feedwater steam turbine.

A tabulation of all seismic Category I valves in the Main Steam Supply System relied upon either to assure safe plant shutdown or to mitigate the consequences of a transient or accident is provided in Table 10.3.3-1. This tabulation also includes the type and size of valve, the actuation type, and the environmental design criteria to which the valves are qualified, as stated in the design specifications.

The safety valves provide over 100 percent relieving capacity to protect the system from overpressure. The relief valves, since they have a set pressure slightly lower than the safety valves, prevent excessive lifting of safety valves. Four atmospheric relief valves have been provided per unit (one per steam generator). Only two valves are required for plant cooldown following any credible accident.

The atmospheric relief valves may also be used, in the event of a flood (see FSAR Section 2.4A.2.2), to maintain the pressure in the secondary side of the steam generators. The atmospheric relief valves can be adjusted by controls in the main or auxiliary control room. Also, a manual loading station and the relief valve handwheel provide additional backup control for each relief valve.

The Main Steam Supply System is designed to comply with the 1974 Edition of ASME Section XI, Inservice Inspection of Nuclear Power Plant Components, to the extent practical under the original design. Class 2 piping and valves which are not accessible for examination by volumetric and surface methods as outlined in the Code will be listed in the detailed inservice inspection program and will be inspected for signs of leakage while under pressure. Inservice testing of Code Class 2 valves will be tested as outlined in the ASME Inservice Valve Testing Program basis document which is referenced in Section 6.8 of the FSAR.

See Section 3.11 and subsection 10.3.6 for Environmental Design of the Main Steam Supply System. Accident considerations, situations, and/or analysis are discussed in subsections 10.3.1 and 10.3.2, and Chapter 15.

In response to a licensing question concerning the NRC staff position (BTP RSB 5-1) for the Residual Heat Removal System (RHR) and the steam generator relief valves, operators, air and power supplies; the following information on the atmospheric relief valves was provided.

The Sequoyah (SQN) steam generator powered atmospheric relief valves are seismically qualified. The air supplies to these valves are from the plant safety grade auxiliary control air system. The power and air supplies to these vales are trainized (two valves per train), receiving necessary electrical power from the 125-volt vital battery system.

The most limiting single failure would be the loss of one train of the safety grade air system, or one channel of vital power. This would prevent control room initiated steam relief via two of the four power-operated relief valves. Only two valves are required. Operating personnel could manually release steam from any affected valves (via handwheels outside of containment).

The second most limiting single failure would be a mechanical breakdown within one of these atmospheric relief valves so that the valve would be "frozen" shut. In this case, the remaining three relief valves are more than sufficient to maintain safe shutdown.

The ability to manually operate the atmospheric relief valves and to communicate with the main control room (MCR) at the same time was verified during preoperational tests W-8.3, "Engineered Safety Features Actuation System Operational Test," and W-10.3, "Steam Dump Control."

A steam flow restriction is supplied in each main steam line inside the containment building to limit flow in the event of a steam line break downstream of the restrictor. The restriction is located as close as feasible to the steam generator outlet nozzle in order to minimize piping preceding the restriction, thereby reducing the probability of a steam line break upstream of the restrictor. The restrictors were removed during steam generator replacement. The replacement steam generators contain an equivalent flow restrictor which is integral with the main steam outlet nozzle to eliminate the possibility of a main steam line break upstream of the flow restrictors. Being fitted inside the main steam outlet nozzle, a steam flow restrictor is not a pressure boundary component. However, component integrity is assured by satisfaction of ANSI B31.1 requirements. CENP-Westinghouse approved the weld procedures, welders test qualifications, inspection procedures, materials, and the quality assurance program used in design and fabrication of the venturi nozzle for the replacement steam generators.

10.3.4 Tests and Inspections

Performance tests of individual components in manufacturer's shop, integrated preoperational tests of the whole system, and periodic performance tests of the actuation circuitry and mechanical components in accordance with approved plant procedures will assure reliable performance.

Vibration tests on system piping are also performed during the preoperational tests. Details of the vibration operational test program are provided in subsection 3.9.1.1.

Preoperational test requirements are given in Chapter 14.

10.3.5 Water Chemistry

10.3.5.1 Purpose

Water purity in the secondary system, and in the steam generators in particular, is maintained within specified limits in order to minimize fouling of steam generator heat transfer surfaces and maintain steam generator tube integrity.

10.3.5.2 Chemistry Specifications

Specifications for chemistry control in secondary systems such as steam generator steam side, feedwater, and condensate chemistry for various operating modes and conditions have been established with consideration given to various sources. The sources include, but are not limited to PWR experience, Westinghouse specifications, and Steam Generator Owner's Group EPRI guidelines.

10.3.5.3 Chemistry Control

The selection of secondary water chemistry is governed by the secondary system operating mode or condition. A discussion of the water chemistry for these modes and conditions is presented below.

1. Power Operation. During power operation, the condensate, feedwater, and secondary side steam generator chemistries are maintained within the specified limits by providing makeup water of adequate purity and by chemical treatment of the condensate and feedwater systems. Chemical addition systems inject the selected chemical solution into the condensate system. Chemical treatment is accomplished as described in Section 5.5.2.

   Steam generator steam side chemistry during power operations is controlled by steam generator blowdown (subsection 10.4.8), condensate polishing and chemical treatment of the feedwater.

   a. Blowdown - To minimize corrosion and sludge accumulation, control of contaminants dissolved or suspended is required. The quantity of contaminants is effectively controlled by blowing down each steam generator. In the event of primary to secondary leakage or condenser inleakage, blowdown is employed to keep the contaminants within limits. Blowdown contributes to the control of radioactive iodine which may occur in the event of primary to secondary leakage.

   b. Condensate Polishing - The Condensate Cleanup System is described in subsection 10.4.6.

   c. Chemical Treatment - Any combination of chemical additives is supplied by the Feedwater Treatment System and is transported through the condensate and main feedwater lines to the steam generator and is carried along with steam through piping, feedwater heaters, and turbines. See Section 5.5.2.

2. Auxiliary Feedwater. During extended periods of Auxiliary Feedwater use, oxygen scavenging and corrosion control chemicals can be manually added to the Steam Generators. During unit heatup and auxiliary feedwater operation, boric acid can be added to the steam generators.

3. Wet Layup. Hydrazine or carbohydrazide, Dimethylamine, and ammonia are normally added during wet layup of the steam generators.

4. Auxiliary System Support. The hydrazine and ammonia addition systems are both capable of feeding various chemicals to the auxiliary boiler feedwater pump suction. Thus, corrosion inhibitors and oxygen scavenging chemicals are available to the Auxiliary Boiler System.

10.3.5.4 Effect of Water Chemistry on the Radioactive Iodine Partition Coefficient

As a result of the basicity of the secondary side , the radioiodine partition coefficents for both the steam generator and the air ejector system are increased (i.e., a greater portion of radioiodine remains in the liquid phase). Partitioning factors to estimated dose are utilized only for inadvertent steam releases through the atmospheric reliefs. These releases can be estimated based on liquid samples.

10.3.6 Instrument Application

Automatic operation of the main steam line isolation valve is initiated by a main steam isolation signal (see Chapter 7). Provisions are made for remote manual operation from the control room. These valves fail closed on loss of electric power or control air.

Control of the atmospheric relief valves is: (1) a non-safety grade automatic modulating controller using steam line pressure with remote manual control of pressure setpoint from the control room, and (2) safety grade remote manual controls for positive open/close action from the MCR. The non-safety grade automatic control is provided by the plant Distributed Control System (DCS).

In response to licensing question concerning IE Information Notice 79-22 on environmental qualification of control systems, TVA performed a systematic (matrix) evaluation of the environmental effects resulting from high-energy pipe breaks inside and outside containment upon nonsafety-related systems. Specifically, safety features required to mitigate the consequences of high-energy pipe break and those required to obtain and maintain a safe shutdown following such an event were evaluated to determine if a single inappropriate actuation of an interfacing nonsafety-related system could unacceptably affect the required safety feature. TVA's conclusion is that although there is a possibility for disruptive signals to be generated, these are in every case acceptable because the operator will always have sufficient indication and time to take corrective action. Consequently, a safe shutdown can be achieved even if a postulated accident is compounded by environmentally induced inappropriate actuation. Operating instructions have been modified as an additional precaution to preclude the event or to alert the operator to the possibility of the event.

The evaluation concerning the environmental effects on the atmospheric relief and main steam isolation bypass valve controls is as follows. The control system for the atmospheric relief valves could be affected by high-energy pipe breaks in the main steam valve room. This inappropriate opening is considered to be acceptable because (1) adequate annunciations provided to alert the operator to the event, (2) adequate time is available for operator action (3) the control system design assures that the operator can override the inappropriate open signal.

An inappropriate opening of a main steam isolation bypass valve (MSIBV) would defeat steam generator isolation. For Appendix R purposes, the fuses are removed from the MSIBVs during normal operation. This also guards against the valve actuation due to environmental effects in the steam valve vaults following a steam line break or flood.

10.4 OTHER FEATURES OF STEAM AND POWER CONVERSION SYSTEM

10.4.1 Main Condenser

10.4.1.1 Design Bases

The design basis for the main condenser is to provide a heat removal rate of at least 7.829 x 10^9 Btu/hr per unit for the steam system by condensing the steam from the turbine exhaust at a back pressure of 1.88 inches of mercury, absolute. During a cold startup, the condenser must also deaerate the initial inventory of water contained within the condensate-feedwater system.

10.4.1.2 System Description

To provide sufficient capability to meet the functional requirements as stated in subsection 10.4.1.1, the main condenser has been designed with the following specifications:

Total surface area, ft^2	757,952
Circulating water quantity, gal/min	530,600
Circulating water pressure drop through condenser, ft	11.76
Circulating water temperature (yearly average), °F	61
Circulating water temperature rise, °F	29.51
Number of shells	3
Number of passes/shell	1
Tubes:	
Effective length, ft	49'-9"
Number Tubes, Size (inches OD), Birmingham Wire Gauge (BWG)	
Internal Condensing Zone	71,220 - 3/4- 24
Impingement (Peripheral) Condensing Zone	3,132 - 3/4-22
Air Cooling Section	3,240 - 3/4-24
Material	Titanium
Tubesheets:	
Base Material, Thickness (inches)	Carbon Steel -1 3/8
Cladding Material, Thickness (inches)	Titanium-3/16
Cleanliness, percent	95
Duty, 10^9 Btu/hr	7.829
Design pressure:	
Shell, lb/in^2g	20
Hotwell, lb/in^2g	20
Waterboxes, lb/in^2g	25
Hotwell storage/shell (normal), gallons	11,000
Oxygen content of condensate, cc/liter	0.005
Bypass system:	
Flow/shell, lb/h	1,987,400
Pressure (at nozzle), lb/in^2g	250
Enthalpy, Btu/lb	1197.5
Air inleakage/shell (SCFM)	8

The condensers are of conventional design, having an expansion joint in the neck and the required impingement baffles to protect the tubes from incoming drains and steam dumps. The hotwell of the condenser has a water storage capacity equivalent to approximately 2 minutes of full load operation. Cross connections are provided for equalization of pressure between condenser shell. Provisions have been made for mounting of three 1/3 capacity low-pressure extraction feedwater heaters in the neck of each condenser.

At the design point, the Main Condenser System will produce a back pressure 1.88 inch Hg absolute when operating at rated turbine output with 61°F cooling water and 95 percent clean tubes. For cooling water temperature variation and various modes of operation of the cooling tower, see subsection 10.4.5, Condenser Cooling Water System. A condenser tube cleaning system is provided to clean the condenser tubes.

The condenser is designed to remove dissolved gases from the condensate, limiting oxygen content to 0.005 cc per liter at any load during normal operation.

During startup the initial inventory of water contained within the Condensate Feedwater System can be deaerated using steam from the opposite unit or auxiliary boiler. A recirculation pipe is run from immediately upstream of the feedwater isolation valves to a perforated pipe running across the full width of each hotwell section. Recirculated condensate is sprayed across the condenser while being deaerated with steam being sprayed up through it from steam sparging nozzles located in a header arrangement in the hotwell.

The condenser can accept a bypass steam flow of approximately 40 percent of maximum guaranteed steam generator flow, without exceeding the turbine low vacuum trip point, or an exhaust hood temperature of 175°F, with circulating water temperature of up to 85°F. This bypass steam dump to the condenser is in addition to the normal duty expected with a throttle flow of 60 percent of maximum guaranteed steam generator flow.

The correct secondary cycle water inventory is maintained by the automatic bypass-makeup condensate system. The level controller(s), which are sensitive to the hotwell level, position the bypass valve or makeup valves (to or from the condensate storage tank) as required to maintain the hotwell water level within preset limits. These level controllers are contained within the DCS.

10.4.1.3 Safety Evaluation

The inventory of radioactive contaminants in the main condensers is a function of the primary coolant radioactivity, the steam generator primary-to-secondary leak rate, and the steam generator and condenser partition factors. Table 10.4.1-1 gives the calculated radioactivity concentrations for a primary-to-secondary leak rate of 20 gallons/day and 0.25 percent failed fuel during power operation. The factors and coefficients are the same as those used in subsection 11.1.

The possible mechanisms for hydrogen production in the secondary system are radiolysis of secondary side water, corrosion, and release of hydrogen from the reactor coolant in the event of primary-to-secondary leakage. Hydrogen generated via these mechanisms is transported to the condenser. Conservative estimates of the extent of hydrogen production by radiolysis shows that negligible amounts of hydrogen (less than 0.001 SCFM) are formed. The water chemistry of the secondary system is such that hydrogen evolution due to corrosion is also

negligible. Of the three possible hydrogen producing mechanisms, only primary-to-secondary leakage has the potential for supplying measurable quantities of hydrogen. However, for large primary-to-secondary leakage rates (1.0 gal/min/unit), the rate of hydrogen release would be less than 0.01 SCFM. This rate is small when compared to the condenser evacuation system capacity of 30 SCFM at 1 inch Hg absolute suction pressure with two vacuum pumps in operation. Thus, hydrogen entering the condenser is effectively exhausted via condenser evacuation system and the potential for hydrogen buildup is negligible.

The condenser could become ineffective because of the loss of some or all of its cooling water and/or excessive air leakage. Either of the above conditions would cause the condenser pressure to increase and upon reaching the setpoint specified in operating procedures, the turbine would be manually tripped. An automatic backup trip is also provided for transient and pressure spike conditions to automatically trip the turbine. Consequently, rising condenser pressure will cause a turbine trip which will produce a reactor trip for power levels greater than 50 percent.

The residual heat would then be removed as steam through the turbine bypass valves until they were tripped closed because of a condenser pressure of approximately 6 inches to 7 inches Hg absolute or the loss of the circulating water pumps. After the turbine bypass valves are tripped closed, the residual heat is removed as steam through the SG power operated relief valves and/or the ASME Code safety valves to the atmosphere.

10.4.1.4 Inspection and Testing

Prior to operation, the condenser was tested for leaks by completely filling the shell with condensate. Currently, other NDT methods (such as eddy current testing to identify leaking condenser tubes) are used to test the condenser. Manways provide access to waterboxes, tube sheets, lower steam inlet section, shell, and hotwell for purposes of inspection, repair or tube plugging.

10.4.1.5 Instrumentation

Sufficient level controllers, level switches, pressure switches, temperature switches, etc., were provided to permit personnel to conveniently and safely operate this condenser system.

10.4.2 Main Condenser Evacuation System

10.4.2.1 Design Bases

The design basis for the main condenser evacuation system is to create and maintain condenser back pressure at 1.0 inch Hg absolute by removing noncondensable gas and air inleakage. The design evacuation rate is 30 SCFM at the above suction pressure and with two pumps in operation.

10.4.2.2 System Description

The Main Condenser Evacuation System is shown on Figure 10.4.2-1. To provide sufficient capability to meet the functional requirements as stated in subsection 10.4.2.1, the Main

Condenser Evacuation System has been designed with the following specifications:

Type of evacuating equipment	Mechanical vacuum pumps
Number of vacuum pumps, per unit	3
Air capacity at suction pressure of 1 inch Hg absolute, SCFM, per pump at normal operation	15
Air capacity at suction pressure of 15 inches Hg absolute, SCFM per pump at startup	1000

The vacuum pumps are two-stage liquid ring type pumps.

Two pumps, operating in parallel, are adequate for the removal of the maximum expected air inleakage of 24 SCFM. The third vacuum pump is arranged to start automatically on decreasing condenser vacuum.

The discharge from all three vacuum pumps can be routed through a HEPA filter-charcoal adsorber train, which consists of an electric duct heater, HEPA filter unit (optional), charcoal adsorber unit (optional), and connecting piping. The discharge is monitored with a low, mid, and a high range noble gas effluent radiation detector before it is exhausted to the outdoors from the turbine roof ventilators. Refer to Figure 10.4.2-1.

The system is designed to cleanup approximately 45 cfm of condenser exhaust. During unit startup, periods of high condenser leakage or periods of zero or low secondary side activity, the flow rate will be allowed to bypass the cleanup system assembly. A pressure differential switch will automatically operate to open the bypass dampers upon an excessive filter pressure drop.

The optional charcoal adsorber must remain dry for efficient operation. Since the condenser exhaust may be expected to be approximately 100°F and 100 percent relative humidity, the 500 watt duct heater is designed to heat the exhaust approximately 30°F and to thus lower the relative humidity to approximately 50 percent before entering the filter units.

10.4.2.3 Safety Evaluation

Depending upon actual air in-leakage to the condenser one or two of the three vacuum pumps are considered to be spares. These spare pump(s) automatically start when the condenser back pressure increases. Should the back pressure continue to increase (because of inadequate air removal capability or a partial loss of cooling water), a high back pressure alarm would sound and the turbine may be manually tripped and consequently may cause a reactor trip. However, an auto trip will occur if back pressure continues to increase beyond the alarmed setpoint.

Details of the radiological evaluation of the condenser evacuation system are contained in Chapter 11.

10.4.2.4 Inspection and Testing

The operating characteristics for each vacuum pump will be established throughout the operating range by factory tests.

A flowmeter is provided in the discharge of each vacuum pump. Periodic readings of these flowmeters will indicate whether or not the air inleakage to the condenser is within acceptable limits. These readings will also indicate the effectiveness of the operating vacuum pumps.

10.4.2.5 Instrumentation

The necessary pressure and temperature switches are provided to automatically start the standby vacuum pump or shutdown a malfunctioning (vacuum) pump. Radiation monitors are provided to detect any radioactivity in the vacuum pump discharge.

10.4.3 Turbine Gland Sealing System

10.4.3.1 Design Bases

The turbine gland sealing is designed to provide means of sealing the main turbine shafts and valve stems and the main feed pump turbine shafts, using steam from upstream of the turbine stop valves. This sealing can be accomplished automatically with steam supply pressures of from 185 to 1100 lb/in^{2}a. Sealing of the turbine glands with the steam supply pressure below 185 psia can be accomplished by manually or remotely opening the steam seal regulating valve bypass valve.

Steam from the opposite unit or auxiliary boiler can be supplied to the seals during startup.

10.4.3.2 System Description

The purpose of the gland steam sealing system is to prevent leakage of air into the turbine casing, and, conversely, prevent the leakage of steam into the turbine room when turbine casing is pressurized.

The system utilizes labyrinth type seals. Each seal is equipped with two annular shaped chambers which are located among the packing rings. The chamber nearest the turbine casing is maintained at a pressure of approximately 16 lb/in^{2}a by the admission of sealing steam or the controlled leak off of higher-pressure steam.

The outer chamber is maintained at a slight vacuum (approximately 3 to 5 inches water) by the Gland Steam Exhauster System. This vacuum causes the sealing steam to leak outward and mix with the inward leaking air. This mixture flows to gland steam condenser where most of the steam component is condensed and returned to the secondary cycle. The noncondensables are forced, by the exhauster, through piping to the outside of the building.

10.4.3.3 Safety Evaluation

Since this is a PWR, radioactive steam in the Steam Seal System is of very small consequence. The exhauster discharge is piped outside of the building to prevent the possibility of accumulating radioactive particles in a stagnant building area. Information regarding the design for monitoring radioactivity is presented in FSAR Section 12.1. The presence of radioactivity in the secondary cycle (main steam) which could leak through the turbine gland seals (in the event

that the gland steam condenser exhausters fail to work properly) would be detected in the discharge of the main condenser vacuum pumps. The radiological effects of this system are negligible during normal operation.

In the event one exhauster is lost, the operator will isolate the ineffective exhauster and start the spare (exhauster). Should both exhausters fail, seal steam will leak into the turbine room.

If the steam seal supply fails, excess air leakage will probably trip the turbine because of low vacuum.

A number of safety valves and rupture diaphragms are installed on this system to protect the various components against high pressure.

10.4.3.4 Inspection and Testing

This equipment will be tested by the vendor in accordance with the various applicable code requirements. Periodic tests will be performed by the operator to verify the integrity of this system with respect to its capability of maintaining the turbine seals.

10.4.3.5 Instrumentation

Sufficient instrumentation has been provided to satisfy all system functional requirements and to permit safe, convenient operation by plant personnel.

System performance is constantly monitored by measuring gland steam exhauster vacuum and supply steam header pressure.

10.4.4 Turbine Bypass System

10.4.4.1 Design Bases

The Turbine Bypass System's design basis reduces the magnitude of nuclear system transients following large turbine load reductions by dumping throttle steam directly to the main condenser, thereby creating an artificial load on the reactor.

The Turbine Bypass System has the following functional requirements:

a. Permit a direct bypass flow to the main condenser of 40 percent of rated turbine flow, thereby allowing a turbine step load reduction of 50 percent without a resultant reactor trip.

b. Permit turbine trip (accompanied by reactor trip) from full load without lifting steam generator safety valves.

c. Provide plant flexibility during operation, by allowing turbine load changes in excess of the base NSSS design without reactor trip.

d. Provide controlled cooldown of the NSSS.

e. Assist in achieving stable startup of the plant.

10.4.4.2 System Description

The Turbine Bypass System is shown on Figure 10.3.2-1 for the main and reheat steam.

The capability for meeting the functional requirements of subsection 10.4.4.1 has been provided by designing the equipment to the following specifications:

Number of valves - 12

Flow per valve - Unit 1 (580,000 lb/hr) Unit 2 (577,000 lb/hr)

Main Steam Pressure at Valve Inlet (for above flow) - Unit 1 - 827 psia Unit 2 - 825 psia

Maximum flow per valve at 1085 lb/in^{2}g inlet pressure - 890,000 lb/hr

Time to open (full stroke) - 3 seconds

Full stroke modulation - 20 seconds

Failure position - Closed

The steam lines from the four steam generators are cross-connected immediately upstream of the turbine stop valves. Piping is run from this header to the 12 turbine bypass valves and then to the triple-shell condenser. Each of the three condenser shells will receive the discharge from four turbine bypass valves.

The normal steam dump operating mode is T_{avg} which compares the average temperature of the reactor coolant (indication of reactor power level) to the turbine impulse chamber pressure (indication of turbine load). When the reactor power level exceeds the analog of the turbine load, the turbine bypass valves will open in proportion to the mismatch.

The second mode of steam dump operation is steam pressure control. This can be either automatic or manual control (direct use of valve loading signal) and would normally be used for unit startup and shutdown.

The Steam Dump T_{avg} and steam pressure controls are contained within the DCS.

Additional details on the Turbine Bypass System controls are provided in Section 7.7, Control Systems Not Required for Safety.

The bypass valves are built in accordance with ANSI Standard B16.5. All piping in the Steam Bypass System is in accordance with ANSI Standard B31.1.

10.4.4.3 Safety Evaluation

Low-low Reactor Coolant System average temperature will block the signals which supply air to the individual turbine bypass valves. A manual bypass (momentary) of this interlock is provided only for the three turbine bypass valves which are designated as "cooldown" valves.

An alternate method of RCS cooldown, below 350°F (i.e., delay RHR cut-in), is provided via the turbine bypass valves. The alternate method provides for disabling the P-12 interlock during cooldown after entering Mode 4. The temporary disablement can be performed procedurally with no permanent hardware modifications to the unit. Permanent control board indication of the bypassed condition is not provided nor is the bypass automatically removed when the permissive conditions are no longer met.

However, cautions per operating procedures shall be placed on the unit control board alerting Operators of the bypassed condition of the P-12 interlock. The use of all twelve turbine bypass valves is optional for the Operator. The turbine bypass valves are controlled using the Steam Pressure Controller before and after the protective interlock is disabled. The interlock disablement procedure for utilization of all twelve valves is performed only after shutdown (and subsequent cooldown) has been initiated and therefore, does not present a reactor trip hazard. An analysis has been performed to assess the cooldown potential following failure of the steam dump controller after placing all twelve turbine bypass valves in service. It was determined that the three turbine bypass “cooldown” valves spuriously opening at the protective interlock setpoint of 540°F can produce a cooldown rate that far exceeds that of all twelve turbine bypass valves opening at 350°F (temperature below which additional valve use is permitted).

Loss of the control air supply to the diaphragms of the bypass valves will prevent the valves from opening; or, if the valves were open, will trip them closed. Loss of control air can result

from indication of inadequate condenser circulating water, high condenser pressure, low-low T_{avg}, or from failure of some system component(s). In the event of loss of control air, the steam generators will still be protected during all transients by the ASME Code safety valves. Steam generator cooldown capability will be available through use of the power-operated relief valves (atmospheric dump).

Inadvertent or accidental opening of any one bypass valve during power operation will not subject the Reactor Coolant System to an uncontrolled cooldown. Refer to Chapter 15. 13

Failure of the Turbine Bypass System can result in discharge of steam to the atmosphere through the steam generator safety valves. If tube leaks were present prior to the incident, some radioactivity accumulated in the steam generator shell side water would be discharged through the safety valves and will be well within criteria established by 10 CFR 100.

10.4.4.4 <u>Inspection and Testing</u>

This equipment will be tested in accordance with the various code requirements. Periodic tests will be performed to assure that the system remains capable of its functional requirements. Inservice inspection for ASME Section XI is not required.

10.4.4.5 <u>Instrumentation</u>

Sufficient instrumentation has been provided to permit this system to:

a. Satisfy all its functional requirements.

b. Protect the reactor (from low-low T_{avg}).

c. Protect the turbine (from high condenser pressure).

10.4.5 <u>Condenser Circulating Water System</u> 13

This section covers the intake channel, skimmer wall, intake pumping station, forebay pool, main circulating water pumps, circulating water conduits, main condenser, discharge gates, discharge pond, cooling tower lift pumps, lift pump station, natural draft cooling towers, and discharge diffusers for the safety-related impacts of this Heat Rejection System on the plant. 13

The primary objective of the Condenser Circulating Water (CCW) System is to provide cooling water to the condensers of the main steam turbines. This system also provides cooling water for auxiliary equipment, and provides an efficient means of rejecting waste heat from the power generation cycle into the ambient surroundings. Because of its capacity and convenience, the condenser circulating water can also be used to dilute and disperse low-level radioactive liquid wastes. 13

10.4.5.1 <u>Design Basis</u>

a. The CCW provides each unit a nominal flow of 535,000 gal/min to the main steam turbine condensers and sufficient flow to the Raw Cooling Water System for use by auxiliary 13

equipment. The main steam condenser mass flows are based on a maximum temperature rise of 29.5°F for the circulating water through the condensers. This water flow is a sufficient quantity to condense the steam at an optimum main condenser back pressure and dissipate all rejected heat.

b. The CCW can dissipate a portion of the waste heat directly to the atmosphere by use of the cooling towers where required to meet thermal criteria.

c. The CCW can provide for dilution and dispersion of low-level radioactive liquid wastes. Refer to Section 11.2.6.

d. The intake pumping station houses the condenser circulating water pumps, traveling screens, and screen wash pumps.

10.4.5.2 System Description

The flow diagrams for the CCW are shown in Figures 10.4.5-1 and 10.4.5-2.

For each unit three pumps are provided in the intake pumping station to pump condenser circulating water through the condensers. Each pump has a capacity of 187,000 gal/min at a design head of 30 feet. Head losses are held to a minimum by maintaining practical velocities and smoothness of flow commensurate with prudent construction and operating costs.

The intake pumping station or intake structure is located at the land end of the intake channel. To provide cooling water to the condensers at a lower heat sink temperature, water from the river flows into the intake channel under a skimmer wall.

The six circulating water pumps mounted on the pumping station deck are the vertical nonpullout, single-stage, mixed-flow, wet-pit type. Adequate suction for these pumps is provided by the reservoir water level. Each group of three pumps operating in parallel supply the full flow requirements of one generating unit. The pumps are driven by 1750 horsepower, vertical, solid shaft, 240 r/min, weather-protected type outdoor motors.

Each pump is installed in a separate suction well with entering water strained by trash racks and a traveling screen. Each of the three pump discharges is equipped with an 84-inch diameter motor-operated butterfly valve. The discharges are brought together in a concrete transition to a single tunnel to the condensers.

The main condenser, when rejecting waste heat to the system at full-load operation, will raise the temperature of the water by approximately 29.5°F. No chemical treatment is provided for the system. Amertap condenser tube cleaning system is provided for cleaning of condenser tubes during normal operation. A vacuum priming system is provided to ensure that all passages are maintained full of water. Seven cooling tower lift pumps and two natural draft cooling towers have been installed. The seven pumps deliver approximately 980,000 gal/min at a head of 82 feet to the two cooling towers. The pumps are located in the cooling tower pumping station located at the downstream end of the discharge pond. The cooling towers are designed to reject waste heat to the atmosphere, thereby cooling the condenser circulating water when river flow/temperatures will not permit direct CCW discharge to the river.

The system is designed to operate in any of three modes: open, helper, or closed. In the open mode the water bypasses the cooling tower lift pumps and is returned to the reservoir through the diffuser pond and the discharge diffusers. In the helper mode the water is pumped into the cooling towers by the lift pumps, passes through the cooling towers where part of the waste heat is liberated directly to the atmosphere, and the cooled water is then returned to the reservoir through Gate Structure 1, the diffuser pond, and the discharge diffusers. In the closed mode the water is pumped through the cooling towers where the waste heat is liberated directly to the atmosphere and then is returned to the intake channel through Gate Structure 2 located in the return channel.

Blowdown from the towers will be taken from the return channel above Gate 1, mixed with the plant effluent, and discharged directly into the diffuser pond. The system is designed to ensure that under no conditions will the radwaste back flow into the return channel. The ERCW discharges into the return channel and will provide a continuous source of blowdown for effluent dilution when CCW is unavailable.

A 1500-foot diked embankment connects to a diffuser discharge system that limits the water temperature gradient in the river and the upper temperature limit of the river. Two corrugated metal diffuser pipes extend under the dike into the river channel. One diffuser is laid to diffuse the water 350 feet across the north side and the other to diffuse the water 350 feet across the south side of the channel. A sluice gate is provided which allows one diffuser to be isolated if necessary.

Filling and operating of the CCW side of the condensers is accomplished by:

a. Venting.
b. Evacuation by the Vacuum System.
c. Operation of at least two circulating water pumps.

Three circulating water pumps can operate in parallel for each unit. However, if one pump is out of service, the two remaining pumps will deliver sufficient flow for full-load operation but with a higher turbine backpressure. A Vacuum System and a Vent System will allow passages to be maintained full of water.

Differential pressure across each traveling screen is monitored by an Air Bubbler System. When a preset differential pressure of water is reached across the screen, the screen wash pump is started. When a preset pressure is established at the screen wash nozzles, the screen motors are automatically started and the screens are washed until the pump is manually stopped.

In addition to the condenser cooling water requirements, the CCW supplies water to the plant raw cooling water pumps and raw service water pumps, which in turn supplies cooling water to nonessential systems. Raw cooling water can be supplied by gravity head from the river via the condenser intake tunnels in case of complete outage of the circulating water pumps.

10.4.5.3 Safety Evaluation

The pumping station is seismic Category I and is designed for tornado winds.

The condenser circulating water pump motors are exposed above the deck. The condenser circulating water pumps are not designed to seismic Category I requirements, but the motor mounts have been analyzed and determined to be capable of withstanding tornadic wind conditions. The intake channel design is described in subsection 2.4.8.

Flooding of the pumping station due to piping or equipment failure of the Condenser Circulating Water System will not adversely affect the performance of the safety-related equipment such as the ERCW headers inside the station.

The operator will be alerted via main control room annunciation to a rising water level in the turbine condenser pit due to a rupture of the circulating water piping inside the turbine building. The power supply to the CCW pumps are provided with diverse remote manual trip capability to allow the operator to trip the pumps upon either loss of communication between the reservoir and the pumping station forebay or rising water in the condenser pit.

The cooling towers, cooling tower supply pumping station, and pumps are not designed to seismic Category I requirements, since their failure could not adversely affect the performance of any safety-related equipment.

The discharge gate structure, discharge gates, associated machinery, power supply, and control system are no longer required to operate since the new ERCW pumping station is operational. The discharge gates have been mechanically disabled in the open position.

The ERCW pumping station is designed to provide water to the ERCW pumps from the reservoir; therefore, when the natural draft cooling towers are used in the closed mode of operation, the temperature of the water to the ERCW pumps is unaffected. The ERCW pumping station meets all of the ultimate heat sink requirements for the plant.

10.4.5.4 Tests and Inspection

No special tests are required. Routine visual inspection of the system components, instrumentation, and alarms is adequate to verify system operability.

10.4.5.5 Instrumentation Application

Sufficient instrumentation has been provided to satisfy all system functional requirements and to permit safe, convenient operation of the CCW by plant personnel.

10.4.6 Condensate Polishing Demineralizer System

10.4.6.1 Design Bases - Power Conversion

The function of the Condensate Polishing Demineralizer System (CPDS) is to remove dissolved and suspended impurities from the secondary system. The CPDS removes corrosion products which are carried over from the turbine, condenser, feedwater heaters (after startup), and piping. The removal of impurities and corrosion products in the secondary system reduces corrosion damage to the secondary system equipment. The CPDS also removes impurities which might enter the system in the makeup water, and removes radioisotopes which will be carried over the secondary cycle in the event of a primary-to-secondary steam generator tube

leak. The CPDS will also be used to remove impurities which enter the secondary system due to condenser circulating water tube leaks. The continuous steam generator blowdown flow may be processed through the CPDS in normal operation, or it may be discharged when the radioactivity level is low. The blowdown will be treated by the CPDS when radioactivity levels exceeding 10^{-1} microcuries/gm are detected in this stream.

The CPDS will polish condensate before startup and restarts. During this mode the steam generator is isolated from the feedwater. This will ensure that the feedwater quality is within limits specified by the Sequoyah Secondary Water Chemistry Program before feedwater is introduced into the steam generator.

The CPDS will have the capability of polishing the full flow of condensate up to a maximum flow of 17,000 gal/min per reactor unit. The CPDS demineralizer service vessel design temperature is 120°F (140°F maximum) and the design pressure is 300 lb/in^{2}g. The pressure drop across the CPDS demineralizer service vessels will not exceed 60 lb/in^{2}d.

10.4.6.2 System Description

The CPDS for each power generating unit consists of a battery of six mixed-bed demineralizer service vessels. Normally, each service vessel will contain a bed of mixed (cation-anion) resins. The demineralizer service vessels may be operated with other resin(s), or may be used empty. The demineralizer service vessels are placed in service as needed. The system also includes an external regeneration facility, shared between the demineralizer service vessels of the two generating units. The basic regeneration system consists of a resin separation/cation regeneration tank, anion regeneration tank, and resin storage tank. The concentrated chemicals used in regeneration are supplied from the acid and caustic storage tanks. Additional equipment is provided in the regeneration system to promote efficiency in the process. A hot water tank supplies hot dilution water at the caustic mixing tee.

High conductivity chemical injection waste and rinse water are collected in the neutralization tank. The tank is provided with the capability to adjust pH to within effluent limits. The inventory of this tank is sampled and the pH adjusted as required prior to being discharged through the cooling tower blowdown. The inventory of this tank may be discharged to the radwaste system for further processing if required (see Chapter 11).

The backwash, final rinse, and resin sluicing water are collected in either of the two high crud tanks. Both tanks are provided with the capability to adjust pH to within effluent limits. The effluents of these tanks is typically routed through a filter unit to remove suspended solids and resins collected during the cleaning/separation step of the regeneration cycle. The design of the waste treatment portion of the condensate demineralizer system includes a high crud filter (HCF) unit. However, the HCF is typically bypassed in favor of a bag filter unit. The HCF is relatively complicated and costly to operate and generates liquid waste in addition to the solid waste produced by the filtering process. In contrast, the bag filters are inexpensive, easy to operate, and generate only solid waste. In addition, the filter sizes in the bag filter units can be easily varied offering an operational flexibility not available with the HCF. The bag filter unit assembly is in series with the High Crud Filter (HCF) and is installed upstream of the HCF. The bag filter assembly itself consists of three individual bag filter vessels in parallel. During normal operating

mode, two bag filters will be in service. The third filter, which is on standby and isolated, may be placed on line while changing out the clogged filters, one at a time, obviating the need to secure flow through the system. The bag filters and/or the HCF are used to meet the National Pollutant Discharge Elimination System (NPDES) permit release requirements. The inventory of these tanks is discharged to the diffuser pond. The inventory of these tanks may be discharged to the radwaste system for further processing as required (see Chapter 11).

The CPDS demineralizer service vessels and all regeneration equipment are located within the condensate demineralizer building. Each set of six demineralizer service vessels is arranged in one shielded compartment and dedicated to a plant unit. All regeneration vessels and reclaim tanks are arranged in individual compartments. The caustic storage tank and hot water tank are also in the condensate demineralizer building. The acid tank is located in a weather-protected housing near the Condensate Demineralizer Building.

The tanks in the CPDS are all rubber-lined to prevent corrosion except the hot water tank (Keysite lined) and the acid storage tank (unlined). All tanks are closed . All closed tanks in the CPDS are designed and fabricated in accordance with the ASME Code for Unfired Pressure Vessels Section VIII, 1974 edition.

The CPDS is not a safety-related system and is not required for the orderly shutdown of the reactor. The condensate demineralizer building housing the CPDS equipment is a nonseismic structure and all piping, piping hangers, and equipment in this system are nonseismic. The system piping is in accordance with American National Standard Institute B31.1.

The CPDS demineralizer service vessels for each unit are arranged in parallel and are supplied by the condenser hotwell pumps via the inlet header. An outlet header collects the effluent from the demineralizer service vessels and supplies suction flow to either the condensate booster pumps or demineralized condensate pumps (see subsection 10.4.7.1). The bypass valve is located across the influent and effluent headers in parallel with the demineralizer service vessels. Outlet piping from each service vessel is equipped with a resin trap.

The CPDS demineralizer service vessels operate in one of three modes as determined by the position of the bypass valve and the service vessel inlet and outlet valves.

- Full flow polishing (bypass valve closed), is normally used during startup and will be used if required to meet the Sequoyah Water Chemistry Program.

- Throttle bypass (bypass valve partially open), will be the operating mode when the pressure differential across the demineralizer service vessel exceeds the setpoint.

- Full bypass (bypass valve fully open), is normally used during initial system startup and will be used if required to meet the Sequoyah water chemistry program. It will also be the operating mode in the event the CPDS experiences loss of control air and/or electrical failure.

Override is provided for manually positioning the automatic bypass valve in the "open," "close," or "throttle" positions. Automatic throttle bypass protects the demineralizer service vessels from excessive pressure drop. The manual bypass valve may be placed in the throttle bypass position when the influent condensate water quality meets the limits specified by the Sequoyah Water Chemistry Program. The manual bypass valve may be placed in the full bypass position (and the demineralizer service vessel inlet valves closed) when the inlet condensate temperature exceeds 130°F in order to protect the functional characteristics of the ion exchange resins. Continued operation is dependent upon influent water condensate quality.

10.4.6.3 Safety Evaluation

Radionuclides are released to the secondary system when there is a steam generator tube leak. The radionuclides have essentially no effect on the resin ion exchange capacity. Although the radionuclide concentrations have no effect on resin capacity, potential activity levels in the demineralizer service vessels and associated regeneration equipment make it necessary to shield the CPDS equipment.

Gaseous waste is removed from the CPDS area by inducing a negative pressure on the demineralizer service vessel cells, valve galleries, and regeneration equipment cells. The unmonitored exhaust is released to the atmosphere (see Section 9.4.6). Liquid releases are continually monitored for radioactivity (See Chapter 11). Liquid radwaste is processed by the Waste Disposal System (refer to Chapter 11).

10.4.6.4 Tests and Inspections

The CPDS is designed so that all demineralizer service vessels, regeneration equipment, and most valves can be individually isolated from the system if testing or inspection is required, with no curtailment or interruption of power generation. Isolation valves on inlet and outlet or demineralizer service vessels and system bypass valves can be tested and inspected during shutdown if required.

10.4.6.5 Instrumentation

Instrumentation and controls are provided to perform the following functions:

1. Measure, indicate, and record condensate conductivity in the influent header and the effluent line of each demineralizer service vessel.

   High specific conductivity downstream of a particular demineralizer service vessel indicates resin exhaustion, and high influent cation conductivity indicates condenser tube leakage.

   High specific conductivity downstream of particular demineralized service vessels and high cation conductivity of the influent header are annunciated at the local control panel.

2. Measure pressure differential between influent and effluent headers, and throttle the valve bypassing the demineralizer service vessels on high differential signal when the bypass valve is closed.

3. Provide local annunciation when the bypass valve is throttled on a high differential pressure signal.

4. Measure and indicate condensate temperature at the influent header. High influent condensate temperature (130°F) is alarmed locally.

5. Measure, record, and indicate flow rates through individual demineralizer service vessels. Flow rates through each demineralizer service vessel indicates extent of crud loading.

6. Annunciate locally high pressure differential across each resin trap.

7. Measure, indicate, and record the sodium content in either the influent condensate header, the effluent condensate header or any 1 of 6 polisher outlet headers. High sodium content is annunciated locally.

10.4.7 Condensate - Feedwater System

10.4.7.1 Condensate - Main Feedwater System

10.4.7.1.1 Design Bases

The Condensate-Feedwater System is designed to supply a sufficient quantity of feedwater to the steam generator secondary side inlet during all normal operating conditions and to guarantee that feedwater will not be delivered to the steam generators when feedwater isolation is required. A complete discussion of feedwater isolation is included in Chapter 15.

The condensate and feedwater system pumps take suction from the main condenser hotwells and deliver water to the steam generators at an elevated temperature and pressure. These systems are capable of delivering water to the steam generators at the rated thermal power as depicted in Figures 10.1-2 and 10.1-3.

10.4.7.1.2 System Description

The flow diagrams for the Condensate-Feedwater System are presented in Figures 10.4.2-1, 10.4.7-1, and 10.4.7-2. Important design parameters are provided in Table 10.1-1.

The ability to meet the design requirements of Subsection 10.4.7.1.1 is provided by the following equipment (per unit):

(a) Hotwell Pumps

(b) Demineralized Condensate Pumps

(c) Condensate Booster Pumps

(d) Main Feedwater Pumps

(e) Main Feedwater Pump Turbine

(f) Main Feedwater Pump Turbine Condenser

Number - 2
Manufacturer - Westinghouse Electric Corporation
304 Stainless Steel
Channel Design Pressure* - 350 lb/in^2g
Channel Design Temperature* - 300°F

(g) Gland Steam Condenser

Number - 1
Manufacturer - Westinghouse Electric Corporation
Tube Material - 316 Stainless Steel
Channel Design Pressure* - 400 lb/in^2g
Channel Design Temperature* - 125°F

(h) Feedwater Heaters

Heater No.	Channel Design Pressure*	Channel Design Temperature*
1	1350 lb/in^2g	460°F
2	725 lb/in^2g	422°F
3	725 lb/in^2g	380°F
4	725 lb/in^2g	300°F
5	350 lb/in^2g	298°F
6	350 lb/in^2g	298°F
7	350 lb/in^2g	298°F

*Channel side design conditions only tabulated here. For shell side design conditions, see subsection 10.4.9, Heater Drains and Vents.

Feedwater heaters are designed in accordance with HEI standards for closed feedwater heaters and the ASME Boiler and Pressure Vessel Code, Section VIII. All piping and valves from the condenser hotwell to the feedwater isolation valve is designed in accordance with ANSI B31.1, 1967, while the remainder of the Feedwater System is designed in accordance with ANSI B31.1 and inspected and tested in accordance with B31.7.

The system boundaries extend from the condenser hotwell to the inlet of the steam generator.

Condensate is taken from the main condenser hotwells by three vertical, centrifugal, motor-driven hotwell pumps. By approximately 70 percent unit guaranteed load on the main feedwater pump, the three horizontal, centrifugal, motor-driven condensate booster pumps are all in service. By approximately 80 percent feedwater flow, all three demineralized condensate pumps have been placed in service. These pumps, when operating in series with the hotwell pumps, are capable of delivering required flow with sufficient NPSH to the main feedwater pumps under all normal operating conditions.

The two turbine driven, variable speed main feedwater pumps are capable of delivering feedwater to the four steam generators under all expected operating conditions. Main feedwater pump speed is automatically adjusted to meet system demands. The main feedwater pump speed control system maintains a differential pressure determined by the average steam flow from all four steam generators. This setpoint is compared to the actual differential pressure between the main steam header and the main feed pump discharge header. Any difference between the steam flow derived setpoint and the actual setpoint changes pump speed accordingly.

The main feedwater pump manual/auto stations provide the operator with the flexibility of choosing various operating modes. The unit operator will have the option to operate (1) both pumps on manual speed control to base load his operation, (2) to operate one pump on manual with the other automatically swinging with plant load changes, or (3) to let both pumps swing with the load changes.

Feedwater flow to the individual steam generators is controlled automatically above 15 percent load by adjustment of a feedwater regulator valve in the piping to each steam generator. The valve's position is determined by a three element controller that uses steam generator water level, steam flow, and feedwater flow as the control variables. The regulator valves are pneumatically operated and are designed to fail closed on loss of air. During startup and operation below 15 percent load, additional control is available from small bypass valves around the feedwater regulator valves.

The bypass valve’s position is determined using steam generator narrow range and wide range levels along with FW temperature, turbine load, and operator entered level setpoint. Prior to the generator sync, the steam generator level with operator entered level setpoint develops a single element control signal that can be modified by a variable gain unit that adjusts the control signal output based upon feedwater temperature to compensate for feedwater mass density. After the generator is placed online, the turbine impulse pressure developed setpoint replaces the operator entered setpoint. The control signal can also be modified based upon the wide range steam generator level. The bypass valve control is designed to reduce the affects of steam generator level shrink and swell at low power. The bypass valve control is placed into automatic at about 2% power and as the plant

escalates in power, the bypass valve continues to open and control level until about 16-18% power. The bypass valve can transfer to three element control at about 13-14% power. (Three element control uses steam generator level, feedwater flow, and steam flow to control the regulating valve.) At about 15-18% power, the Distributed Control System begins to open the main feedwater regulating valve and begins the process of transferring control from the bypass valve to the main regulating valve.

The feedwater system normally operates at full load with three hotwell, three demineralized condensate, three condensate booster, and two main feedwater pumps in service.

Heating of the condensate-feedwater is accomplished by passing it through a series of closed heat exchangers as described below:

a. Gland Steam Condenser - This exchanger condenses the steam leakoff from all turbine shaft seals and removes the noncondensables (the result of shaft inleakage of air) from this steam. A weighted check valve is provided in a bypass around the condenser to ensure minimum required flow through the condenser at low condensate flow conditions and to minimize pressure drop through the condenser during high condensate flow conditions.

b. Main Feedwater Pump Turbine Condensers - Each main feedwater pump turbine is equipped with an individual surface type condenser. Control valves in the inlet and outlet condensate piping to these condensers provide the ability to isolate a condenser if its associated turbine is rendered inoperative and to force 100 percent condensate flow through the operating condenser, thus allowing maximum power operation of the remaining turbine. In order to ensure the availability of a condensate flow path following a trip of both main feedwater pumps, only one of the two condensers can be automatically isolated at any given time. The hotwell pumps will automatically trip if this flow path is not available.

c. Feedwater Heaters - Three parallel strings of heaters, each consisting of three low pressure feedwater heaters, three intermediate pressure feedwater heaters, and one high pressure feedwater heater are provided.

   The heaters are numbered from 1 to 7 with the highest pressure heater designated as No. 1. Motor-operated isolation valves are provided at the inlet to each No. 7 heater and the outlet of each No. 5 heater, the inlet to each No. 4 heater and the outlet of each No. 2 heater, and at the inlet and outlet of each No. 1 heater. High-high level in an applicable heater shell will cause the isolation of the group of heaters in the string in which the high-high level occurred (either the 5, 6, 7, heaters, 2, 3, and 4 heaters, or No. 1 heater in either the A, B, or C string).

Tubes for all heaters are 304 Stainless Steel (SS) except for heaters 5, 6, and 7. The tubes for heaters 5, 6, and 7 are SA-688-304 SS. Tube-to-tube sheet joints in the No. 1 and No. 2 heaters are expanded and welded; tube-to-tube sheet joints are only expanded in the No. 3 through No. 7 heaters.

Minimum flow bypasses are provided for equipment protection. The Condensate System minimum flow bypass is located immediately upstream of the No. 7 heaters. The bypass control valve receives its operating signal from the station flow nozzle located upstream of the gland steam condenser. The valve plug's position is modulated to maintain approximately 5500 gal/min flow through the flow nozzle. This flow is sufficient to protect the hotwell and demineralized condensate pumps and to provide adequate cooling water to the gland steam condenser at all times.

The condensate booster pumps are protected by automatic recirculation control valves. The checking elements of these valves are calibrated to actuate pilot valves which, in turn, open or close the recirculation valves to maintain a minimum flow of approximately 1500 gal/min through each pump.

The Feedwater System has a minimum flow bypass line located downstream of each main feed pump to permit direct recirculation back to the condensers. The minimum flow bypass valve can be modulated automatically in a manner similar to the condensate minimum flow valve or manually to maintain a minimum flow of approximately 3500 gal/min through each operating main feed pump. Operation of the minimum flow bypass valves in automatic is no longer required for pump protection, since the main feed pumps receive redundant trip signals (Train A and B) on main feedwater isolation (i.e., the only time at which the downstream flow path is isolated while the main feed pumps are operating).

Piping is provided around the main feedwater pumps to allow filling the steam generators without operating the main feedwater pumps.

Additional components of the condensate and feedwater systems include an injection water system to provide sealing water to all system pumps, condensate storage tanks which provide capability of controlling feedwater inventory by regulating condenser hotwell level and which provide storage of the water required for operation of the Auxiliary Feedwater System, and facilities for injection of chemicals for oxygen scavenging and feedwater pH control. Complete isolation of feedwater to all steam generators results only from any one of the following Feedwater Isolation (FWI) signals from the Reactor Protection System:

1. High-high steam generator level
2. Safety injection signal
3. Reactor trip along with a low T-average

10.4.7.1.3 <u>Safety Evaluation</u>

The Feedwater System from the steam generator back through the motor operated isolation valve and check valve is a safety system and is designed to TVA class B. This portion of the Feedwater System can be considered an integral part of the Auxiliary Feedwater System.

Feedwater flow to the steam generators is normally interrupted within 9.0 seconds of initiation of a FWI signal. This isolation, accompanied by a reactor trip, is accomplished by closure of redundant valves in the piping to each steam generator and tripping of the main feedwater pumps. The feedwater regulator valves will close in a nominal 7.0 seconds. The FW isolation response time, which includes FW regulator valves closure time and all electronic delays will be less than nine seconds. The signal to initiate closure of these valves is available from both power train A and power train B. The ASME class 2 motor operated containment feedwater isolation valves will close within 7.5 seconds (13 seconds when including load tap changer response time). The isolation valves associated with steam generators 1 and 3 are connected to power train A while those associated with steam generators 2 and 4 are connected to power train B. (Closure of the startup valves bypassing the feedwater regulator valves is guaranteed within nine seconds. Each bypass valve can be closed by a train B signal for steam generators 1 and 3 or train A signal for steam generators 2 and 4.) Each main feedwater pump can be tripped from either a train A or train B signal. If power is not available, condensate booster, demineralized condensate, hotwell, and heater drain tank pumps will deliver no feedwater to the steam generators. Closure of the feedwater regulator and the feedwater isolation

valves and main feedwater pump trip (along with the pump trips during the blackout condition) satisfies feedwater isolation requirements.

The Unit Main Turbine Generator will receive a signal to run the unit back to 77% (Unit 2) and 76.6% (Unit 1) load if: (a) either No. 3 Heater Drain Tank bypass valve is open, (b) the main turbine generator is loaded to greater than 82% (Unit 2) and 81.6% (Unit 1), and (c) after receiving a delayed indication of less than 5500 gpm from the discharge header of the No. 3 Heater Drain Tank Pumps.

A main feed pump trip is annunciated in the Main Control Room, thereby alerting the operator of the potential need for a turbine runback.

When the unit is operating with both main feed pumps in service above approximately 77 percent (Unit 2) and 76.6 percent (Unit 1) guaranteed load and a loss of one main feed pump occurs, the following actions are automatically initiated:

1. Starting of all auxiliary feedwater pumps.

2. Isolation of the main feed pump turbine condenser associated with the tripped pump. Thus 100 percent condensate flow is passed through the active main feed pump turbine condenser allowing maximum power operation of the active feed pump turbine.

3. Acceleration of the active drive turbine to its maximum speed.

4. Turbine runback.

The above actions assist in maintaining steam generator secondary water inventory and decrease the potential for a reactor trip. Should steam generator secondary water inventory not be maintained, a reactor trip will either be manually initiated on decreasing steam generator water level or automatically initiated on low-low steam generator water level.

Insufficient NPSH at the main feed pump suction can result in a decrease in steam generator level. Low NPSH at the main feed pump suction is annunciated in the main control room, thereby alerting the unit operator of the need for a load runback to avoid a reactor coolant system transient.

10.4.7.1.4 Inspection and Testing

The operating characteristics for each system pump have been established throughout the operating range by factory tests. Each hotwell and condensate booster pump casing has been tested hydrostatically to 150 percent of its shutoff head plus maximum suction pressure. All parts of each turbine driven main feed pump subject to hydraulic pressure in service have been hydrostatically tested to not less than 150 percent of the maximum pressure to which these parts are subjected when the pump is operating at rated speed and zero flow, with maximum suction pressure from the hotwell and condensate booster pumps.

All parts and assemblies of parts of the feedwater heaters have been hydrostatically tested and tested otherwise as required by applicable sections of the Heat Exchange Institute Standards for Closed Feedwater Heaters; Standards of Feedwater Heater Manufacturers Association, Incorporated; and Section VIII, Unfired Pressure Vessels of the ASME Boiler Code. Heater tubes have been tested as required by ASTM B111, latest edition, except parts 10.1 and 10.2.1 were applicable.

Hydrostatic and other testing of the parts and assemblies of parts of the main feed pump turbine condensers channels and tubes were in accordance with applicable sections of the Heat

Exchange Institute Standards for Closed Feedwater Heaters and Section VIII, Unfired Pressure Vessels, of the ASME Boiler Code.

Manways or removable heads are provided on all heat exchangers to provide access to the tube sheet for inspection, repair, or tube plugging.

A general routine visual surveillance of the system components and piping during operation and maintenance periods for signs of leakage and distress shall be performed to verify system integrity.

The Class B portions of the Feedwater System are designed to comply with the 1974 edition of ASME Section XI, Inservice Inspection of Nuclear Power Plant Components, to the extent practical under the original design. Inservice inspection will be in accordance with the Inservice Inspection program and procedures (section 5.2.8). Inservice testing of Code Class 2 valves will be performed in accordance with ASME Section XI (see Section 6.8).

10.4.7.1.5 Instrumentation

Sufficient level controllers, flow controllers, level switches, limit switches, temperature switches, etc., will be provided to permit personnel to conveniently and safely operate the Condensate-Feedwater System.

10.4.7.2 Auxiliary Feedwater System

10.4.7.2.1 Design Bases

The Auxiliary Feedwater (AFW) System supplies, in the event of a loss of the main feedwater supply, sufficient feedwater to the steam generators to remove primary system stored and residual core energy. It may also be required in some other circumstances such as the evacuation of the main control room, cooldown after a loss-of-coolant accident for a small break, maintaining a water head in the steam generators following a loss-of-coolant accident, or a flood above plant grade.

The system is designed to start automatically in the event of a loss of offsite electrical power, a safety injection signal, low-low SG water level, a trip of one or both main feedwater pumps, any of which will result in, may be coincident with, or may be caused by a reactor trip, or an AMSAC Initiation. Specific details are listed in 10.4.7.2.2. It will supply sufficient feedwater to prevent the relief of primary coolant through the pressurizer safety valves and the uncovering of the core. It has adequate capacity to maintain the reactor at hot standby and then cool the Reactor Coolant (RC) System to the temperature at which the Residual Heat Removal (RHR) System may be placed in operation, but it cannot supply sufficient feedwater for power generation.

Engineered Safety Feature (ESF) standards are met for the AFW System except for the condensate water supply, which is backed up by the Essential Raw Cooling Water (ERCW) System. The ESF grade portion of the system is designed for seismic conditions and single failure requirements, including consideration that the rupture of a feedwater line could be the initiating event. It will provide the required flow to two or more steam generators regardless of any single active or passive failure in the long term.

The AFW System serves as a backup system for supplying feedwater to the secondary side of the steam generators at times when the feedwater system is not available, thereby maintaining the heat sink capabilities of the steam generator. As an Engineered Safeguards System, the AFW System is directly relied upon to prevent core damage and system overpressurization in the event of transients such as a loss of normal feedwater or a secondary system pipe rupture, and to provide a means for plant cooldown following any plant transient. An auxiliary feedwater pump start shall close the SGB isolation valve and SGB sampling isolation valve. The SGBD isolation valves outside containment do not go closed if the AFWP(s) are in operation and receive an auto-start signal for design basis accident mitigation. See Reference 5 for the acceptability of SGBD in service with AFW in service.

Following a reactor trip, decay heat is dissipated by evaporating water in the steam generators and venting the generated steam either to the condensers through the steam dumps or to the atmosphere through the steam generator safety valves or the power-operated relief valves. Steam generator water inventory must be maintained at a level sufficient to ensure adequate heat transfer and continuation of the decay heat removal process. The water level is maintained under these circumstances by the AFW System which delivers an emergency water supply to the steam generators. The AFW System must be capable of functioning for extended periods, allowing time either to restore normal feedwater flow or to proceed with an orderly cooldown of the plant to the reactor coolant temperature where the RHR System can assume the burden of decay heat removal. The AFW System flow and the emergency water supply capacity must be sufficient to remove core decay heat, reactor coolant pump heat, and sensible heat during the plant cooldown. The AFW System can also be used to maintain the steam generator water levels above the tubes following a LOCA. In the latter function, the water head in the steam generators serves as a barrier to prevent leakage of fission products from the Reactor Coolant (RC) System into the secondary plant.

The reactor plant conditions which impose safety-related performance requirements on the design of the AFW System are as follows for the Sequoyah plant:

a. Loss of Main Feedwater Transient
   - Loss of main feedwater with offsite power available
   - Loss of Offsite Power (i.e., loss of main feedwater without offsite power available)

b. Secondary System Pipe Ruptures
   - Feedline rupture
   - Steamline rupture

c. Loss of all Alternating Current Power (only for diverse power source consideration)

d. Loss-of-Coolant Accident (LOCA)

e. Cooldown

<u>Loss of Main Feedwater Transients</u>

The design loss of main feedwater transients are those caused by:

a. Interruptions of the Main Feedwater System flow due to a malfunction in the feedwater or condensate system

b. Loss of offsite power (LOOP) with the consequential shutdown of the system pumps, auxiliaries, and controls

Loss of main feedwater transients are characterized by a rapid reduction in steam generator water levels which results in a reactor trip, a turbine trip, and auxiliary feedwater actuation by the protection system logic. Following reactor trip from high power, the power quickly falls to decay heat levels. The water levels continue to decrease, progressively uncovering the steam generator tubes as decay heat is transferred and discharged in the form of steam either through the steam dump valves to the condenser or through the steam generator safety or power-operated relief valves to the atmosphere. The reactor coolant temperature increases as the residual heat in excess of that dissipated through the steam generators is absorbed. With increased temperature, the volume of reactor coolant expands and begins filling the pressurizer. Without the addition of sufficient auxiliary feedwater, further expansion will result in water being discharged through the pressurizer safety and relief valves. If the temperature rise and the resulting volumetric expansion of the primary coolant are permitted to continue, then (1) pressurizer safety valve capacities may be exceeded causing overpressurization of the RC System and/or (2) the continuing loss of fluid from the primary coolant system may result in bulk boiling in the RC System and eventually in core uncovering, loss of natural circulation, and core damage. If such a situation were ever to occur, the Emergency Core Cooling (ECC) System would be ineffectual because the primary coolant system pressure exceeds the shutoff head of the safety injection pumps, the nitrogen overpressure in the accumulator tanks, and the design pressure of the RHR Loop. Hence, the timely introduction of sufficient auxiliary feedwater is necessary to arrest the decrease in the steam generator water levels, to reverse the rise in reactor coolant temperature, to prevent the pressurizer from filling to a water solid condition, and eventually to establish stable hot standby conditions. Subsequently, a decision may be made to proceed with plant cooldown if the problem cannot be satisfactorily corrected.

The LOOP transient differs from a simple loss of main feedwater in that emergency power sources must be relied upon to operate vital equipment. The loss of power to the electric-driven condenser circulating water pumps results in a loss of condenser vacuum and condenser dump valves. Hence, steam formed by decay heat is relieved through the steam generator safety valves or the power-operated relief valves. The calculated transient is similar for both the loss of main feedwater and the LOOP, except that reactor coolant pump heat input is not a consideration in the LOOP transient following loss of power to the reactor coolant pumps.

Secondary System Pipe Ruptures

The feedwater line rupture accident not only results in the loss of feedwater flow to the steam generators but also results in the complete blowdown of one steam generator within a short time if the rupture should occur downstream of the last nonreturn valve in the main or auxiliary feedwater piping to an individual steam generator. Another significant result of a feedline rupture may be the spilling of auxiliary feedwater out of the break as a consequence of the fact that the auxiliary feedwater branch line may be connected to the main feedwater line in the region of the postulated break. Such situations can result in the spilling of a disproportionately large fraction of the total auxiliary feedwater flow because the system preferentially pumps water to the lowest pressure region in the faulted loop rather than to the effective steam generators which are at relatively high pressure. The system design must allow for terminating, limiting, or minimizing that fraction of auxiliary feedwater flow which is delivered to a faulted loop or spilled through a break in order to ensure that sufficient flow will be delivered to the

remaining effective steam generator(s). The concerns are similar for the main feedwater line rupture as those explained for the loss of main feedwater transients.

Main steamline rupture accident conditions are characterized initially by plant cooldown and, for breaks inside containment, by increasing containment pressure and temperature. Auxiliary feedwater is not needed during the early phase of the transient and flow to the faulted loop will contribute to an excessive release of mass and energy to containment.

Thus, steamline rupture conditions establish the upper limit on auxiliary feedwater flow delivered to a faulted loop. Eventually, however, the RC System will heat up again and auxiliary feedwater flow will be required to be delivered to the unfaulted loop, but at somewhat lower rates than for the loss of feedwater transients described previously. Provisions must be made in the design of the AFW System to limit, control, or terminate the auxiliary feedwater flow to the faulted loop as necessary in order to prevent containment overpressurization following a steamline break inside containment and to ensure the minimum flow to the remaining unfaulted loops.

Loss of All Alternating Current Power (Station Blackout [SBO])

The loss of all alternating current power is postulated as resulting from accident conditions wherein not only onsite and offsite alternating current power is lost but also alternating current emergency power is lost as an assumed common mode failure. Battery power for operation of protection circuits is assumed available. This transient is not evaluated relative to typical criteria listed in Table 10.4.7-1 since multiple failures of safety-grade components or equipment must be assumed; but is considered as a basis for establishing the requirements for providing both an auxiliary feedwater pump power and control source which are not dependent on alternating current power and which are capable of maintaining the plant at hot shutdown until alternating current power is restored.

During a SBO, main feedwater flow to the SGs is terminated as a result of the main feedwater pumps tripping and feedwater regulating valves closing (loss of AC power). The transient is identical to a "Loss of Main Feedwater Transient with LOOP" in which one motor-driven auxiliary feedwater pump (MDAFWP) is needed to provide sufficient cooling water flow to two SGs. The turbine-driven auxiliary feedwater pump (TDAFWP) has a greater flow capacity than one MDAFWP and is capable of supplying all four SGs. The AFW system is actuated on a SBO and the TDAFWP is relied upon to provide sufficient cooling/SG level during the four hours SBO. The SG level can be maintained by controlling TDAFWP speed and by closing the TDAFWP LCVs (if required) using available air from accumulator tank and high pressure air cylinder. On loss of air, the TDAFWP LCVs will fail open.

Loss-of-Coolant Accident (LOCA)

The large break loss-of-coolant accident does not impose AFW System flow requirements above those required by the other accidents addressed in this section.

Small break LOCA's are characterized by relatively slow rates of decrease in RC System pressure and liquid volume. The principal contribution from the AFW System following such small break LOCA's is basically the same as the system's function during hot shutdown or following spurious safety injection signal which trips the reactor. Maintaining a water level inventory in

the secondary side of the steam generators provides a heat sink for removing decay heat and establishes the capability for providing a buoyancy head for natural circulation. The AFW System is utilized to assist in a system cooldown and depressurization following a small break LOCA while bringing the reactor to a cold shutdown condition.

Cooldown

The cooldown function performed by the AFW System is a partial one since the RC System is reduced from normal zero load temperatures to a hot leg temperature of approximately 350°F. The latter is the maximum temperature recommended for placing the RHR System into service. The RHR System completes the cooldown to cold shutdown conditions.

Cooldown may be required following expected transients, following an accident such as a main feedwater line break, loss-of-load/turbine trip, loss of normal feedwater, loss of off-site power, small break LOCA, steam generator tube rupture, or it may be a normal cooldown prior to refueling or performing reactor plant maintenance. If the reactor is tripped following extended operation at rated power level, the AFW System is capable of delivering sufficient auxiliary feedwater to remove decay heat and Reactor Coolant (RC) Pump heat following reactor trip while maintaining the steam generator water level. Following transients or accidents, the recommended cooldown rate is consistent with expected needs and at the same time does not impose additional requirements on the capacities of the auxiliary feedwater pumps, considering a single failure. In any event, the process consists of being able to dissipate plant sensible heat in addition to the decay heat produced by the reactor core.

The primary function of the AFW System is to provide sufficient heat removal capability for heatup accidents following reactor trip to remove the decay heat generated by the core and prevent RC System overpressurization. Other plant protection systems are designed to meet short-term or pretrip fuel failure criteria. The effects of excessive coolant shrinkage are evaluated by the analysis of the rupture of a main steam pipe transient. The maximum flow requirements determined by other bases are incorporated into this analysis, resulting in no additional flow requirements.

Table 10.4.7-1 summarizes the criteria which are the general design bases for each event discussed above. Specific assumptions used in the analyses to verify that the design bases are met are discussed in subsection 10.4.7.2.3.

10.4.7.2.2 System Description

System Design

Except for the common miniflow line to and supply line from the condensate tanks and some shared support facilities such as the condensate storage tanks and parts of the Control System, the two reactor units have separate AFW Systems, as shown in Figure 10.4.7-5. As on all other engineered safeguards, the independence of the two systems will be guaranteed in accordance with General Design Criterion 5. The nonessential condensate supply is isolated from the essential portion of the AFW System by check valves as shown on Figure 10.4.7-5.

The safety-related portion of the Auxiliary Feedwater System is housed in the Auxiliary and Reactor Buildings and steam valve rooms. These structures are designed to withstand the

effects of natural phenomena such as earthquakes and tornadoes as discussed in Chapter 3. Protection of the system from internal and external missiles is addressed in Section 3.5. The description of the supply of feedwater to the steam generators during flood conditions is presented in Appendix 2.4A.

Each system has two 440 gal/min electric motor-driven pumps and one 880 gal/min turbine-driven pump. Each of the electric pumps serves two steam generators; the turbine pump serves all four. All three pumps automatically deliver the minimum safeguards flow upon loss of offsite power, loss of both main feedwater pumps, or a safety injection signal. The electric pumps also start on a two-out-of-three low-low-level signal in any steam generator; and the turbine pump starts on a two-out-of-three low-low level signal in any two steam generators. All three pumps also start automatically upon initiation of Anticipated Transient Without Scram (ATWS) Mitigation System Actuation Circuitry (AMSAC). Refer to Subsection 7.7.1.12 for system description. All three pumps also start on a main feedwater pump trip with plant load greater than 77 percent (Unit 2) and 76.6 percent (Unit 1) in order to lessen the feedwater system transient. Each electric pump supplies sufficient water for evaporative heat removal to prevent operation of the primary system relief valves, or the uncovering of the core. Pump runout protection is provided for all pumps. Each electric motor-driven pump is equipped with a cavitating venturi, which has a small throat area designed to limit flow by choking. The venturi pressure recovery cone allows the pressure loss across the venturi to be minimized. Electric motor-driven pump runout is designed to be limited to 650 gpm to the steam generators, which is less than that which would result in pump cavitation. The turbine-driven pump utilizes the turbine speed control which uses a flow signal to control the flow to the steam generators to 880 gal/min.

The preferred sources of water for all auxiliary feedwater pumps are the two condensate storage tanks that are qualified to the requirements of Design Criteria SQN-DC-V-48.0. A minimum usable level of 240,000 gallons is required per the technical specifications for an operable tank and is reserved for the AFW System by means of an administrative limit based upon indicated level. As an unlimited backup (seismic Category I) water supply, a separate trained ERCW System header feeds each electric pump. The turbine pump can receive backup (seismic Category I) water from either train A or B ERCW header. The ERCW supply can be remote-manually aligned based on CST level or automatically on a two-out-of-three low-pressure signal in the AFW suction line. Consequently, even assuming the worst single active failure, auxiliary feedwater can be supplied indefinitely from the ERCW System. However, since the ERCW System supplies poor quality water, it is not used except in emergencies when the condensate supply is unavailable. The ERCW System is described in subsection 9.2.2. In addition, the Fire Protection (FP) System may be connected downstream of each electric pump by opening a pair of isolation valves to supply unlimited raw water directly to the steam generators in the unlikely event of a flood above plant grade as discussed in Appendix 2.4A.

The AFW System is designed to deliver 40°F to 120°F CST water for pressures ranging from the RHR System cut-in point (equivalent to 110 lb/in^{2}g in the steam generator) to the steam generator safety valve set pressure. System piping is designed for pressures up to approximately 1650 lb/in^{2}g where necessary. Criteria for the AFW System design basis conditions are shown in Table 10.4.7-1. Significant pump design parameters are given in Table 10.4.7-2. Pump characteristics and power requirement curves are given in Figures 10.4.7-6 and 10.4.7-7.

.

Separate 1E power subsystems and fully qualified control air subsystems serve each electric-driven AFW pump and its associated valves. The valves associated with the turbine-driven pump are served by both 1E electric and fully qualified control air subsystems, with appropriate measures precluding any interaction between the two subsystems. The turbine-driven pump receives control power from a third direct current electric channel that is distinct from the channels serving the electric pumps and is not dependent on alternating current power for a period of 4 hours during SBO. The essential components of the AFW System and subsystems necessary for safe shutdown can function as required in the event of a loss of offsite power.

Steam-water slugging (waterhammer) in the feedwater lines of the Sequoyah Nuclear Plant is not expected to occur. One of the prerequisites for waterhammer of this nature is for steam generator level to fall below the feedring and for steam to enter the feedring and feedwater line. Design modifications to the feedring on each steam generator as described below effectively minimize the extent to which steam can accumulate in the feedwater line therefore reducing the likelihood of waterhammer and its magnitude should it occur.

The Sequoyah Nuclear Plant previously utilized Westinghouse Model 51 Steam Generators which contained a feedring design with bottom flow holes for distribution of feedwater to the steam generator. This particular design has been susceptible to the initiation of steamwater slugging (waterhammer) in the feedwater lines under certain operating conditions at other plants. Modifications to the feedring include the plugging of the bottom flow holes and the addition of J-tubes to the top of the feedring. This modification is identical to that made at various other plants of similar design and tested successfully at both the Trojan Nuclear Plant and Indian Point 2. In addition, there is no horizontal section in the feedwater lines adjacent to the steam generators. The feedwater lines turn down immediately outside the steam generators. This provides the optimum arrangement for resistance to steam water slugging and no modifications to the feedwater lines were necessary.

Historical - A special waterhammer test was performed on the Sequoyah Unit 1, original steam generator No. 2, to verify that the potential for waterhammer was eliminated by the present steam generator feedwater ring and associated feedwater piping design. The waterhammer phenomenon observed at other plants without the J-tube design occurred on the recovery of steam generator water level from below the feedwater ring while using the AFW System for makeup. The special test consisted of lowering the level of the water in steam generator No. 2 to below the feedring while the unit was at hot standby conditions. The level was maintained there without any water addition for approximately 2 hours to allow time for the feedwater ring to drain. After the draining and waiting period, approximately 440 gal/min of auxiliary feedwater was injected into steam generator No. 2. No water hammer was observed by plant and NRC personnel or measured by test instrumentation. The test procedure was reviewed and approved by the NRC and the test witnessed by NRC personnel.

The currently installed replacement steam generators also incorporate top discharge sparger nozzles and gooseneck eliminating the steam leakage into the feedring through the header joints. These design features are intended to prevent the initiation of steam-water slugging or waterhammer. In light of the design compliance with applicable USNRC Regulatory Guides and Branch Technical Positions, waterhammer is not considered as a potential hazard to normal and safety-related operations of the replacement steam generators.

Portions of the AFW System have been evaluated as a high-energy system to determine the effects of pipe whip and jet impingement. The evaluation is described in subsections 3.6.1.1 and 3.6.1.2, and TVA's EN DES report 72-22 and CEB report 76-3.

10.4.7.2.3 Safety Evaluation

For the design bases considerations given in subsection 10.4.7.2.1, sufficient feedwater flow can be provided over the required pressure ranges for the design basis accidents/transients, even when assuming the worst single failure.

Analyses were performed for the limiting transients to define the AFW System performance requirements. Specifically, the limiting transients are:

- Loss of Main Feedwater (LOOP)

- Rupture of a Main Feedwater Pipe

- Rupture of a Main Steam Pipe Inside Containment

- Small Break Loss-of-Coolant Accident

In addition to the above analyses, calculations were performed specifically for the Sequoyah Plant to determine the plant cool down flow (storage capacity) requirements. The loss of all alternating current power is evaluated via a comparison to the transient results of a blackout, assuming an available auxiliary pump having a diverse (nonalternating current) power supply. The large break LOCA analysis, as discussed in subsection 10.4.7.2.1, is not performed for the purpose of specifying AFW System flow requirements. AFW flow is conservatively not modeled in the large break LOCA analysis. Each of the analyses listed above are explained in further detail below.

Loss of Main Feedwater (LOOP)

A loss of feedwater, assuming a loss of power to the reactor coolant pumps, was performed in FSAR Section 15.2.9 for the purpose of showing that for a loss of offsite power transient, a single motor-driven auxiliary feedwater pump delivering flow to two steam generators does not result in filling the pressurizer. Furthermore, the peak RC System pressure remains below the criterion for Condition II transients and no fuel failures occur (refer to Table 10.4.7-1). FSAR Section 15.2.9 summarizes the assumptions used in this analysis. The transient analysis begins at the time of reactor trip. This can be done because the trip occurs on a steam generator level signal, hence the core power, temperatures and steam generator level at time of reactor trip do not depend on the event sequence prior to trip. Although the time from the loss of feedwater until the reactor trip occurs cannot be determined from this analysis, this delay is expected to be 20-30 seconds.

The analysis assumes that the plant is initially operating at 102 percent (calorimetric error) of the Engineered Safeguards Design (ESD) rating, a very conservative assumption in defining decay heat and stored energy in the RC System. The reactor is assumed to be tripped on low-low steam generator level, allowing for level uncertainty. The above FSAR Section (15.2.9) shows that there is a considerable margin with respect to filling the pressurizer. A loss of normal feedwater transient with the assumption that the two smallest auxiliary feedwater pumps and reactor coolant pumps are running even results in more margin.

This analysis may establish the minimum capacity of the smallest single pump and also train association of equipment so that this analysis remains valid assuming the most limiting single failure.

Rupture of Main Feedwater Pipe

The double-ended rupture of a main feedwater pipe downstream of the main feedwater line check valve is analyzed in FSAR Section 15.4.2.2. Reactor trip is assumed to occur when steam generators are at the low-level setpoint (adjusted for errors) and the faulted loop is assumed to be empty. This conservative assumption maximizes the stored heat prior to reactor trip and minimizes the ability of the steam generator to remove heat from the RC System following reactor trip due to a conservatively small total steam generator inventory. As in the loss of normal feedwater analysis, the initial power rating was assumed to be 102 percent of the ESD rating. FSAR Section 15.4.2.2 summarizes the assumptions used in this analysis.

The FSAR analysis shows that a minimum AFW system flow of 410 gal/min to at least 2 intact (non-faulted) steam generators within one minute (following the initiation of a low-low steam generator level signal in any steam generator) at the AFW system design pressure is sufficient to mitigate the event. For the case where the break location results in all of the AFW flow spilling out of the break (i.e., the motor-driven pump aligned to the intact steam generators is assumed to fail), a minimum AFW system flow of 1070 gal/min after 10 minutes to the 3 remaining intact steam generators at the AFW system design pressure is sufficient to mitigate the event. In this case, operator action is credited for isolating the AFW system from the break within 10 minutes following the generation of the low-low steam generator water level reactor trip signal, and the required flow is supplied from a combination of the remaining motor-driven AFW pump and the turbine-driven AFW pump. After event turnaround, less AFW is required to continue plant cooldown. The secondary side steam pressure in the unfaulted steam generators, which drives the turbine-driven pump, reaches and remains at approximately the Main Steam safety valve setpoint pressure during the critical transient time (AFW initiation until event turnaround) and after event turnaround. For both scenarios, the criteria listed in Table 10.4.7-1 are met.

The analysis of the 10 minute case in FSAR Section 15.4.2 assumes the turbine-driven pump supplies 660 gal/min to three steam generators (220 gal/min to each intact steam generator) and that the motor-driven pump supplies 410 gal/min to one steam generator, for a total of 1070 gal/min. To provide the 1070 gal/min total AFW flow, the AFW System at Sequoyah Nuclear Plant provides 440 gal/min from the motor-driven pump, and 630 gal/min from the turbine-driven pump. It has been determined that this flow split does not impact the FSAR analysis results, and therefore is acceptable.

This analysis may establish the capacity of single pumps, establishes requirements for layout to preclude indefinite loss of auxiliary feedwater to the postulated break, and establishes train association requirements for equipment so that the AFW System can deliver the minimum flow required assuming the worst single failure.

Rupture of a Main Steam Pipe Inside Containment

Because the steamline break transient is a cooldown, the AFW System is not needed to remove heat in the short term. Furthermore, addition of excessive auxiliary feedwater to the faulted

steam generator will affect the peak containment pressure following a steamline break inside containment. This transient is performed at three power levels for several break sizes. Auxiliary feedwater is assumed to be initiated at the time of the break, independent of system actuation signals. The maximum flow is used for this analysis, considering a case where runout protection for the largest pump fails and also assuming that the faulted steam generator is at atmospheric pressure. It is assumed that the AFW System is manually realigned by the operator to isolate auxiliary feedwater to the faulted steam generator at 10 minutes. FSAR Sections 15.4.2.1 and 6.2.1.3.11 summarizes the assumptions used in this analysis. The criteria stated in Table 10.4.7-1 are met.

This transient establishes the maximum allowable auxiliary feedwater flow rate to a single faulted steam generator assuming all pumps operating, established the basis for runout protection, if needed, and establishes layout requirements so that the flow requirements may be met considering the worst single failure. See FSAR Sections 15.4.2.1, 6.2.1.3.11, and AFW Flow Considerations for Containment Pressure Analysis - Steamline Break," (this section) for additional discussion.

Small Break Loss-of-Coolant Accident

The loss of reactor coolant from small ruptured pipes or from cracks in large pipes which actuates Emergency Core Cooling System is evaluated in FSAR Section 15.3.1. For the small break LOCA event, the amount and duration of AFW flow required is dependent on the break size and its location, the reactor power level and power history, and the initial secondary side steam generator inventory. Sufficient AFW flow is necessary to maintain peak clad temperatures within acceptable limits. For the limiting case identified in FSAR Section 15.3.1, a minimum AFW system flow of 660 gal/min distributed equally to 4 steam generators at the AFW system design pressure must be available within one minute (maximum AFW delivery delay time). The secondary side steam pressure, which drives the turbine-driven AFW pump, remains at or near the Main Steam safety valve (MSSV) set point pressure until normal termination of the transient.

The asymmetric flow splits resulting from an AFW pump combination consisting of a motor-driven AFW pump and a turbine-driven AFW pump (coincident single failure of one motor-driven AFW pump train), are difficult to model. Due to this difficulty, the small break LOCA analysis assumes a turbine-driven AFW pump flow rate of 660 gal/min split equally to 4 steam generators and 0 gal/min from the motor-driven AFW pumps. The AFW system is not a balanced flow design, therefore, an equal split is not actually achieved. To account for this, the AFW system at Sequoyah Nuclear Plant meets the small break LOCA flow requirements by delivering a combined flow from 2 motor-driven pumps (single failure of turbine-driven pump) to 4 steam generators in excess of 660 gal/min, and by delivering 660 gal/min from the turbine-driven pump (single failure of a motor-driven pump) with an additional flow contribution from the remaining motor-driven pump. The additional motor-driven AFW pump flow provides assurance that the analysis assumptions are bounded by actual system performance, since the total AFW delivered to the four steam generators as well as the individual flows to each steam generator is increased.

This analysis may establish the capacity of single pumps, and establishes train association requirements for equipment so that the AFW System can deliver the minimum flow required assuming the worst-single failure.

Plant Cooldown

Maximum and minimum flow requirements from the previously discussed transients meet the flow requirements of plant cooldown. A cooldown (reference Table 10.4.7-1) however, defines the requirements and establishes the minimum storage volume for AFW in the CST.

The cooldown is assumed to commence at the ESD rated power, and maximum trip delays and decay heat source terms are assumed when the reactor is tripped. Subsequent to reactor trip, the plant is held in MODE 3 for 2 hours followed by a cooldown to RHR entry conditions (MODE 4) within 6 hours (for a total of 8 hours). Primary metal, primary water, secondary system metal and secondary system water are all included in the stored heat to be removed by the AFW System. See Table 10.4.7-3 for the items constituting the sensible heat stored in the NSSS. Some of the important input conditions are: CST maximum temperature of 120°F; steam generator refill to 39% narrow range level at RHR cut-in; ANS 1994 decay heat standard; B&W heavy actinide heating. Cooldown is analyzed to establish the minimum water volume of 240,000 gallons for each unit for auxiliary feedwater fluid source normal alignment (Reference 3 and 4) .

System Capabilities

Flow rates for all of the design transients described above have been met by the system for the worst single failure. The flows for those single failures considered are tabulated for the various transients in Table 10.4.7-4 including the following:

A. Alternating current train failure
B. Turbine-driven pump failure
C. Motor-driven pump failure
D. LCV failure (turbine-driven pump system)
E. LCV failure (motor-driven pump system)
F. Pressure switch failures (motor and turbine pump systems)
G. AFW System check valve failure (failure to close on reverse flow)

Credit is taken for operator intervention within 10 minutes to meet the minimum flow requirements on the feedline rupture and the maximum flow requirements for the main steamline break inside containment.

The auxiliary feedwater pumps design takes into consideration allowances for pump wear, seal leakage, and pump recirculation flow.

Figure 10.4.7-5 shows the major features, components and isolation capability of the AFW System for the Sequoyah Nuclear Plant.

A comparison of the Sequoyah Nuclear Plant's AFW System with NRC's Standard Review Plan 10.4.9 and with branch technical position ASB 10-1 was provided to the NRC by the April 28, 1980, TVA letter from L. M. Mills to L. S. Rubenstein. An updated version of this comparison is provided in Table 10.4.7-5.

In response to a licensing question concerning short-term and long-term recommendations resulting from a general NRC investigation of the AFW System, the information listed in Table 10.4.7-6 was provided to the NRC by L. M. Mills' January 25, 1980, letter to L. S. Rubenstein.

Following a large break LOCA, the AFW System may be used for supplying water to the steam generators to develop a waterhead within the vessels and thereby prevent potential tube sheet leakage from the primary to the secondary side of the steam generators (refer to subsection 10.4.7.2.1). The two electric motor-driven pumps will be used to supply the feedwater from the condensate water supply or, as a backup, from the seismically qualified, ERCW System. In the event of a failure of one of the electric motor-driven pumps or of one of the emergency electrical power trains, the water supply to two of the steam generators would be available from the turbine driven auxiliary feedwater pump during the short term. During the long term, the two steam generators can be filled from either train of the ERCW System by opening the isolation valves between the ERCW System and the AFW System upstream of the turbine-driven pump. A steam supply to the turbine-driven pumps is not required for this operation. All necessary transfers and controls for this use of the AFW System can be accomplished from the Main Control Room.

Material Compatibility, Codes, and Standards

Generally, components are of carbon steel. Carbon steel components, damaged by erosion corrosion, may be replaced with Cr Mo Steel or other erosion resistant steel. The condensate storage tanks are lined to prevent corrosion, other components are protected by chemical additions to the water.

The industry codes and standards and seismic classification corresponding to these TVA classifications are given in Chapter 3 and Table 3.2.2-1.

System Reliability

In addition to using high quality components and materials, the AFW System provides complete redundancy in pump capacity and water supply for all cases for which the system is required. Under all credible accident conditions, at least one AFW pump is available to supply each steam generator not affected by the accident with its required feedwater.

Redundant electrical power and air supplies assure reliable system initiation and operation. The electric motor-driven pumps are powered by offsite or onsite sources; the turbine-driven pump takes steam from either of two main steam lines upstream of isolation valves.

The Limiting Condition for operation of the AFW System is given in Technical Specification 3.7.5.

In response to NUREG 0585, TMI-II Lessons Learned Task Force Final Report, the following information concerning reliability studies on the Sequoyah AFW System was provided: TVA agrees that reliability studies can be useful tools for safety evaluations. TVA initiated a comparative risk analysis of the Sequoyah Plant AFW System.

In response to a licensing question concerning the ability of the AFW System to automatically switchover from the condensate storage tank to the ERCW supply without damage to operating

auxiliary feedwater pumps in the event that the condensate storage tanks are damaged by an OBE, the following information was provided: The automatic, backup transfer to the ERCW takes advantage of the amount of water stored in the seismically qualified suction piping to allow transfer to take place without loss of NPSH to the three auxiliary feedwater pumps. The eight transfer valves are seismic Category I, and the transfer system with associated controls meets the requirements of IEEE-279. Numerical analysis and actual plant tests have been performed, and have verified the proper operation of this transfer scheme. In order to ensure that these pumps are not suction-starved during such an emergency automatic switchover, combinations of suction pressure switches and time-delay devices are used. The pressure set point and timer coordinated valve actions are set so that the pumps will have adequate NPSH under all conditions.

AFW Flow Considerations for Containment Pressure Analysis - Steamline Break

In a response to a licensing question on the generic implications of a letter from Virginia Electric and Power Company on the possibility of overpressurizing the containment during a main steamline break inside containment, the following additional information concerning the effects of auxiliary feedwater flow on the containment pressure analysis was provided (also see Chapter 6.0 of this FSAR and Section 6.2.1 of the Watts Bar Nuclear FSAR for additional details).

The AFW System will be actuated shortly after the occurrence of a steamline break. The mass addition to the faulted steam generator from the AFW System may be conservatively determined by using the following assumptions:

a. The entire AFW System is assumed to be actuated at the time of the break and instantaneously pumping at its maximum capacity.

b. The affected steam generator is assumed to be at atmospheric pressure.

c. The intact steam generators are assumed to be at the safety valve set pressure.

d. Flow to the affected steam generator is calculated from AFW System head curves assumptions b and c above and the system line resistances. The effects of any flow limiting devices are considered.

e. The flow to the faulted steam generator from the AFW System is assumed to exist from the time of rupture to and until realignment of the system is completed.

f. The failure of auxiliary feedwater runout control was considered separately, as a single failure. For this case, the auxiliary feedwater flow was determined using all the assumptions listed above and in addition failure of runout control on an auxiliary feedwater pump.

The assumptions made in the main steamline break inside containment analysis are:

a. Breaks were assumed to be double-ended ruptures occurring at the nozzle of one steam generator.

b. Blowdown from the broken steamline is assumed to be saturated steam.

c. Steamline and feedwater line isolation are completed at 10 seconds (see References 1 and 2 for discussion of common station service transfer additional time delay for the feedwater isolation) after the break occurs. The isolation signal is generated by low steam line pressure signal from the Solid State Protection (SSPS) System.

d. Plant power levels of 100.7 percent of nominal full-load power, 30 percent of nominal full-load power, and zero power were considered.

e. Full double-ended guillotine, 0.6 square foot, and 0.4 square foot ruptures were evaluated.

f. Failures of a main steam isolation valve, a diesel generator, a feedwater isolation valve, and auxiliary feedwater runout control were considered individually.

g. The AFW System is manually realigned by the operator after 10 minutes.

h. For the full double-ended ruptures, the main feedwater flow to the steam generator with the broken steamline was calculated based on an initial flow of 100 percent of nominal full power flow and a conservatively rapid steam generator depressurization. The peak value of this flow occurring just before isolation is 377 percent of nominal for breaks at the exit of the steam generator (i.e., upstream of the flow restrictor) and 326 percent of nominal for breaks at the flow measuring nozzle (i.e., downstream of the flow resistrictor). For the smaller breaks, the same feedwater transient was conservatively assumed.

The AFW System on Sequoyah has not been changed in any way that would adversely affect the conclusions of the original analysis.

The following auxiliary feedwater flow rates are used in the analysis:

(1) With runout protection operational a constant auxiliary feedwater flow rate of 1400 gal/min to the faulted steam generator.

(2) Failure of runout protection was simulated by assuming a constant auxiliary feedwater flow rate of 2040 gal/min to the faulted steam generator.

The maximum auxiliary feedwater flow rates calculated using the assumptions outlined above are provided in Table 10.4.7-4. The analyses performed by Westinghouse for the Sequoyah BIT Removal Analysis addressed the steamline break transients and demonstrated that the limits discussed in the original report were still met for an auxiliary feedwater flowrate of 2250 gpm to a faulted steam generator. Therefore, this analysis bounds the Table 10.4.7-4 values.

The analysis of a spectrum of small steamline breaks used an auxiliary feedwater flow rate of 1380 gal/min. The small break cases have been reanalyzed using auxiliary feedwater runout flow in excess of 2000 gal/min. The blowdown rates are different from those analyzed previously. However, since the peak containment temperature in ice condenser plants is primarily sensitive to the peak enthalpy in the blowdown, no change in peak temperature was observed. The transient temperature response was very similar.

The AFW System will be actuated shortly after the occurrence of a steamline break. In the analysis, the auxiliary feedwater flow to the faulted steam generator was assumed to exist from the time of the rupture until realignment of the system is complete. The AFW System is

assumed to be manually realigned by the operator after 10 minutes. Therefore, the analysis assumes maximum auxiliary flow to a depressurized steam generator for a full 10 minutes. The actions taken by the operator to terminate auxiliary feedwater to the faulted steam generator are discussed below.

Operator action is assumed to terminate the auxiliary feedwater flow to the affected steam generator within 10 minutes. Diagnostic information and emergency instructions are available immediately upon initiation of accident to guide the operator to isolate the faulted SG.

Several failures can be postulated which would impair the performance of various steamline break protection systems and therefore would change the net energy releases from a ruptured line. These are:

1. Main Steam Isolation Valve Failure increases the volume of steam piping which is not isolated from the break. When all valves operate, the piping volume capable of blowing down is located between the steam generator and the first isolation valve. If this valve fails, the volume between the break and the isolation valves in the other steam lines including safety and relief valve headers and other connecting lines will feed the break.

2. Failure of a diesel generator would result in the loss of one containment safeguards train resulting in minimum heat removal capability.

3. Failure of a feedwater isolation valve could only result in additional inventory in the feedwater line which would not be isolated from the steam generator. The mass in this volume can flush into the steam generator and exit through the break. The feedwater isolation valve and the feedwater regulating valve close in no more than 7.5 and 7 seconds, respectively, (Valve closure times reflect original analysis, refer to Sections 10.4.7.1.3 and 6.2.1.3.11.) precluding any additional feedwater from being pumped into the steam generator. The additional line volume available to flush into the steam generator is that between the feedwater isolation valve and the feedwater regulating valve, including all headers and connecting lines.

4. Failure of the auxiliary feedwater runout control equipment would result in higher auxiliary feedwater flows entering the steam generator before realignment of the auxiliary feed system.

The effect of these failures is to provide additional fluid which may be released to the containment by the break or reduce the heat removal capability of the containment safeguard systems.

In the analysis presented in Watts Bar FSAR Section 6.2.1.3.10 and referenced for the Sequoyah Nuclear Plant, the single failures listed above have been combined with various combinations of power level and break size to determine the worst steamline break cases.

Failure of the auxiliary feedwater isolation valve to close has not been considered. The maximum auxiliary feedwater flow that can be delivered to a faulted steam generator has been assumed in the analysis for 10 minutes, two cases being considered: (1) with runout protection operational, and (2) with failure of runout protection.

The operator takes action to isolate auxiliary feedwater to the broken steam generator within 10 minutes. At that time, if remote controlled auxiliary feedwater isolation valves fail to close, the operator can trip one or both of the auxiliary feedwater pumps feeding the broken steam generator as required to isolate auxiliary feedwater until the failed valve or other(s) in the line is (are) manually closed.

An analysis of a spectrum of steamline break at various power levels assuming several different single failures is reported in FSAR Section 6.2.1.3.12. These analyses include cases assuming failure of auxiliary feedwater runout protection. Operator action to realign auxiliary feedwater has been assumed at 10 minutes. Since the mass and energy release rates are considerably less than the RC System, the reactor plant conditions which impose safety related double-ended breaks and their total integrated energy is not sufficient to cause ice bed meltout, the containment pressure transients generated for the RC System breaks will be more severe.

The mass and energy release data for the various cases analyzed is provided in Watts Bar FSAR Section 6.2.1.3.10 and Chapter 6.0. The assumptions made regarding the time at which active containment heat removal systems become effective and justification for the same are also provided in Chapter 6.0.

NUREG-0578 Item 2.1.7.a

In response to NUREG 0578, the following information concerning auxiliary feedwater was provided:

AUTO INITIATION OF AUXILIARY FEEDWATER (AFW)

SEQUOYAH NUCLEAR PLANT RESPONSE

SUMMARY

Sequoyah complies with all of the requirements of 2.1.7 of NUREG 0578.

Response

The AFW System is automatically initiated by redundant, coincident logic to preclude loss of function due to a single failure and to provide online testability. The AFW System and initiating logic are described in TVA's response to NRC-OIE Bulletin 74-06A and also in this FSAR Section. The auxiliary feedwater control circuitry including the automatic initiating circuitry which performs a safety related function, is safety-grade, Class 1E, and is powered from a power source connected to the emergency power system. Each auxiliary feedwater pump has manual initiation capability independent of the automatic initiation. The alternating current motor-driven pumps and valves are included in the automatic alignment of the loads to the emergency power system.

CLARIFICATION ITEMS

1. Automatic and manual initiation of AFW are provided at Sequoyah.

2. Online testability is provided.

3. Initiating signals are powered from the emergency power system.

4. The alternating current motor-driven pumps and valves are included in the automatic alignment of loads to the emergency power system.

5. Manual initiation capability is provided independent of the automatic initiation.

6. Appropriate electric power is supplied via the emergency power system for all valves where control air is needed for operation.

10.4.7.2.4 Tests and Inspections

Performance tests of individual components in the manufacturer's shop, integrated preoperational tests of the whole system, and vibration tests on system pumps and piping have been performed to assure reliable performance. Periodic performance tests of the actuation circuitry and mechanical components will continue to assure reliable performance. Vibration tests on system pumps and piping are also performed during system preoperational tests. Details of the vibration operational test program are provided in subsection 3.9.1.1.

During plant startup or shutdown, the system can be tested by pumping condensate storage water to the steam generators. ERCW water will not be fed to the steam generators during this test. The functionality of the ERCW admission valves is tested without feeding ERCW to the SG. Capability of the ERCW pumps is discussed in Section 9.2.

The Class 2 and 3 components of the AFW System are designed to comply with ASME Section XI, Inservice Inspection of Nuclear Power Plant Components, to the extent practical under the original design. Class 2 and 3 components will be inspected per the Inservice Inspection Program (Section 5.2.8). Inservice tests of the AFW system pumps and valves will be performed in accordance with ASME XI (see Section 6.8).

Auxiliary feedwater pump endurance tests for both motor-driven and the turbine-driven pumps were performed prior to exceeding 5 percent power in accordance with the operating license and NRC Task Action Plan Item II.E.1.1. See Table 10.4.7-6.

Surveillance test requirements are given in Technical Specification 3.7.5, Auxiliary Feedwater System.

10.4.7.2.5 Instrumentation Application

The three pumps and support systems start automatically on a loss of offsite power (under voltage on the 6.9 kV shutdown boards), stoppage of both main feedwater pumps, a safety-injection signal, or loss of one main feedwater pump at loads greater than approximately 77 percent (Unit 2) and 76.6 percent (Unit 1). The electric motor-driven supply also starts automatically on a two-out-of-three low-low-level signal from any steam generator, and the turbine-driven supply starts automatically on a two-out-of-three low-low level signal from any two steam generators. The automatic low-low level signal is delayed at low power levels by a trip time delay (TTD) function as described in

FSAR Chapter 7.2. All three pumps also start automatically upon initiation of Anticipated Transient Without Scram (ATWS) Mitigating System Actuation Circuitry (ASMAC) when there is a common mode failure within RPS and low-low steam generator levels exist in three (3) out of four (4) steam generators coincident with plant power levels above approximately 40 percent. Refer to Subsection 7.7.1.12 for system description. All pumps can be started either remote-manually or locally and satisfy the requirements of Regulatory Guide 1.62.

Located between the motor-driven pumps and each steam generator fed by the pump is a modulating level control valve. The valves are normally closed and upon receipt of an opening, arming or enable signal the control transfers from manual to automatic modulating level control. These valves will automatically maintain steam generator water level during AFW System operation. At low steam generator pressure, the control signal is automatically transferred to a smaller level control valve for the motor-driven pumps which is designed for extended operation at low flows and high pressure drops. The system may be controlled manually. If the above systems are being tested in the manual mode and an automatic start signal is received, the controls will revert to automatic. After an accident, the operator can take manual control by blocking the accident signal with the handswitch (the block is reset when the accident signal is removed). However, if the original signal clears and another accident signal occurs after a first accident signal was reset (such as would happen if the operator allowed the steam generator water level to drop to the low-low-level) then the controls will again revert to automatic. Each level control valve has been provided with a local air vent valve to mitigate spurious closure of the valves. This allows the flow to be throttled locally to maintain steam generator level. Between the level control valves and steam generators 1 and 4, an additional air operated valve has been provided with local control air stations to allow the turbine driven and motor driven auxiliary feedwater flow to be throttled locally from outside the West Valve Vault. These air stations have been provided air from the SBO air cylinders. The number of valve operations is limited due to the limited quantity of air available inside the cylinders.

Located between the turbine-driven pump and each steam generator is an air operated level control valve. The valves are normally closed and automatically open upon receipt of an accident/enable signal. When one or both motor-driven auxiliary feedwater pumps are not available, the main control room operator must take manual control of the turbine-driven pump and valves to maintain level in the steam generators which would have been fed by the inoperable motor-driven pump(s). Provisions are also available for manual steam generator level control from the local auxiliary feedwater control panel should the main control room become uninhabitable. When the turbine-driven pump is required to maintain steam generator level, the operator will control the steam generator level by manually adjusting auxiliary feedwater flow via the auxiliary feedwater turbine controller. If required, the valves between the turbine-driven pump and each steam generator may be closed or opened by the operator. The number of valve operations is limited during SBO due to the limited quantity of air available in accumulators upon loss of normal control air supply. The level control valves for Steam Generators 2 and 3 are located outside the West Valve Vault and have been provided with a local air vent valve to mitigate spurious closure of the valves. This allows the flow to be throttled locally to maintain steam generator level. The level control valves for steam generators 1 and 4 are located inside the West Valve Vault; these valves have been provided with local control air stations to allow the turbine driven and motor driven auxiliary feedwater flow to be throttled locally from outside the West Valve Vault. The air control stations can isolate the normal controls to the level control valves. These air stations have been provided air from the SBO air cylinders. The number of valve operations is limited due to the limited quantity of air available inside the cylinders.

The bypass modulating level control valves for the motor-driven AFW System are air operated and are fail-close valves. The normal level control valves for the motor-driven AFW are fail-open. The turbine-driven pump level control valves are fail-open and have air accumulators and high-pressure air cylinders. This air supply is adequate to stroke open/close (manually) the LCV as necessary in order to enhance system's ability to supply water to the steam generator during the SBO. In the event of a

single failure of one level control valve (which affects flow to one steam generator from either a motor-driven pump or the turbine-driven pump), auxiliary feed flow can still be provided to all four steam generators.

The ERCW supply valves for the AFW System are automatic, multiple, qualified valves which admit ERCW water (a fully qualified system) to the suctions of the AFW pumps when required to supply adequate NPSH and suction pressure to these pumps. An alarm for low pressure in the suction lines of the three AFW pumps will annunciate in the Main Control Room.

Appropriate instrumentation such as valve position, flow, pressure, and steam generator level is provided to permit verification of proper system operation. The operation of the AFW System can be monitored using Class 1E instrumentation located in the control room. There is a single indication of the flows into each steam generator, and pump operating status lights for the motor-driven pumps. There is one indication in the main control room for the level in each condensate storage tank. There is local indication for suction and discharge pressure for the turbine- driven AFW pump.

Figures 10.4.7-3 and 10.4.7-4 give details of the pump logic. TVA's logic and control symbols are explained in Appendix 7A.

In response to a licensing question concerning the heatup of the steam generator level measurement (reference leg) instrumentation used for auxiliary feedwater control during a pipe break, the following information was provided: The Sequoyah AFW Systems use transmitters separate from the NSSS System. These transmitters share sense lines, so the heatup problem will affect both. TVA believes the AFW System is satisfactory in that the insulation on the sense line delays the heatup so operator action will not be required for 10 minutes. Sequoyah's emergency procedures specify criteria (levels, etc.) which take into account temperature effects on the reference leg for use during transients involving adverse containments. To further ensure that water is reaching the steam generator, AFW flow to each steam generator is indicated in the control room. The AFW flow transmitters are located in the Auxiliary Building (in a harsh environment and are qualified for this environment).

10.4.8 Steam Generator Blowdown System (SGB)

10.4.8.1 Design Bases

a. To achieve optimum effectiveness in the control of steam generator water chemistry, continuous blowdown is normally maintained from each steam generator during plant operation.

b. The minimum and maximum blowdown flowrate will be 20 gpm and 270 gpm as measured downstream of the second stage heat exchanger.

c. Blowdown may be discharged to the cooling tower blowdown (CTB) provided that the radioactivity concentration of the blowdown effluent can be properly diluted. If the concentration exceeds the high activity monitor setpoint while in the cooling tower mode, the blowdown will automatically be terminated. In addition, SGB Sample System drains must be realigned from the Turbine Building sump to the FDT. Monitor setpoints are based on blowdown rate, available dilution flow as specified in the ODCM and permissible discharge concentrations.

The SGB System discharge will normally be sampled and analyzed at least daily by either online monitors or grab samples during power operation. When blowdown is being treated, analyses will be performed as often as necessary for evaluation of equipment performance.

SGB System components will be designed in accordance with the following:

Blowdown Flash Tank

Type: Carbon steel designed to ASME Boiler and Pressure Vessel Code, Section VIII, Division 1
Quantity: One per unit
Pressure: Design for 150 lb/in^2g and 30 inch Hg vacuum

Heat Exchangers

Stacked Heat Exchangers

TEMA type:	NFU
TEMA class:	R (specifies ASME Section VIII, Division I)
No. of shells:	2
Maximum cooling water pressure drop (tube side):	4 psi
Maximum blowdown pressure drop (shell side):	20 psi
Duty:	73.557×10^6 Btu/hr
Tube side design pressure temperature:	410 psig and 300°F
Shell side design pressure and temperature:	1085 psig and 600°F

Second Stage Heat Exchanger

TEMA type:	NFU
TEMA class:	R (specifies ASME Section VIII, Division I)
No. of shells:	1
Maximum cooling water pressure drop (tube side):	3 psi

Maximum blowdown pressure drop (shell side):	20 psi
Duty:	4.008×10^6 Btu/hr
Tube side design pressure temperature:	410 psig and 200°F
Shell side design pressure and temperature:	1085 psig and 200°F

Control Valves at Individual Stations

To achieve optimum effectiveness in the control of steam generator water chemistry, continuous blowdown is normally maintained at between 20 and 270 gal/min (as measured downstream of the second stage heat exchangers). The blowdown rate will be manually increased or decreased to meet water chemistry requirements. The blowdown rate will be controlled by the manual adjustment of the Blowdown Regulating Valve which is located downstream of the heat exchangers. Any "balancing" or "proportioning" of the flow from the four individual steam generators will be accomplished with the Manual Throttling Valves.

The safety related isolation valves are air operated, spring failed closed, globe valves.

The SGB isolation valves inside containment, SGB sampling isolation valves, and SGB isolation valves outside containment shall close upon receipt of a containment "phase A" isolation signal. Auxiliary feedwater initiation signal shall close the SGB isolation valve outside containment and SGB sampling isolation valve. The SGBD isolation valves outside containment do not go closed if the AFWP(s) are in operation and receive an auto-start signal for design basis accident mitigation. See Reference 5 for the acceptability of SGBD in service with AFW in service.

The CTB valves shall be closed when radioactivity concentrations reach monitor setpoints.

10.4.8.2 System Description

A flow diagram of the SGB System is shown in Figure 10.4.8-1.

Each steam generator is provided with a blowdown connection for controlling the solids and soluble content of the secondary coolant. The blowdown flow rate from each steam generator can be individually regulated using manual throttling valves. The normal blowdown rate from each steam generator ranges from 5 to 60 gal/min.

The individual SGB lines join into a common header and from there can be routed for processing or discharge through one or two flow paths, through the SGB flash tank or through the SGBD heat exchangers. Vapors from the flash tank are routed to the main condenser. Liquid from the heat exchanger path can be routed to the CTB for discharge or to the CPDS. Choice of flow path and process is dependent upon plant operating mode and secondary chemistry.

The water discharge from the blowdown system will be monitored for radioactivity by a radiation monitor during release. The high activity alarm will alert the operator of an increasing radioactivity level. If the radioactivity concentration (except tritium) exceeds the high activity setpoint when dumping to the CTB, the water discharge from the steam generator blowdown will be terminated.

The monitor obtains a representative sample from the blowdown liquid effluent discharge system in the turbine building. The radiation level associated with each individual steam generator blowdown line can be determined by chemistry sampling through sampling points just outside containment such that the leaking steam generator can be identified.

The SGB System also provides for an additional blowdown path during the abnormal event of a flood above plant grade. The normal blowdown paths are isolated and blowdown may be released to the roof of the main steam relief valve room. This system permits both constant low-flow and intermittent high-flow blowdown. Manually operated blowdown valves are provided that are accessible during the flood condition. The design for this flood event assumes that offsite power is not available and that this mode of operation will exist for at least 100 days.

10.4.8.3 Safety Evaluation

Capacity

The SGB System provides capacity to handle a maximum of 270 gal/min of blowdown flow per unit to be sent to the CDPS or discharged. This system is sufficient to treat the highest expected blowdown flow rate from the steam generators.

Radioactivity Releases

During normal operation, the system uses heat exchangers to cool the blowdown liquid. When using the flash tank, the vapor carries with it radioactive materials, principally iodine and noble gases. This vapor is routed to the condenser and is contained in the secondary system. When operating in the heat exchanger flow path, all radioactive materials are also retained in the secondary system.

During operation of a unit with significant primary-to-secondary leakage, all of the blowdown liquid is treated by the CDPS.

Operation with primary-to-secondary leakage results in a buildup of radioactivity in the secondary system. When a leak occurs in one of the steam generators, the radioactivity level increases in that steam generator. If the radioactivity concentration exceeds the high activity setpoint at the blowdown discharge, an alarm alerts the operator of the increasing radioactivity level. If blowdown is being discharged to the CTB and the radioactivity concentration exceeds the high activity setpoint, the blowdown is automatically terminated. At that point, the plant must also realign the SGB sample drains from the Turbine Building sump and divert them to the FDCT. The high activity setpoint is based on blowdown rate, available dilution flow as specified in the ODCM and permissible discharge concentration.

Figure 10.4.8-2 shows gross radioactivity concentrations (except tritium) in the secondary system after 1 year as a function of blowdown rate. The curve is based on the following assumptions:

Primary-to-secondary leak rate, 100 lb/day
Percent of fuel leaking radioactivity, 0.12 percent

The ability to process radioactive blowdown at high rates has a significant effect on the release of airborne radioactive iodine from the plant.

Figure 10.4.8-3 shows releases of I-131 from the vacuum pumps exhaust and turbine building ventilation air as a function of blowdown rate. The following assumptions were used:

Primary-to-secondary leak rate, 110 lb/day
I-131 in primary coolant, 0.625 μCi/gram (0.25 percent of fuel releasing radioactivity)
Steam generator partition factor, 0.01
Main condenser/vacuum pumps decontamination factor, 2000
Air ejector HEPA filter/charcoal absorber decontamination factor, 10
Turbine building steam leak rate, 1700 lb/h

Radioactivity releases due to normal operation of the SGB System are discussed in subsection 11.2.

System Performance During Abnormally High Primary-to-Secondary Leakage

Abnormally high primary-to-secondary leakage has no significant effect on the blowdown system. A leak rate in excess of the technical specification limit requires shut down of the unit. The blowdown system is capable of operating with a leak rate approaching 1 gal/min. A 1 gal/min leak rate would not require that the blowdown rate be increased above 60 gal/min in order to maintain specified secondary system water chemistry unless it occurred at a time when condenser inleakage was high. With a 1 gal/min leak and about 0.12 percent failed fuel, radiation levels in the vicinity of the blowdown treatment system equipment would be higher than with normal operating levels, but would be below design levels.

In the event of a primary-to-secondary leak in excess of 1 gal/min, the blowdown system could be operated after unit shutdown in order to clean the secondary system.

Failure Analysis of System Components

Analyses of various failures in the system are given in Table 10.4.8-1.

10.4.8.4 Tests and Inspections

Prior to operation of the SGB System, instruments will be calibrated, and interlocks and controls will be tested to verify that they function properly.

The Class B portions of the SGB System are designed to comply with the 1974 edition of ASME Section XI, Inservice Inspection of Nuclear Power Plant Components, to the extent practical under the original design. Class B piping and valves will be inspected per the Inservice Inspection Program discussed in subsection 5.2.8. Inservice testing of Code Class 2 valves will be tested as outlined in the ASME Inservice Valve Testing Program basis document which is referenced in Section 6.8 of the FSAR.

Routine inspections and maintenance will be performed on system components in accordance with approved plant procedures.

10.4.8.5 Instrumentation Applications

Instrumentation is provided to perform the logic functions, described herein.

10.4.9 Heater Drains and Vents

10.4.9.1 Design Bases

The Heater Drain system is designed to remove and dispose of all drainage from the moisture separators, reheaters, feedwater heaters, main feed pump turbine condensers and gland steam condensers during all modes of unit operation by returning the condensed water back to the Condensate- Feedwater System.

The Vent System is designed to adequately vent all heat exchangers to assure complete removal of noncondensable gases during all modes of unit operation.

10.4.9.2 System Description

The flow diagrams for the Heater Drains and Vent System are shown in Figures 10.4.9-1 and 10.4.9-2.

To accomplish the design objectives of subsection 10.4.9.1, the following equipment is provided (per unit):

a. No. 3 heater Drain Pumps

b. No. 7 Heater Drain Pumps

c. Feedwater Heaters

Shell side design conditions only given here. See subsection 10.4.7, Condensate-Feedwater System, for channel side design conditions.

Number - 21 (3 strings of 7 heaters)

Heater No.	Shell Design Pressure	Shell Design Temperature
1	450 lb/in^2g	650°F
2	300 lb/in^2g	650°F
3	232 lb/in^2g	380°F
4	75 lb/in^2g	380°F
5	50 lb/in^2g	650°F
6	50 lb/in^2g	650°F
7	50 lb/in^2g	650°F

d. Main Feed Pump Turbine Condensers

Shell side design conditions only given here. See subsection 10.4.7, Condensate-Feedwater System, for channel side design conditions.

Number - 2
Shell Design Pressure - 20 lb/in^2 and 30 inches Hg vacuum
Shell Design Temperature - 160°F

e. No. 7 Heater Drain Tank

Number - 1
Design Pressure - 1 inch of Hg absolute to 50 lb/in^{2}g
Design Temperature - 175°F

f. No. 3 Heater Drain Tank

Number - 1
Design Pressure - 200 lb/in^{2}g
Design Temperature - 377°F

g. Moisture Separator Drain Tanks

Number - 6
Design Pressure - 250 lb/in^{2}g
Design Temperature - 401°F

h. High Pressure Reheater Drain Tanks

Number - 6
Design Pressure - 1200 lb/in^{2}g
Design Temperature - 567°F

i. Low Pressure Reheater Drain Tanks

Number - 6
Design Pressure - 500 lb/in^{2}g
Design Temperature - 467°F

j. Main Feed Pump Turbine Condenser Drain Tanks

Number - 1
Design Pressure - 1 inch of Hg absolute to 16 lb/in^{2}g
Design Temperature - 101°F

k. Main Feed Pump Turbine Condenser Drain Pumps

Number - 2
Manufacturer - Crane Deming Pumps
Type: 3M, single stage, single suction, centrifugal
Design Point: 380 gal/min, 57 feet head
Motor Design: 10 hp, 3 ph, 60 Hz, constant speed
Motor Manufacturer - (Unit 1) - U.S. Electric Motors
(Unit 2) - Baldor Electric Company

The shell side of feedwater heaters are equipped with manually valved vent lines as necessary for ventilation during unit startup. The tube side of feedwater heaters are also equipped with manually valved vent lines as necessary for ventilation during unit startup. Feedwater heaters No. 3 & 7 do not have manually valved startup vent lines for ventilation to the atmosphere. Venting to the main condenser of the heater's shell side during normal operation is accomplished through continuous "free blowing" orifices, sized in accordance with recommendations of the Heat Exchange Institute Standards for Closed Feedwater Heaters, 1968. The venting scheme for the high pressure reheaters and low pressure reheaters use air operated valves routed to the condenser during startup. Venting during normal operation is accomplished through air operated valves to the #1 or #2 extraction lines for the high pressure and low pressure reheaters, respectively.

The heaters are numbered from 1 to 7 with the highest pressure designated as No. 1. During normal unit operation, the No. 1 heater drains, composed of the high pressure reheater drains and the No. 1 extraction, cascade into the shell of the No. 2 heater. The No. 2 heater drains, the No. 1 drains, plus the No. 2 extraction and the low pressure reheater drains, cascade into the No. 3 heater drain tank. The No. 3 heater drains (No. 3 extraction) and the moisture separator drains also flow into the No. 3 heater drain tank. Water from the No. 3 heater drain tank is then pumped forward into the condensate cycle (between the No. 3 and No. 2 heaters) by the No. 3 heater drain pumps.

The first extraction from the low pressure turbines is condensed in the No. 4 heaters. These drains are cascaded into the shell of the No. 5 heaters. No. 5 heater drains (No. 5 extraction plus No. 4 heater drains) cascade to the No. 6 heater, whose drains cascade in turn to the No. 7 heater drain tank. The condensed No. 7 extraction and other miscellaneous drains are routed to the No. 7 heater drain tank. These main feed pump turbine condenser drains are pumped to the piping between the No. 7 heater drain tank and the No. 7 heater drain pumps. Water from the main feed pump turbine condenser drains and the No. 7 heater drain tank is pumped forward into the condensate system (at a point between the No. 7 and No. 6 heaters) by the No. 7 heater drain pumps.

Proper level is maintained in the Nos. 1, 2, 4, 5, and 6 feedwater heaters by modulating level control valves that receive their control signal from level indicating controllers mounted on the heater shells. Should the level drop below the normal control range, a low level alarm is sounded. High level in the shells of the No. 2, 5, and 6 heaters results in annunciation of a high level alarm. The No. 1, 2, and 4 heaters are equipped with modulating bypass to condenser valves. Should the level in a No. 1, 2 or 4 heater exceed the normal control level, the bypass valve begins to open. Indication is given in the control room when the bypass valve leaves its seat. If the level exceeds the control range of the bypass valve, high level annunciation occurs. High-high level in a No. 1 heater results in isolation (of both feedwater and extraction steam) of that heater. High-high level in a No. 2 or No. 4 heater results in isolation of the appropriate bank of No. 2, 3, and 4 heaters. High-high level in a No. 5 or 6 heater results in isolation of the appropriate bank of No. 5, 6, and 7 heaters.

All No. 3 and No. 7 heaters are "dry" shelled heaters. Thus, particular care in piping design was taken to ensure that choking of drains as a result of steam entrainment will not occur.

Level in the No. 3 heater drain tank is maintained within the proper range by modulating level control valves at the discharge of the No. 3 heater drain pumps. Level in excess of normal

control range initiates opening of modulating bypass to condenser valves. Indication that the bypass to condenser valve has left the fully closed position is given in the control room. Additional increase in level to a point above the range of the bypass valves annunciates a high level alarm. Low level in the drain tank results in a trip of all operating No. 3 heater drain pumps.

A level control scheme similar to that for the No. 3 heater drain tank is provided for the No. 7 heater drain tank.

No. 3 and No. 7 Heater Drain Tank level control is provided by the DCS.

The moisture separator drains are routed to the No. 3 heater drain tank, low pressure reheater drains to the No. 2 heater shells, and the high pressure reheater drains to the No. 1 heater shells.

Since all moisture separators and reheaters are "dry" shelled vessels, particular care in design of drain piping was taken to prevent choking of drain flow due to steam entrainment between these vessels and their individual drain tanks.

MSRH drain control is provided by maintaining proper level in drain tanks connected to the individual moisture separators, HP reheaters and LP reheaters. This level is controlled in the individual drain tanks by modulating level control valves (one per tank).

Level in excess of the normal control range causes a modulating bypass to condenser valve (one per tank) to open. Indication that a bypass valve has left the fully closed position is given in the main control room. Increase in level to above the control range of the bypass to condenser valve results in a high level alarm being annunciated in the control room. Low level alarm is also annunciated if the level drops below the normal control range.

Air assisted nonreturn valves are provided in each MSRH drain line downstream of the point where the bypass to condenser piping is connected so that, in the event of a turbine pressure transient due to a load rejection, the water stored in the feedwater heaters cannot flash back to the MSRH. The bypass to condenser valves will still be available for level control during a transient of this type.

Feedwater heaters are designed in accordance with applicable sections of Heat Exchange Institute Standards for Closed Feedwater Heaters, Standards of Feedwater Heater Manufacturers Association, Incorporated, and Section VIII, Unfired Pressure Vessels, of the ASME Boiler Code. The No. 3 and No. 7 heater drain tanks are designed in accordance with Section VIII, Unfired Pressure Vessels of the ASME Boiler Code. All moisture separators, reheaters, and associated drain tanks are designed to Section VIII of the ASME Code. All piping and valves in the Heater Drains and Vents System are designed in accordance with ANSI B31.1.

A single drain tank receives the drains from both main feed pump turbine condensers. Normal water level in the tank is maintained by a level control valve at the drain pump discharge that receives its control signal from a level indicating controller mounted to the drain tank. Level below the control range of the controller results in annunciation of a low level alarm. Level above the control range results in annunciation of a high level alarm and coincides with opening of a bypass to condenser valve. Direct operator action is required to close bypass valve after it has opened. The main feed pump condenser drains are equipped with two pumps which take suction from a single drain tank. One pump is started manually while the second pump is put on

standby by placing the selector switch in the auto position. Should the pressure in the discharge of the active pump drop below 25 lb/in^{2}a, the standby pump is automatically started. All pumps conform to applicable paragraphs of the centrifugal pump section of the standards of the Hydraulic Institute in effect when the pumps were purchased.

The three No. 3 heater drain pumps are started as the unit load increases. Conditions that must be satisfied before any pump can start include:

a. Level in the No. 3 heater drain tank above a permissive level set point.

b. Sufficient lubricating oil pressure.

The pumps are manually tripped as load decreases and are no longer needed. In addition, the pumps may be tripped by low level in the No. 3 heater drain tank, low lube oil pressure, or a motor protection signal.

Minimum flow for pump protection is provided by an automatic recirculation control valve at the discharge of each pump.

The No. 7 heater drain pumps are controlled in the same manner as the No. 3 heater drain pumps. A trip of the main turbine will result in manual tripping of all No. 3 and No. 7 heater drain pumps due to low flow.

Typically, at feedwater flows less than 40 percent, all No. 3 and No. 7 heater drains are routed to the condenser. This allows the drain flow to pass through the condensate demineralizers during low load operation. This increases the cleanup rate of the feedwater and prevents corrosion products from the heater drains, which could build up during an outage, from being introduced into the steam generator.

10.4.9.3 Safety Evaluation

With few exceptions, the operating mode of the Heater Drains System has no effect on the Reactor Coolant System and the ability of the Condensate-Feedwater System to deliver feedwater to the steam generators in sufficient quantity to meet all system demands. However, some transient conditions can exist that do require proper interfacing between the heater drains system and other secondary cycle systems to prevent a reactor trip.

With all drains from the No. 3 heater drain tank being bypassed to the condenser (and being passed through the hotwell, demineralized condensate, and condensate booster pumps) the Condensate-Feedwater System can deliver approximately 82 percent (Unit 2) and 81.6 percent (Unit 1) guaranteed flow to the steam generators. Sufficient capacity does exist in the Condensate-Feedwater System pumps however, such that if the No. 3 heater drain pumps discharge exceeds 5500 gpm, full load operation for the unit can be maintained. However, due to TVA-imposed limitations, the Unit Main Turbine Generator will receive a signal to run the unit back to approximately 77% (Unit 2) and 76.6% (Unit 1) load if: (a) either No. 3 Heater Drain Tank bypass valve is open, (b) the main turbine generator is loaded to greater than approximately 82% (Unit 2) and 81.6% (Unit 1), and (c) after receiving a delayed indication of less than 5500 gpm from the discharge header of the No. 3 Heater Drain Tank Pumps.

Trip of a No. 3 heater drain pump during operation at unit load in excess of approximately 82 percent (Unit 2) and 81.6 percent (Unit 1) produces a low differential pressure across the No. 3 heater drain pump station (indicating that the remaining pumps are passing excessive flow and are in danger of damage due to insufficient NPSH). As a result, one of the two level control valves in the drain pump discharge is tripped closed for pump protection. This action may cause opening of the bypass to condenser valve and subsequent runback to the 77 percent (Unit 2) and 76.6 percent (Unit 1) load condition.

A trip of a No. 3 or No. 7 Heater Drain tank pump or a feedwater heater string isolation may require operator action to reduce load to maintain adequate Main Feedwater pump inlet pressure.

10.4.9.4 Inspection and Testing

All pumps, heaters, and pressure vessels in the Heater Drains, and Vents System will be tested by the manufacturer in accordance with the codes under which they were manufactured. Since there are no ASME, Section III components in this system, no inservice inspection is required.

10.4.9.5 Instrumentation

Sufficient instrumentation is provided to permit personnel to conveniently and safely operate this system and to provide proper interfacing with the Reactor Coolant System.

TABLE 10.4.7-1

CRITERIA FOR AUXILIARY FEEDWATER SYSTEM DESIGN BASIS CONDITIONS

Condition or Transient	Classification*	Criteria*	Additional Design Criteria
Loss of main feedwater	Condition II	Peak RCS pressure not to exceed design pressure. No consequential fuel failure	
Loss of Offsite Power (LOOP)	Condition II	(same as LMFW)	Pressurizer does not fill with 1 single motor-driven auxiliary feed pump feeding 2 SGs
Feedline rupture	Condition IV	10 CFR 100 dose limits. Containment design pressure not exceeded	Core does not uncover
Loss of all alternating curent power	NA	Note 1	Same as LOOP assuming turbine-driven pump. Station Blackout (SBO) Rule.
Loss of coolant	Condition III	10 CFR 100 dose limits 10 CFR 50 PCT limits	
	Condition IV	10 CFR 100 dose limits 10 CFR 50 PCT limits	
Cooldown	NA	Technical Specification Bases 3.7.6	100° F/hr 547° F to 350° F

*Ref: ANSI N18.2 (This information provided for those transients performed in the FSAR).

Note 1: Although this transient establishes the basis for AFW pump powered by a diverse power source, this is not evaluated relative to typical criteria since multiple failures must be assumed to postulate this transient.

Electric Driven, each	2900
Turbine Driven	2600

TABLE 10.4.7-3

SUMMARY OF SENSIBLE HEAT SOURCES

Primary Water Sources (initially at ESD power temperature and inventory)
- RCS fluid
- Pressurizer fluid (liquid and vapor)

Primary Metal Sources (initially at ESD power temperature)
- Reactor coolant piping, pumps, and reactor vessel
- Pressurizer
- Steam generator tube metal and tube sheet
- Steam generator metal below tube sheet
- Reactor vessel internals

Secondary Water Sources (initially at ESD power temperature and inventory)
- Steam generator fluid (liquid and vapor)
- Main feedwater purge fluid between steam generator and AFWS piping

Secondary Metal Sources (initially at ESD power temperature)
- All steam generator metal above tube sheet, excluding tubes.

TABLE 10.4.7-4 (Sheet 1)

AUXILIARY FEEDWATER FLOW [(1)] TO STEAM GENERATORS

FOLLOWING AN ACCIDENT/TRANSIENT WITH SELECTED SINGLE FAILURE - GAL/MIN

Single Failure

Accident/Transient	Elec. Train Failure A	TD Pump Failure B	MD Pump Failure C	LCV Failure TDAFP System D	LCV Failure MDAFP System E	Pr. Sw Failure MD F	CV[(2)] Failure G
1. Loss of main FW	1070	880	1070	1510	1510	1510	1540
2. Feedline rupture	(3)	440	(3)	440	440 (4)	440	440
3. Blackout	1070	880	1070	1510	1510	1510	1540

5. Main steamline rupture	(3)	440	(3)	440	440	440	440
6. Main steamline (flow through break)	<1440	<1440	<1440	<2250(5)	<1440	<1440	<1440

TABLE 10.4.7-4 (Sheet 2)

AUXILIARY FEEDWATER FLOW [1] TO STEAM GENERATORS

FOLLOWING AN ACCIDENT/TRANSIENT WITH SELECTED SINGLE FAILURE - GAL/MIN

Single Failure

Notes:

(1) Items 1 through 5 are minimum available flows to intact loops; item 6 is maximum possible flow to the faulted loop.

(2) Including only those CV's in the AFWS. "Failure" is interpreted as failure to close on reverse flow; failure of the CV to open to permit flow in the normal direction is not considered.

(3) Ten minute operator action is assumed to isolate AFW flow to faulted loop. After switchover to the bypass, LCV (MD pump) feeding the faulted loop, flow is ~200 gal/min to unfaulted loops; after operator action, flow is >1070 gal/min to unfaulted loops.

(4) Flow is >440 gal/min to one steam generator. After 10 minutes (with operator action to isolate AFW flow to faulted loop), total available flow will be >1070 gal/min.

(5) Maximum flow through mainsteam break is <2250 gal/min. This is based on a turbine runout protection failure (turbine runs up to its high speed stop) and not an LCV failure (TDAFP). For LCV failure (TDAFP), flow through break would be <1440 gal/min.

TABLE 10.4.7-5

AUXILIARY FEEDWATER SYSTEM COMPARISON
TO SRP 10.4.9 AND BTP ASB 10-1

The following comments evaluate the Sequoyah Auxiliary Feedwater System (AFWS) with respect to the acceptance criteria of SRP 10.4.9. The numbering corresponds to part II of SRP 10.4.9. Each requirement of SRP 10.4.9 has been previously addressed in the Sequoyah FSAR or in previous responses to NRC questions. Reference will be made to this existing material as appropriate.

1. GDC2 - See FSAR sections 10.4.7.2.1, 10.4.7.2.2, and 10.4.7.2.3.
2. GDC4 - See FSAR section 10.4.7.2.2.
3. GDC5 - See FSAR section 10.4.7.2.2.
4. GDC19 - See the entire FSAR section 10.4.7.2.
5. GDC44
    (a) Same as number 4 above.
    (b) See FSAR sections 10.4.7.2.1, 10.4.7.2.2, and 10.4.7.2.3.
    (c) The only nonessential portion of the auxiliary feedwater (AFW) is the condensate supply which is isolated from the remainder of the system by check valves. All components required to maintain the essential functions of the AFW, including isolation of disabled equipment, are self-actuated, automatic, or operable from the main control room. This information is included in FSAR sections 10.4.7.2.1, 10.4.7.2.2, and 10.4.7.2.3, but not explicitly stated. These statements are made here for clarification.
6. GDC45 - See FSAR section 10.4.7.2.4.
7. GDC46 - See FSAR sections 10.4.7.2.4 and 14.1, FSAR Table 14.1-1 and STS section 3/4.7.1.
8. RG 1.26 - System components were classified in accordance with the draft version of ANS 18.2 issued August 1970. A point-by-point comparison with RG 1.26 quality groups shows no significant differences for the AFW. See FSAR Sections 10.4.7.2.3, 10.4.7.2.4, 3.2.2; Figure 10.4.7-5, Tables 3.2.1-2, 3.2.2-1 and 3.2.2-2.
9. RG 1.29 - See FSAR sections 10.4.7.2.3 and 3.9.2.5.1.
10. RG 1.62 - See FSAR sections 10.4.7.2.2, 10.4.7.2.3, and 10.4.7.2.5.
11. RG 1.102 - See FSAR section 10.4.7.2.2 and 2.4A.
12. RG 1.117 - See FSAR section 10.4.7.2.2 and 3.5.
13. BTP ASB 3-1 and MEB 3-1 - See FSAR section 10.4.7.2.2 and TVA' EN DES Report No. 72-22, and CEB Report No. 76-3.
14. BTP ASB 10-1 - The AFW meets all requirements of this BTP as described in FSAR section 10.4.7 with one exception. Each AFW train cannot supply any combination of steam generators. Diverse means are provided to supply AFW to any steam generator. The steam-driven AFW pump delivers AFW to all four steam generators. Train A of the motor-driven supply delivers AFW to steam generators 1 and 2. Train B of the motor-driven supply delivers AFW to steam generators 3 and 4.

TABLE 10.4.7-6 (Sheet 1)

AFWS

RESPONSES TO SHORT- AND LONG-TERM RECOMMENDATIONS
RESULTING FROM A GENERAL NRC INVESTIGATION OF AFWS

Short-Term

1. Tech Spec time limit on one train out of service.

   Response:

   Technical Specification 3.7.1.2 limits operation with one train out of service to 72 hours.

2. Tech Spec on any single suction valves that can defeat system. Administrative control to lock open and verify position.

   Response:

   Administrative controls exist to lock open common suction valves from the CST. The ERCW system supplies safety grade backup suction.

3. Reevaluate commitments to limit AFW flow for reduction of water hammer effects.

   Response:

   The AFW flow rate will not be limited for any reasons related to the prevention or reduction of water hammer. The Sequoyah steam generator feedwater ring headers have been modified so that water hammer will not be a problem. On automatic start, the AFWS goes to full flow until normal water level is established on the steam generators.

4. Emergency procedure to connect backup water source.

   Response:

   Each auxiliary feedwater pump has its own safety grade instrumentation that will sense low pump suction pressure prior to draining of the normal water source and will automatically align the safety grade backup water source to the pump. Isolation from the normal water source occurs automatically by closure of a check valve in each pump suction line due to back pressure on the valve open alignment of the qualified water source. The qualified water source is essential raw cooling water.

Long-Term

1. Make manual start systems automatic.

   Response:

   The AFWS is fully automatic with manual actuation capability as well.

2. Provide a redundant path where primary and alternate water supplies pass through a single valve.

TABLE 10.4.7-6 (Sheet 2)

AFWS

RESPONSES TO SHORT- AND LONG-TERM RECOMMENDATIONS
RESULTING FROM A GENERAL NRC INVESTIGATION OF AFWS

Response:

Alternate water supplies to the AFW pump suctions do not share the same flow path with any valves in the normal water supply lines.

3. Eliminate dependence of one train of AFW on ac power.

Response:

The turbine-driven AFW pump can run for 4 hours during station blackout using only battery power for control and a dc powered room fan to remove heat from the pump room.

4. Prevent multiple pump damage due to loss of suction resulting from natural phenomena.

Response:

Pump damage is prevented by the automatic transfer to the alternate water source which is essential raw cooling water.

5. Upgrade auto start signal to safety grade.

Response:

The auto start signals for AFW are safety grade.

6. Emergency procedure for operator action for the AFWS in a total ac blackout.

Response:

Operator action for the AFWS in a total ac blackout is covered in Emergency Instructions.

7. Tech Spec AFWS flow verification following maintenance outage.

Response:

Technical Specification 4.7.1.2 requires that each AFW pump be demonstrated operable. (See also the response to item 12).

8. Upgrade auto start signal for AFWS.

Response:

There are three, safety grade, automatic start modes for the AFWS. They are loss of offsite power, safety injection actuation, and low-low steam generator level.

TABLE 10.4.7-6 (Sheet 3)

AFWS

RESPONSES TO SHORT- AND LONG-TERM RECOMMENDATIONS
RESULTING FROM A GENERAL NRC INVESTIGATION OF AFWS

9. Auto actuation of AFWS.

   Response:

   See response for item 8.

10. Redundant low level indication and alarm in MCR of primary water source.

    Response:

    There is a level indicator in the main control room for each condensate storage tank. Level alarms for each tank are actuated in the main control room for both "low" and "low-low" level. The "low-low" level is to warn of imminent tank emptying and occurs when sufficient water remains in the tank to allow for operator action in accordance with emergency procedures. In the event that the operator fails to align the AFW pumps to the secondary water source, they will automatically align.

11. 72-Hour pump endurance test.

    Response:

    The 72-hour recommendation has been reduced to 48 hours following discussion with the NRC staff. TVA is currently reviewing its records to determine if a pump endurance test has been performed. In the event that pump test information is not available, the appropriate tests will be performed to demonstrate the adequacy of the AFWS pumps. (A 48-hour endurance test was successfully performed and the test results were submitted to the NRC by L. M. Mills' letter dated November 4, 1980, to Harold R. Denton.)

12. Flow indication to each steam generator (same as 2.1.7b of NUREG 0578).

    Response:

    Auxiliary feedwater flow is indicated in the main control room for each of the four steam generators. The transmitters are mounted on four separate, seismically qualified panels and powered from power sources connected to the emergency power system. The cables are in low level signal conduits and are kept separate from all power cables. In addition, the total flow from the turbine-driven auxiliary feedwater pump is indicated in the main control room. The auxiliary feedwater flow instrument channels are powered from the emergency buses consistent with the diversity requirements of the AFWS.

13. Tech Spec for two-train systems which require valve realignment during surveillance testing.

    Response:

    The Sequoyah Nuclear Plant AFWS has three individual trains; one steam driven and two

Table 10.4.7-6 (Sheet 4)

AFWS

RESPONSE TO SHORT-AND LONG-TERM RECOMMENDATIONS
RESULTING FROM A GENERAL NRC INVESTIGATION OF AFWS

motor driven. These trains are characterized by parallel injection lines and open suction lines. The injection lines join together downstream of any control valve. In testing a given train, the control valves for that train only will be closed during testing. At power these valves are closed. For maintenance, only the control valves on the affected train would be disabled. For pump maintenance, the suction isolation valve for that pump would be closed. There are no common suction valves that must be closed for maintenance or testing.

Table 10.4.8-1 (Sheet 1)

FAILURE ANALYSIS, STEAM GENERATOR BLOWDOWN SYSTEM

Failure	Consequences	Action
(1) Rupture of blowdown line between steam generator and isolation valve inside containment.	Hot water under pressure partially flashes to steam. Pressure in lower compartment increases and vapor passes through ice beds. Water level in affected steam generator increases (swell). Radioactivity present in steam generator remains inside containment.	When containment pressure reaches the HI setpoint, SIS is initiated, reactor is automatically tripped, and containment isolation valves close. Main feedwater lines isolate and auxiliary feedwater pumps start. Blowdown isolation valves are automatically closed. If the break happens to be in a blowdown line between the isolation valve and the containment penetration, automatic closure of the isolation valves initiated by the containment pressure signal terminates the release. If the break is ahead of the isolation valve, when the fault is identified, auxiliary feedwater to the affected steam generator is isolated, and that steam generator is allowed to boil and drain itself dry.

Table 10.4.8-1 (Sheet 2)

FAILURE ANALYSIS, STEAM GENERATOR BLOWDOWN SYSTEM

Failure	Consequences	Action
(2) Rupture of blowdown line from outside containment to flash tank or heat exchangers.	Hot water under pressure escapes into main steam valve vault outside the building or inside the turbine building and partially flashes to steam. Some of the radioactive material in the blowdown will escape directly to atmosphere or be carried out with turbine building ventilation exhaust, depending on where the rupture occurs.	When the leak is discovered, the operator closes all blowdown isolation valves and then opens them one at a time to locate the leak. The unit is shutdown if necessary to repair the leak.
(3) Rupture of blowdown line downstream of flash tank or heat exchangers.	Water under pressure escapes into the turbine building and is collected by liquid waste system.	Same as (2)
(4) Failure of blowdown regulating valve.	Flow will increase to maximum value allowed by manual throttling valves.	When the failure is discovered, the blowdown isolation valves will be closed so that the regulating valve can be repaired.

TABLE OF CONTENTS

TABLE OF CONTENTS

TABLE OF CONTENTS

LIST OF TABLES

LIST OF TABLES

LIST OF FIGURES

11.0 RADIOACTIVE WASTE MANAGEMENT

11.1 Source Terms

The fission product inventory in the reactor core and the diffusion to the fuel pellet/cladding gap are provided in Subsection 15.1.7. The total fission product inventory released from the reactor core following a large break LOCA for environmental qualification per 10 CFR 50.49 analyses are provided in FSAR Table 15.5.3-8. Post large break LOCA source terms released from the reactor core used in the 10 CFR 100 off site public analyses and 10 CFR 50 Appendix A GDC-19 plant personnel analyses are provided in FSAR Table 15.5.3-5.

11.1.1 Radioactivity

11.1.1.1 Design Activities in the Reactor Coolant

The parameters used in the calculation of the reactor fission product design inventories together with the pertinent information concerning the design coolant cleanup flow rate and demineralizer effectiveness, are summarized in Table 11.1.1-1. The results of the calculations are presented in Tables 11.1.1-2 through 11.1.1-4. In these calculations the defective fuel rods are assumed to be present at the initial core loading and to be uniformly distributed throughout the core; thus, the fission product escape rate coefficients are based upon average fuel temperature.

For fuel failure and burnup experience see Subsection 4.2.1.3.

The fission product activities in the reactor coolant during operation with small cladding defects (fuel rods containing pinholes or fine cracks) are computed using the following differential equations:

for parent nuclides in the coolant:

$$\frac{dN_{wi}}{dt} = D\upsilon_i \, NC_i - \left(\lambda_i + R\eta_i + \frac{B'}{B_o - tB'}\right) N_{wi}$$

for daughter nuclides in the coolant:

$$\frac{dN_{wj}}{dt} = D\upsilon_j \, NC_j - \left(\lambda_j + R\eta_j + \frac{B'}{B_o - tB'}\right) N_{wj} + \lambda_i N_{wi}$$

symbols:

N = nuclide concentration

D = clad defects, as a fraction of rated core thermal power being generated by rods with clad defects coolant system volumes per sec.

R = purification flow, coolant system volumes per sec.

B_o = initial boron concentration, ppm

B′ = boron concentration reduction rate by feed and bleed, ppm per sec

η = removal efficiency of purification cycle for nuclide

λ = radioactive decay constant

υ = escape rate coefficient for diffusion into coolant

t = time

subscripts:

C = refers to core

w = refers to coolant

i = refers to parent nuclide

j = refers to daughter

11.1.1.2 Volume Control Tank Activities

Table 11.1.1-3 lists the activities in the volume control tank using the assumptions summarized in Table 11.1.1-1.

11.1.1.3 Pressurizer Activities

The activities in the pressurizer are separated between the liquid and the steam phase and the results obtained are given in Table 11.1.1-4 using the assumptions summarized in Table 11.1.1-1.

11.1.1.4 Gaseous Waste Processing System Activities

The activities to be found in the Gaseous Waste Processing System are given in Table 11.1.1-5.

11.1.1.5 Secondary Coolant Design Activities

The secondary cleanup system design activities used for shielding design calculations are discussed in Subsection 12.1.3.

11.1.2 Realistic Model for Radioactivities in Systems and Components

The parameters used to describe Sequoyah are given in Table 11.1.2-1, together with the range of values utilized in NUREG-0017 (Reference 1,3). All parameters other than the weight of water in the steam generator, steam generator blowdown rate, and the stripping fraction are within the prescribed range. In order to obtain primary coolant activities for fission products and transuranics, the correction formulae from standard ANS N237 (Reference 2), were applied. The activities of corrosion products, being independent of the failed fuel fraction assumed, are the same as in the design case.

Secondary side water and steam activities for fission products and transuranics were similarly obtained from the values given in N237 with the appropriate corrections. Secondary side corrosion product activities were calculated by applying the ratio of secondary-to-primary activity from the data in N237 to the primary side corrosion activities.

The primary coolant specific activities for calculations issued before April 30, 1987, are given in Table 11.1.2-2. The primary coolant activities used in calculations issued after April 30, 1987 are based on the new ANSI/ANS-18.1-1984 (Reference 4) standard and are given in Table 11.1.2-3. When a revision of sufficient degree is made to a calculation that was issued prior to April 30, 1987, primary coolant activities in accordance with the methodology of standard ANSI/ANS-18.1-1984 will be used. The ANSI-18.1-1984 activities are based on available data from operating plants for pressurized water reactors with U-tube steam generators such as SQN.

The secondary side coolant specific activities for calculations issued before June 27, 1996 are given in Table 11.1.2-2. The secondary side coolant activities used in calculations issued after June 27, 1996 are based on the new ANSI/ANS-18.1-1984 (See Reference 11.1.4.4 and 11.1.4.5) standard and are given in Table 11.1.2-4. When a revision of sufficient degree is made to a calculation that was issued prior to June 27, 1996, secondary side activities in accordance with the methodology of standard ANSI/ANS-18.1-1984 will be used.

11.1.3 Leakage Rates

As a necessary part of the effort to reduce effluent of radioactive liquid wastes, Westinghouse has been surveying various PWR facilities which are in operation, to identify design and operating conditions influencing reactor coolant and nonreactor grade leakage and hence the load on the Waste Processing System. Liquid leakage sources have been identified primarily in connection with pump shaft seals and valve stem leakage.

Where packed glands are provided, a leakage problem may be anticipated, while mechanical shaft seals provide essentially zero leakage. Valve stem leakage was experienced where the originally specified packing was used. A combination of a graphite filament yarn packing sandwiched with asbestos sheet packing is used with improved results in several plants. For Sequoyah, the majority of the valves used are diaphragm valves. This type of valve provides positive control stem leakage and is suitable for use as an isolation valve as well as a throttling valve.

Expected leakage rates of liquids to be treated in the Liquid Waste Processing System are summarized in Table 11.2.2-1.

Total plant liquid and gaseous releases are discussed in Subsections 11.2.6 and 11.3.6, respectively. Release pathways for gaseous effluents are described in Subsection 12.2.2.

TABLE 11.1.1-1 (Sheet 1)

PARAMETERS USED IN THE CALCULATION OF REACTOR COOLANT FISSION AND CORROSION PRODUCT DESIGN ACTIVITIES

1.	Core thermal power, MWt (Base load)	3582
2.	Clad defects, as a percent of rated core thermal power being generated by rods with clad defects	1.0
3.	Reactor coolant liquid volume, ft^3	12,600
4.	Reactor coolant full power average temperature, °F	590
5.	Purification flow rate (normal) gal/min	75
6.	Effective cation demineralizer flow, gal/min	7.5
7.	Volume control tank volumes	
	a. Vapor, ft^3	240
	b. Liquid, ft^3	160
8.	Fission product escape rate coefficients:*	
	a. Noble gas isotopes, sec^{-1}	6.5×10^{-8}
	b. Br, I and Cs isotopes, sec^{-1}	1.3×10^{-8}
	c. Te isotopes, sec^{-1}	1.0×10^{-9}
	d. Mo isotopes, sec^{-1}	2.0×10^{-9}
	e. Sr and Ba isotopes, sec^{-1}	1.0×10^{-11}
	f. Y, La, Ce, Pr isotopes, sec^{-1}	1.6×10^{-12}
9.	Mixed bed demineralizer decontamination factors:	
	a. Noble gases and Cs-134, 136, 137, Y-90, 91, and Mo-99	1.0
	b. All other isotopes including corrosion products	10.0
10.	Cation bed demineralizer decontamination factor for Cs-134, 136, 137, Y-90, 91, and Mo-99	10.0

*Escape rate coefficients are based on fuel defect tests performed at the Saxton reactor. Recent experience at two plants operating with fuel rod defects has verified the listed escape rate coefficients.

11.2 LIQUID WASTE SYSTEMS

11.2.1 Design Objectives

The Liquid Waste Processing System is designed to receive, segregate, process, recycle for further processing and discharge liquid wastes. The system design considers potential personnel exposure and assures that quantities of radioactive releases to the environment are as low as practicable. Under normal plant operation, the activity from radionuclides leaving the discharge canal is a small fraction of the limits in 10 CFR Parts 20 and 50.

The plant is designed to meet the regulations during operation with a combination of equipment faults which could occur with moderate frequency, including fuel cladding defects in combination with such occurrences as:

1. Steam generator tube leaks
2. Malfunction in Liquid Waste Processing System
3. Excessive leakage in Reactor Coolant System Equipment
4. Excessive leakage in Auxiliary System Equipment

The expected annual activity releases (by isotope) are presented in Subsection 11.2.6, and the estimated doses are presented in Subsection 11.2.9.

11.2.2 System Descriptions

The Liquid Waste Processing System was initially designed to collect and process potentially radioactive wastes for recycle to the Reactor Coolant System or for release to the environment. The liquid waste processing system was, by original design, arranged to recycle as much reactor grade water entering the system as practical. This was implemented by the segregation of equipment drains and waste streams which prevents the intermixing of liquid wastes. The layout of the liquid waste processing system, therefore, consists of two main subsystems designed for collecting and processing reactor grade (tritiated) and non-reactor grade (non-tritiated) water, respectively. All liquids are now routinely processed as necessary for release to the environment instead of recycling and are no longer maintained segregated based on tritium content during processing. This includes reprocessing the contents of tanks which accumulate waste water for discharge which may be unsuitable for direct release (e.g., Monitor Tank to FDCT for reprocessing via Radwaste Demineralizer System, or similar). Provisions are made to sample and analyze fluids before they are discharged. Based on the laboratory analysis, these wastes are either released under controlled conditions via the cooling water system or retained for further processing. A permanent record of liquid releases is provided by analyses of known volumes of waste. The system is shown on the Process Flow Diagram (Figures 11.2.2-1, -2, 11.3.2-1, and -2). Table 11.2.2-2 gives approximate radionuclide inventories of the various tanks in the liquid waste processing system. Actual radionuclide inventories of plant effluents are submitted to the NRC as a requirement of 10CFR50 by Nuclear Chemistry Offsite Dose Calculation Manuel (ODCM). Expected volumes to be processed by the Waste Processing System are given in Table 11.2.2-1.

In addition a system is provided for handling laboratory samples which may be tritiated and may contain chemicals. Capability for handling and storage of spent demineralizer resins is also provided.

The plant system is controlled from a central panel in the auxiliary building and a panel in the main control room. Abnormalities in the system, high sump level, for example, actuate an alarm/level switch in the auxiliary building, and annunciates in the control room. All system equipment is located in or near the auxiliary building, except for the reactor coolant drain tank and drain tank pumps and the various reactor

building floor and equipment drain sumps and pumps which are located in the containment building.

The Radwaste Demineralizer System (Rad DI) is located and operated in the Auxiliary Building waste packaging area when the vendor's service is requested.

At least two valves must be manually opened to permit discharge of liquid to the environment. One of these valves is normally locked closed. A control valve trips closed on a high effluent radioactivity level signal. Administrative controls prevent discharge without dilutions.

Parts of the Liquid Waste Processing System is shared by the two units. However, as the system serves no emergency function, the safety of either unit is not affected.

Shared Components

The Liquid Waste Processing System consists of one reactor coolant drain tank with two pumps, an auxiliary reactor building floor and equipment drain sump with two pumps, a keyway sump with one pump, and a reactor building floor and equipment drain sump with two pumps inside the containment building of each unit and the following shared equipment inside the auxiliary building: one sump tank and two pumps, one tritiated drain collector tank with two pumps and one filter, one floor drain collector tank with two pumps and one strainer, monitor tank and two pumps, a chemical drain tank and pump, two hot shower tanks and pump, a spent resin storage tank, a cask decontamination tank with two pumps and two filters, auxiliary building floor and equipment drain sump and two pumps, a passive sump, a Radwaste Demineralizer System, and the associated piping, valves and instrumentation.

The following shared components are located in the condensate demineralizer building for receiving, processing, and transferring wastes from the regeneration of condensate demineralizers: high crud, low conductivity tanks, pumps and filters; a neutralizer tank and pumps; and a non-reclaimable waste tank and pumps.

Separation of Tritiated and Nontritiated Liquids

Waste liquids which are high in tritium content are routed to the tritiated drain collector tank, while liquids low in tritium content are routed to the floor drain collector tank. All tritiated and nontritiated liquid waste are processed for discharge to the environment.

Tritiated Water Processing

Tritiated reactor grade water is processed for discharge to the environment or recycle to the primary water storage tank. The water enters the liquid waste disposal system from equipment leaks and drains, valve leakoffs, pump seal leakoffs, tank overflows, and other tritiated and aerated water sources including draindown of the CVCS holdup tanks, as desired.

The equipment provided in this channel consists of a tritiated drain collector tank, pumps, and filter and Radwaste Demineralizer System. The primary function of the tritiated drain collector tank is to provide sufficient surge capacity for the radwaste processing equipment.

The liquid collected in the tritiated drain collector tank contains boric acid, and fission product activity. The liquid can be processed as necessary to remove fission products so that the water may be reused in the Reactor Coolant System or discharged to the environment.

Nontritiated Water Processing

Nontritiated water is sampled and processed as necessary for discharge to the river. The sources include floor drains, equipment drains containing nontritiated water, certain sample room and radiochemical laboratory drains, hot shower drains and other nontritiated sources. The equipment provided in this channel consists of a floor drain collector tank, pumps, and strainer, Radwaste Demineralizer System, hot shower tanks and pump, cask decontamination collector tank and pumps, monitor tank and pumps.

Liquids entering the floor drain collector tank are from small volume, low activity sources. If the activity is below permissible discharge levels following analysis to confirm acceptably low level, then the tank contents may be discharged without further treatment other than filtration. Otherwise, the tank contents are processed through the Radwaste Demineralizer System.

The hot shower drain tanks normally need no treatment for removal of radioactivity. The inventory of these tanks may be discharged directly to the cooling tower blowdown via the hot shower tank strainer or to other tanks in the liquid waste system.

The liquid waste system is also designed to process blowdown liquid from the steam generators of a unit having primary-to-secondary leak coincident with significant fuel rod clad defects. The blowdown from the steam generators is passed through the condensate demineralizer (refer to Subsections 10.4.6 and 10.4.8) or directly to the cooling tower blowdown line.

Radwaste Demineralizer System Processing of Tritiated and Nontritiated Waste (If being utilized)

Flow from both the tritiated and nontritiated tanks is routed to the Radwaste Demineralizer System by use of the waste evaporator and auxiliary waste evaporator feed pumps. Processed water from the system is routed to either the monitor tank or the cask decontamination tank. The contents of these tanks are either recycled, reprocessed, or discharged as described in previous sections. The Radwaste Demineralization System removes soluble and suspended radioactive materials from the waste stream via ion exchange and filtration. Once the resin and filter media is expended, it is processed for disposal. Filters are air-dried and placed into containers for disposal.

Laboratory Sample Processing

Laboratory solutions which contain chemicals can be discarded in a separate sink which drains to the chemical drain tank. Low activity drains from the laboratory, such as flush water, are routed to the floor drain tank. Excess tritiated samples not contaminated by chemicals during analysis can be directed to the tritiated drain collector tank.

Processing of Waste from Regeneration of Condensate Demineralizer

High conductivity chemical regenerate and rinse wastes produced during condensate demineralizer regeneration are routed to the neutralization tank (NT) or, alternately, to the nonreclaimable waste tank (NRWT) where they are collected and neutralized. If the contents of either tank (NT or NRWT) are not radioactive or if the radioactivity level is less than the dischargeable limit, it is transferred to the turbine building sump and subsequently discharged through the low volume waste treatment pond, or alternately it is discharged to the cooling tower blowdown. If the contents of either the NT or NRWT are radioactive, they may be discharged to the cooling tower blowdown if the radioactivity level is within specification; otherwise, they are processed by the radwaste system (see nontritiated water processing).

Low conductivity waste water produced during condensate demineralizer regeneration is routed to the high crud tanks (HCT-A and HCT-B) where it is collected and neutralized (if necessary). If the contents of HCTs are not radioactive or if the radioactivity level is within dischargeable limits, they are transferred to the turbine building sump and subsequently discharged through the low volume waste treatment pond or yard pond, or discharged to the cooling tower blowdown. If the contents of the HCTs are radioactive, they maybe processed through the radwaste system or released via the cooling tower blowdown.

Spent Resin Processing

Spent resin is stored in the spent resin storage tank (SRST). To remove spent resins from the storage tank for packaging, the resin is agitated by bubbling nitrogen through the tank to the vent header. The resin is slurried from the SRST, by nitrogen pressure, to the railroad bay where it is received in liners and dewatered prior to shipment offsite, or storage in Sequoyah's Low Level Radwaste (LLRW) on-site storage facility (see Section 11.5.6.3).

11.2.3 System Design

11.2.3.1 Component Design

A summary of principal design parameters are given in Table 11.2.3-1. Design codes for the components of the Liquid Waste Processing System are given in Chapter 3. Materials of the Liquid Waste Processing System are selected to meet the material requirements of the system and applicable codes. All parts of components in contact with borated water are fabricated or clad with austenitic stainless steel. In addition, all pumps are provided with vent and drain connections. The Radwaste Demineralizer System is constructed to the applicable sections of Regulatory Guide 1.143, Rev. 1, 1979.

Reactor Coolant Drain Tank and Pumps

The reactor coolant drain tank (RCDT) (one tank per unit) collects reusable clean reactor coolant type water from inside the reactor containment building. Two pumps are set up on a common header to take suction from either the RCDT or the pressurizer relief tank (PRT). These pumps can transfer the liquid from the drain tank to the Chemical and Volume Control System holdup tanks and to transfer water from the refueling canal to the refueling water storage tank. The maximum load on the pumps occurs when the pressurizer relief tank drains and the excess letdown flow are imposed simultaneously or when the refueling canal is being drained. The normal load on the pumps is a small quantity mainly from leakoffs, although the excess letdown flow can be expected for relatively long periods of time during plant heatup. Pump A is sized for 50 gpm and is used for normal operation; Pump B is sized for 150 gpm and is used for peak loads.

The reactor coolant drain tank is normally vented to the vent header. Since there is oxygen in the refueling water, the tank can be isolated from the vent header and vented locally to the containment sump or containment atmosphere if necessary.

Chemical Drain Tank and Pump

The shared chemical drain tank receives radioactive wastes from the radiochemical laboratory drains and from the decontamination room. The pump is provided to transfer the tank contents. If activity and chemical contamination are very small and within applicable release limits, tank contents are pumped to the monitor or cask decontamination collector tanks for discharge. Under certain conditions (high activity and no harmful chemicals) the tank contents are pumped to the floor drain collector tank using the hot shower tanks' pump.

Sump Tank and Pumps

The sump tank collects tritiated liquid wastes from equipment and lower elevation drains, which cannot drain by gravity to the tritiated drain collector tank. Two pumps are furnished to transfer the liquid collected to the tritiated drain collector tank. The tank vents to the building exhaust system.

Tritiated Drain Collector Tank and Pumps

The shared tank retains radioactive liquids from the primary plant which contain tritiated water, boric acid, and fission products. The primary function of the tank is to provide sufficient surge capacity for the radwaste processing equipment. Two shared pumps are provided to transfer the tank contents to the Radwaste Demineralizer System. When the Radwaste Demineralizer System is used to remove soluble and suspended radioactive material, boron is passed through the system and can be discharged to the cooling tower blowdown via the liquid radwaste tanks.

Floor Drain Collector Tank and Pumps

The shared tank retains primarily non-reactor grade type fluids and some nonrecycleable reactor grade water from certain drains in the Auxiliary Building. Following analysis to confirm acceptably low activity level, the tank contents can be discharged to the environment without further treatment other than filtration. However, provisions are also made to provide further processing through the radwaste demineralizer should high activity fluids enter the tank. Two shared pumps are provided to transfer the tank contents to the radwaste demineralizer.

Hot Shower Tanks and Pump

The hot shower tanks serve for collection of radioactive wastes from the hot shower drains. A pump is utilized to transfer the liquid for processing or for discharge. A recirculation line is provided to permit mixing the contents of the isolated tank before taking samples for activity analysis. If the activity concentration is too high for direct discharge, the waste may be pumped to the floor drain collection tank for further processing.

Spent Resin Storage Tank

This tank is supplied for the storage of used demineralizer resins. Resin is held in this tank for decay of short-lived isotopes and periodically removed to preclude the possibility of resin agglomeration. A layer of water is maintained over the resins to prevent degradation due to decay heat.

Outdoor Tanks

The two refueling water storage tanks, the two primary makeup water storage tanks, and the two condensate storage tanks have the potential to contain radioactive liquid.

Each of the two refueling water storage tanks has redundant high level alarms actuated by separate level switches. The tanks also have an overflow.

The overflow line leads to the pipe tunnel which connects the refueling water storage and the primary makeup storage tank with the auxiliary building. Liquid overflowing the tank is discharged onto the floor of the tunnel from which it flows down a gutter to floor drains at the end of the tunnel adjacent to the auxiliary building. The floor drains are directed to the floor drain collector tank of the liquid radwaste system.

Each primary makeup water storage tank has a high level alarm and an overflow. The overflow line discharges into the same pipe tunnel into which the refueling water storage tank overflow discharges. From the tunnel the liquid drains into the liquid radwaste system.

Each condensate storage tank has a high-level alarm and an overflow. The overflow line terminates beside the tanks just above ground level. Liquid overflowing the tanks would be collected in nearby drains and be discharged into the diffuser pond. From the diffuser pond, liquid is discharged via the diffuser. Table 10.4.1-1 shows the expected radioactivity concentrations in the condenser (and the condensate storage tanks) based on 20 gallons per day primary to secondary leakage and 0.25 percent failed fuel.

Filters

The filters provided are of two types, the first being a bag type made of felt using either polyester, polypropylene, or an equivalent material. Each filter is a once through design using 1 to 2 filters or strainers or a combination of a filter and strainer which are nested one inside of the other. This allows for different combination of filters and/or strainers to obtain acceptable water qualities. The other type of filter is a round cartridge or spun cartridge type construction which relies on a tortuous path to filter particles rather than a carefully controlled absolute hole size. Because of the type of construction no absolute rating is given.

The methods employed to change filters and screens are dependent on activity levels. Filters are valved out of service with a pressure indicator between the isolation valves to assure the valves are not leaking through and the filter is not at system pressure. The filter is drained to the appropriate tank and vented locally. If the radiation level of the filter is low enough, it is changed manually. If activity levels do not permit manual change, the spent filter is removed remotely with temporary shielding to reduce personnel exposure. The spent filter is placed in a shielded drum for removal to the solid waste storage area. A new filter is installed, the housing is reassembled, vent and drain valves are closed and the filter is valved into service. Filters are normally changed because of high differential pressure rather than high radiation levels.

Floor Drain Collector Tank and Tritiated Drain Collector Tank Discharge Filters

Filters or strainers are provided to remove particulate matter from the tritiated and floor drain collector tanks recirculation paths. The vessels are constructed of austenitic stainless steel and the replaceable filter element is nylon, or an equivalent material.

Hot Shower Tank Basket Strainer

The hot shower tank basket strainer is a perforated stainless steel sheet within a stainless steel casing. It is designed to prevent particles from entering the floor drain collector tank.

Cask Decontamination Collector Tank

The cask decontamination collector tank can receive water used in the decontamination of the spent fuel shipping cask except during dry cask storage operation wherein the HI-TRAC transfer cask is decontaminated locally on the auxiliary building refueling floor. The cask decontamination collector tank is normally used as one of two available clean release tanks whose contents may be processed as needed for release to the environment.

Cask Decontamination Collector Tank Pumps

Two pumps are provided to pump cask decontamination waste or clean liquid from the cask decontamination collector tank through the cask decontamination collector tank filter (cask decon waste only) to the waste discharge line or to the monitor tank for reprocessing. Normally, only one pump is used. The pumps are also used to recirculate the tank contents prior to sampling.

Cask Decontamination Collector Tank Filters

Two filters are provided to remove particulate matter larger than 25 microns from the cask decontamination waste. The vessels are constructed of stainless steel and the replaceable filter elements are polyester or polypropylene. Normally, only one filter is used. The filter is normally by-passed when the cask decon tank is used as a clean release tank.

Condensate Demineralizer Waste Processing Equipment High Crud Tanks

These tanks collect high crud, low conductivity waste produced during the backwash phase of condensate demineralizer regeneration. Nonradioactive high crud waste can be routed directly to the turbine building sump or filtered and discharged to cooling tower blowdown, provided discharge permit requirements are satisfied. Radioactive, high crud waste can be discharged to cooling tower blowdown only when the activity is within specified limits. If not within limits, the waste is transferred to the liquid radwaste treatment system for further processing.

High Crud Pumps

Two 180 gpm pumps are provided to circulate the contents of the high crud tanks for sampling, and to pump the tank contents through the bag filters and the high crud filter, to discharge, or to the liquid radwaste treatment system. Normally, only one pump is used.

Bag Filters

Three bag filters are provided upstream of the high crud filter to filter the discharge stream. The vessels are constructed of stainless steel and the replaceable filters elements are polypropylene. During normal operating mode, two bag filters will be in service. The third filter, which is on standby and isolated, may be placed in service while changing out the clogged filters, one at a time, obviating the need to secure flow through the system.

Neutralization Tank

This tank collects spent regenerant chemicals and rinses from condensate demineralizer regeneration (low crud, high conductivity waste). Sulfuric acid or sodium hydroxide is added to adjust the pH to a value between 6.0 and 9.0. The tank contents are circulated during pH adjustment. After neutralization, the tank contents are analyzed for radioactivity and if within limits they are pumped to the turbine building sump, cooling tower blowdown, or the liquid radwaste treatment system.

Neutralization Tank Pumps

Two 150 gpm pumps are provided to circulate the contents of the neutralization tank and to transfer the waste to the desired destination. Normally, only one pump is used.

Non-Reclaimable Waste Tank

The non-reclaimable waste tank receives the same type waste as the neutralization tank. The capability to adjust pH in the tank is provided. The contents of the tank can be routed to the turbine building sump, cooling tower blowdown, or the liquid radwaste treatment system.

Non-Reclaimable Waste Pumps

Two 150 gpm pumps are provided to pump contents of the non-reclaimable waste tank to discharge or to the liquid radwaste treatment system. Normally, only one pump is used.

Liquid Waste Processing System Valves

The design code for the valves is ANSI B16.5. All valves in the liquid waste processing system are stainless steel. The valves involved are diaphragm valves (Saunders patent type) or others, as necessary. This type of valve provides positive control of stem leakage and is suitable for use as an isolation valve or in throttling service.

Valves are supplied for isolation of each major equipment item for maintenance, to direct and control the flow of waste through the system and for isolation of tanks.

Liquid Waste Disposal Piping

The piping design code is ANSI B31.1. The piping is austenitic stainless steel and the piping joints are welded, except where flanged connections are used at pump, valve, and instrument connections to facilitate removal for maintenance. There are a few locations with threaded end fittings where mobile/temporary equipment may be connected.

Facilities for Venting and Draining

Provisions have been made for venting and draining equipment which may require maintenance during the plant life. Vents and drains are provided either on the components themselves or in the pipe lines between the isolation valves. In general, each pipe line and component vent and drain is provided with a valve plus a backup leakage barrier.

Radwaste Demineralization System

The radwaste demineralizer system (also referred to as portable demineralizer or Rad DI) is utilized when required to process radioactive liquid waste. The demineralizers and associated equipment are located in the Auxiliary Building waste packaging area.

The Radwaste Demineralizer System is vendor owned and operated, and is utilized as required for efficient radioactive liquid waste processing via ion exchange and filtration. This is accomplished by use of a combination of chemical treatment, filtration, and ion exchange technology.

All radwaste demineralizer equipment configurations used by the vendor meet the applicable regulatory requirements for the overall radwaste process system, including 10CFR20 and Regulatory Guide 1.143.

11.2.3.2 Instrumentation Design

The instrumentation readout is located mainly on the Waste Processing System (WPS) panel in the Auxiliary Building. Some instruments are read where the equipment is located. Alarms are located on their respective WPS panel. Some instruments are located in the main control room along with handswitches for operating some radwaste pumps and control valves.

Most pumps are protected against loss of suction pressure by a control setpoint on the level instrumentation for the respective vessels feeding the pumps.

Pressure indicators upstream and downstream of filters provide local indications of pressure drops across each component. Releases to the environment are monitored for radioactivity as described in Section 11.4. This instrumentation is further described in Section 11.4.

11.2.4 Operating Procedures

Administrative controls are exercised through the use of instructions covering such areas as valve alignment for various operations, equipment operating instructions, and other instructions pertinent to the proper operation of the processing equipment. Sign off procedures are followed in sampling and analyzing any radioactive liquid to be discharged to assure proper valve alignments and other operating conditions before a release. These procedures are signed and verified by those personnel performing the analysis and approving the release.

Preventive maintenance is performed in accordance with approved plant maintenance program procedures.

The operating procedures and administrative controls used at the Sequoyah Nuclear Plant are written and maintained considering the experience gained in system operation at Sequoyah and considering applicable industry experience, including vendor recommendations. This insures the Sequoyah Nuclear Plant liquid waste management system is operated in as efficient a manner as practical.

Operation of the Liquid Waste Processing System is essentially the same during all phases of normal reactor plant operation; the only differences are in the load on the system. The following sections discuss the operation of the system in performing its various functions. In this discussion, the term "normal operation" should be taken to mean all phases of operation except operation under emergency or accident conditions. The Liquid Waste Processing System is not regarded as a safeguard system.

Liquid Waste Processing

Normal Operation

During normal plant operation the system processes liquids from the following sources:

1. Equipment drains and leaks
2. Radioactive chemical laboratory drains
3. Radioactive hot shower drains
4. Decontamination area drains
5. Demineralizer flushing and backwashing
6. Sampling system
7. CVCS holdup tank (as desired)

The system's reactor coolant drain tanks collect liquids from the following sources and then transfers them for processing to CVCS or radwaste.

1. Reactor coolant loops
2. Reactor coolant pump No. 2 seal leakage
3. Excess letdown during startup
4. Accumulators
5. Valve and reactor vessel flange leakoffs
6. Refueling canal drains

The Pressurizer Relief Tank drains directly to the common header for the reactor coolant drain tank pumps, effectively by-passing the reactor coolant drain tank itself, and is normally pumped to the CVCS holdup tank.

Liquid flows to the reactor coolant drain tank and is discharged directly to the CVCS holdup tanks by the reactor coolant drain tank pumps which are operated automatically by a level controller near the tank. There is one reactor coolant drain tank with two reactor coolant drain tank pumps located inside the containment building of each unit.

Normally, the reactor coolant drain tank pumps are operated in the automatic mode, which allows pump operation and reactor coolant drain tank level to be controlled automatically. The pumps can also be operated manually to control the tank level.

Where possible, waste liquids drain to the waste disposal system floor and tritiated drain collector tanks by gravity flow.

Separation of Tritiated and Nontritiated Liquids

Waste liquids which are high in tritium content are routed to the tritiated drain collector tank, while liquids low in tritium content are routed to the floor drain collector tank. The tritiated liquids and the nontritiated liquids are processed as necessary prior to release.

Tritiated Water

The water enters the liquid waste disposal system via equipment leaks and drains, valve leakoffs, pump seal leakoffs, tank overflows, and other tritiated and aerated water sources.

The equipment consists of a tritiated drain collector tank, two waste evaporator feed pumps, waste evaporator feed filter, and the radwaste demineralizer system.

The tritiated liquids from equipment leaks and drains, and valve leakoffs whose elevations are too low to drain to the tritiated drain collector tank, are drained to the Auxiliary Building floor and equipment drain sump and can be pumped to the tritiated drain collector tank or the floor drain collector tank.

A function of the tritiated drain collector tank is to provide surge capacity.

Nontritiated Water

Nontritiated water can be processed as necessary prior to discharge to the river. The sources include floor drains, equipment drains containing nontritiated water, certain sample room and radiochemical laboratory drains, hot shower drains, and other nontritiated sources. The equipment consists of a floor drain collector tank, two auxiliary waste evaporator feed pumps, auxiliary waste evaporator feed strainer, hot shower tanks and pump, and radwaste demineralizer system.

Hot Shower Drains

One of the two hot shower tanks is valved to receive waste at all times. When one tank is filled, it is valved out and the other tank is valved in. The full tank is then aligned with the hot shower pump to mix the waste by recirculation. A sample can be taken from a local sample connection to determine what subsequent handling of the waste liquid is required. Normally no treatment is required for removal of radioactivity. Low sudsing cleaning agents are used to minimize foaming.

Laboratory Samples

Laboratory samples which contain chemicals used in analysis can be discarded in a fume hood sink which drains to the chemical drain tank.

The operation of the chemical drain tank pump and control of the tank level is manual, with the exception that the pump is shut off automatically on low tank level.

Low activity drains from the laboratory, such as flush water, can be routed to the floor drain tank. Excess tritiated samples not contaminated by chemicals during analysis can be directed to the tritiated drain collector tank.

Shipping Cask Decontamination Drains

Liquid used to decontaminate the spent fuel shipping cask is drained to the 15,000 gallon cask decontamination collector tank except during dry cask storage operation wherein the HI-TRAC transfer cask is decontaminated locally on the auxiliary building refueling floor. The liquid is expected to be low enough in radioactivity content that it can be discharged without processing other than by filtration. Following analysis, the liquid is pumped through the cask decontamination filter and is discharged. In the unlikely event that the radioactivity level is such that further processing is required, the liquid may be reprocessed.

Condensate Demineralizer Waste

The condensate demineralizer system is described in Subsection 10.4.6. Subsection 10.4.6 includes a discussion of the regeneration process. Treatment of regeneration wastes is described in this section.

As described in Subsection 10.4.6, the condensate demineralizer regeneration system is designed to separate wastes into two fractions, one a high crud, low conductivity liquid, and the other low crud, high conductivity liquid. These fractions are collected in separate tanks. The first fraction results from backwash which precedes chemical regeneration and from rinses which follow chemical regeneration. The volumes of these fractions will vary depending on the duration of each backwash and regeneration. The total volume of each usually averages about 60,000 gallons per regeneration.

Treatment of High-Crud, Low-Conductivity (HCLC) Waste

The high crud waste is normally low in conductivity. Liquid in the HCLC tank is recycled with a HCLC pump to achieve a uniform mixture and the waste is sampled for pH and neutralized if required. If the activity of the waste is low, it is discharged to the turbine building sump or cooling tower blowdown. If the activity of the waste is too high to be routed to the Turbine Building Sump, it is sent to the cooling tower blowdown. If the activity of the waste is high enough to cause NRC discharge limits to be exceeded, it can be processed through the radwaste system.

Treatment of Low Crud, High-Conductivity (LCHC) Waste

The LCHC waste, consisting of the spent regeneration chemicals, is collected in both the neutralizer and non-reclaimable waste tanks. The waste is neutralized in either tank and then recycled and sampled for NPDES criteria. If the activity of the waste is low, it is discharged to the Turbine Building Sump or cooling tower blowdown. If the activity of the waste is too high to be routed to the Turbine Building Sump, it is sent to the cooling tower blowdown. If the activity of the waste is high enough to cause NRC discharge limits to be exceeded, it can be processed through the radwaste system.

Discharge of Regeneration Wastes

Waste liquids from the condensate demineralizer regeneration that are to be discharged are first sampled and analyzed to ensure that the NPDES criteria are within acceptable limits. The discharge is directed to the Turbine Building Sump or to the cooling tower blowdown line after passing through control valves and a radiation monitor. The control valves is arranged to close on a high radiation signal from the monitor.

Spent Resin Handling

This portion of the system sluices resin from the demineralizers.

Resin Sluicing From Demineralizers

Resin sluicing from the demineralizer is performed by using primary water to fluff the bed prior to sluicing and for performing the resin sluicing operation. All spent resins are sluiced to the Spent Resin Storage Tank and a resin inventory is maintained for the Spent Resin Storage Tank. When the desired amount of resin has been sluiced to the Spent Resin Storage Tank, then the spent resins are transferred to a shipping container for disposal using primary water and nitrogen.

Sluicing operation of the demineralizer is monitored by taking radiation readings on vessel to determine when demineralizer is empty of resins. A negligible amount, if any, of resins is expected to remain in a demineralizer after flushing.

All water used for sluicing operations is routed to the TDCT.

Resin Storage

Spent resin are stored in the Spent Resin Storage Tank until time for disposal. Removal and transport of resin from the tank is covered under FSAR Section 11.5.3.1. The level indicating system in the Spent Resin Storage Tank is a differential pressure level indicator. Because the system indicates only total level and not the amount of resin and the amount of water, an inventory of spent resins in the tank is maintained. Since the resin volumes flushed from demineralizers are known and the resin volumes shipped are known, the resin level in the tank is also known.

Refueling

Operation of the Liquid Waste Processing System is the same during refueling as during normal operation except when the holdup tanks are utilized to provide water to the refueling canal. The holdup tanks can be utilized as storage or a source of water for the refueling canal to support maintenance and refueling activities. When refueling is complete, the water remaining in the refueling canal following normal drain-down by the Residual Heat Removal System, is drained to the reactor coolant drain tank and pumped back to the refueling water storage tank with the reactor coolant drain tank pumps. The pumps normally operate in the automatic mode during this operation. Since there is oxygen in the refueling water, the drain tank may be isolated from the vent header during this transfer and the tank is vented to the containment atmosphere. It is necessary to purge the tank with nitrogen before connecting it back to the vent header.

Faults of Moderate Frequency

The system is designed to handle the occurrence of equipment faults of moderate frequency such as:

1. Malfunction in the Liquid Waste Processing System

   Malfunction in this system could include such things as pump or valve failures or radwaste demineralizer failure. Because of pump standardization throughout the system, a spare pump can be used to replace most pumps in the system. There is sufficient surge capacity in the system to accommodate waste until the failures can be fixed and normal plant operation resumed. The Auxiliary Building passive sump has sufficient capacity to contain unprocessed water in the event of a radwaste demineralizer failure.

2. Excessive Leakage in Reactor Coolant System Equipment

   The system is designed to handle a one gpm reactor coolant leak in addition to the expected leakage during normal operation. Operation of the system is almost the same as for normal operation except the load on the system is increased. A one gpm leak into the reactor coolant drain tank is handled automatically but will increase the load factor of the radwaste processing system. If the one gpm leak enters the tritiated drain collector tank,

operation is the same as normal except for the increased load on the system. Abnormal liquid volumes of reactor coolant resulting from excessive reactor coolant or auxiliary building equipment leakage (1 gpm) can also be accommodated by the floor drain collector tank and processed by the Radwaste Demineralizer System.

3. Excessive Leakage in Auxiliary System Equipment

   Leakage of this type could include water from steam side leaks inside the containment building which are collected in the reactor building floor and equipment drain sump. Although the sump pump discharge is normally routed to the floor drain collector tank, the flow could be diverted to the tritiated drain collector tank. Other sources could be component cooling water leaks, service water leaks, and secondary side leaks. This water will enter the floor drain collector tank and will be processed and discharged the same way as during normal operation.

4. Steam Generator Tube Leaks

   During periods of operating with fuel defects coincident with steam generator tube leaks radioactive liquid can be discharged via the steam generator blowdown system. The releases from the secondary side are within the 10 CFR 20 limits on a short term basis and meet existing regulations.

<u>Releases of Waste</u>

Release of radioactive liquid from the Liquid Waste Processing System can be from the cask decontamination collector tank, CVCS monitor tank, hot shower tanks, or chemical drain tank to the cooling towers blowdown line. The cooling tower blowdown line empties into the diffuser pond which discharges into the river through the diffuser pipes. Liquid wastes from the condensate demineralizer system are released from the high crud low conductivity tanks, the non-reclaimable waste tank, and the neutralization tank.

The condenser circulating water (CCW) system operates in three modes: open, closed, and helper. In the open mode, the cooling towers are not used. Cooling water is pumped from the intake and through the condenser, and is discharged into the diffuser pond. Dilution water for the radioactive liquid is provided by the Diffuser Pond, which is continuously supplied CCW or ERCW Pumps. A weir at Gate Structure 1 ensures that under most river level conditions, the ERCW flow is diverted through the cooling tower blowdown line. The radioactive liquid is mixed with ERCW in the cooling tower blowdown line and flows into the diffuser pond where it is diluted by CCW Pump discharge.

In the closed mode, CCW is recirculated between the cooling towers and the condenser. In this mode of operation, the cooling towers blowdown flows at a minimum of 150,000 gpm into the diffuser pond in order to maintain the solids in the cooling water at an acceptable level.

In the helper mode, the CCW from the condenser goes through the cooling towers and is released to the diffuser pond through Gate Structure 1 and the cooling tower blowdown line.

Release of the radioactive liquids from the liquid waste system is made only after laboratory analysis of the tank contents. Once the fluids are sampled, they are pumped to the discharge pipe through a remotely operated control valve, interlocked with a radiation monitor.

Minimum dilution flow shall be determined by verification of at least 2 CCW Pumps running from either Unit during normal operations. When less than 2 CCW Pumps are running minimum dilution flow shall be verified via ERCW flow instrumentation or by periodic flowrate estimation in accordance with the SQN ODCM.

A similar arrangement is provided for wastes discharged from the condensate demineralizer waste system. The flow control valve is interlocked with a radiation monitor. Release of wastes will be automatically stopped by a high radiation signal.

The steam generator blowdown system also may discharge radioactive liquid. Liquid waste from this system is not collected in tanks for treatment, but is continuously monitored for radioactivity and may discharge to the cooling tower blowdown, or recirculate to the condensate system upstream of the condensate demineralizers. The flow control valve in the discharge line is interlocked with a radiation monitor. Minimum dilution flow shall be determined by verification of at least 2 CCW Pumps running from either Unit during normal operations. When less than 2 CCW Pumps are running minimum dilution flow shall be verified via ERCW flow instrumentation or by periodic flowrate estimation in accordance with the SQN ODCM. Refer to Section 10.4.8 for a description of the steam generator blowdown system operation and/or Section 11.4.2.1.4 for a description of its monitoring system.

The Turbine building sump collects liquid entering the turbine building floor drain system or from clean water sources in the Auxiliary Building that are transferred to the Turbine Building sump. When the sump is nearly full (maximum capacity 30,000 gallons), the liquid is automatically discharged (level initiated) to the low-volume waste treatment pond or the yard drainage pond. Water in the yard drainage pond overflows and drains by gravity to the diffuser pond, from which it flows to the river via the diffusers.

Station Blackout

The Liquid Waste Processing System does not normally operate during a blackout. If necessary, equipment can be manually connected to the emergency power source.

Loss-of-Coolant Accident

The Liquid Waste Processing System does not operate during, or immediately following, a loss-of-coolant accident. As in the case for a station blackout, equipment may be started manually, as required, when electrical power is available.

Operating Experience

Waste Evaporators

The original waste and auxiliary waste evaporators and CDWE have been isolated from the system and abandoned in place. The contents of the tritiated drain collector tank, floor drain collection tank, and CVCS holdup tanks are pumped to the Radwaste Demineralizer System for processing.

Demineralizers

Operational data on demineralizer decontamination factors for selected isotopes has been obtained. The measured range of decontamination factors for these isotopes are given in Table 11.2.4-1. These values were observed across mixed bed demineralizers containing cation resin in the lithium-7 form and anion resin in the borated form. The minimum values in Table 11.2.4-1 were generally observed just prior to resin flushing and recharging, while during the operating life of the demineralizer, decontamination factors were consistently closer to the maximum values.

Although specific operating decontamination factors have not as yet been measured for other isotopes, their behavior in a mixed bed demineralizer may be inferred from this data. One would anticipate, for example, tellurium and bromine to have decontamination factors similar to those given for iodine and fluorine.

11.2.5 Performance Tests

Initial performance tests were performed to verify the operability of the components, instrumentation and control equipment and applicable alarms and control setpoints.

The specific objectives demonstrated the following:

1. Pumps are capable of producing flow rate and head as required.

2. Waste filters are capable of passing required flow rate.

3. Instrumentation, controllers and alarms operate satisfactorily to maintain levels, pressures and flow rates and indicates, records and alarms as required.

4. All sampling points are available for sampling.

During reactor operation the Radwaste Demineralizer System is used as needed.

Data is taken periodically for use in determining decontamination factors of demineralizers and evaporators.

11.2.6 Estimated Releases

11.2.6.1 NRC Requirements

The following documents have been issued by the NRC to provide regulations and guidelines for releases of radioactive liquids:

1. 10 CFR 20, Standards for Protection Against Radiation.

2. 10 CFR 50, Domestic Licensing of Production and Utilization Facilities.

The following summarizes the basic radioactive liquid release limits established by the above documents:

1. The concentration limit on an unidentified instantaneous release basis as defined in Appendix B of 10 CFR 20 is 10^{-6} μCi/ml.

2. The concentration limit on an identified basis is defined in Appendix B, Table 2, of 10 CFR 20.

Concentration limits for the major isotopes are as follows:

Isotope	μCi/ml
Mo-99	2×10^{-5}
I-131	1×10^{-6}
I-133	7×10^{-6}
Cs-134	9×10^{-7}
Cs-136	6×10^{-6}
Cs-137	1×10^{-6}

3. The water effluent concentration limit for tritium on an identified basis as given in Appendix B, Table 2 of 10 CFR 20 is 1×10^{-3} μCi/ml.

11.2.6.2 Expected Liquid Waste Processing System Releases

The quantities and isotopic concentration in liquids assumed discharged to the Liquid Waste Processing System, and hence the releases to the environment, are highly dependent upon the operation of the plant. The analysis for Sequoyah is based on engineering judgment with respect to the operation of the plant and the Liquid Waste Processing System and realistic estimation of the potential input sources. Hence, the results are representative of typical releases from Sequoyah Liquid Waste Processing System.

The input sources assumed in the study are summarized in Table 11.2.2-1 and the isotopic activities at key locations in the Liquid Waste Processing System are given in Table 11.2.2-2 with the locations indicated on the Process Flow Diagram, Figures 11.2.2-1 and 11.2.2-2. The expected isotopic composition of reactor grade water is based on 0.12% failed fuel. The associated releases in curies per year per nuclide are given in Table 11.2.2-2.

The Liquid Waste Processing System is assumed to operate as described in Subsection 11.2.4.

11.2.7 Release Points

Radioactive liquid wastes are released from the plant through the cooling tower blowdown line and through the diffuser pond system. The discharge points from the waste disposal system is shown in Figure 11.2.2-2. The connection to the cooling tower blowdown line is shown in Figure 10.4.5-2. The discharge points from the Liquid Waste Processing System are downstream of all waste tanks. The location of the cooling tower blowdown line in relation to the site boundary is shown on Figures 2.1.2-2 and 10.4.5-2 collectively.

11.2.8 Dilution Factors

The offsite dose calculations for drinking water are based on the assumption that the liquid effluent will be mixed with 60 percent of the river flow between the point of discharge and Chickamauga Dam. Although further mixing will occur, 60 percent dilution is assumed to be maintained for approximately 14 miles until Chickamauga Dam (TRM 471.0) is reached where 100 percent dilution is assumed to occur. A complete description of available dilution calculations is in Section 2.4.12.

11.2.9 Estimated Doses from Radionuclides in Liquid Effluents

Doses from the ingestion of water, from the consumption of fish, and from shoreline recreation are calculated for exposures to radionuclides routinely released in liquid effluents.

11.2.9.1 Assumptions and Calculational Methods

Internal doses are calculated using methods outlined in Nuclear Regulatory Commission (NRC) Regulatory Guide 1.109, Rev. 1. This model is used for estimating the doses to bone, gastrointestinal tract, thyroid, liver, and total body of man from ingestion of water and consumption of fish and from external exposures due to recreational activities.

Population doses are estimated for the year 2020 based on the current populations. Projections are based on an assumed increase of 2% per year in exposed populations.

1. Doses to Man from the Ingestion of Water

Data listed in Table 11.2.9-1 for public water supplies on the Tennessee River within a 50-mile radius downstream of Sequoyah Nuclear Plant are used to calculate dose commitments from the consumption of Tennessee River water. Dilution is calculated using average annual flow data for the Tennessee River as measured during the 31 year period 1959 - 1990. The flow averages approximately 30,000 ft^3/s at the nuclear plant site.

Radioactive decay are based on estimates of the transport time calculated from flow data. Additional radioactive decay is considered between the time of intake in a water system and the time of consumption. This time is set equal to 12 hours to allow for processing and distribution time. Maximum and average consumption rates are those recommended in Regulatory Guide 1.109.

Due to a lack of definitive data, no credit is taken for removal of activity from the water through absorption on solids and sedimentation, by deposition in the biomass, or by processing within water treatment systems.

Internal doses, for an organ from a single radionuclide are calculated using the relation

$$D = DCF \times I \qquad (1)$$

where DCF = The dose commitment factor for the organ from ingestion of the radionuclide; the values used were taken from NRC Regulatory Guide 1.109, Rev 1, (mrem/pCi).

I = The activity of the radionuclide taken into the body annually via ingestion, (pCi).

Resultant calculated dose commitments are shown in Table 11.2.9-2.

2. Doses to Man from the Consumption of Fish

Current estimates of Tennessee River fish harvests are 3.04 lb/acre/year. It is assumed that these rates will increase with the population expansion, so that the dose calculations

are based on harvests of 5.51 lb/acre in the year 2020. The Tennessee River within 50 miles downstream of SQN is segmented into 4 reaches in order to facilitate the calculations of fish harvests and radioactivity concentrations. The radioactivity levels in the fish from each reach are estimated by the product of an average activity concentration in the reach and a concentration factor for each radionuclide. Concentration factors are taken from Regulatory Guide 1.109. The population dose is calculated using the assumption that all of the edible fish harvested are consumed by humans living within the 50-mile radius. The annual rates of consumption for maximum and average individuals are also taken from Regulatory Guide 1.109. Radioactive decay is considered between the time the fish is removed from the water and the time of consumption.

Dose commitments are calculated with equation 1 as discussed for water ingestion in the previous section, and the results are shown in Table 11.2.9-2.

There should be no significant radiological impact from human utilization of shellfish. Shellfish are not currently being harvested commercially in the Tennessee River, and consumption of shellfish by humans is assumed to be negligible.

3. <u>Doses to Man Due to Shoreline Recreation</u>

Estimates of the annual doses D from recreation around the Tennessee River are calculated for each radionuclide using the following equation.

D = (RDCF) C x T(mrem) (2)

where (RDCF) = The shoreline recreation dose commitment factor, mrem/hour per pCi/m^3, from Regulatory Guide 1.109, Table E-6.

T = Exposure time pertaining to the k <u>th</u> pathway;yr.

C = The concentration of the radionuclide in the sediment, pCi/m^3; calculated using NRC Regulatory Guide 1.109, Rev. 1, methodology.

Doses from shoreline recreational activities are estimated using the methodology outlined in NRC Regulatory Guide 1.109, Rev. 1. Equation A-5 from the Regulatory Guide is used to determine the 15-year buildup concentration of radionuclides in sediment. Having these concentrations, combined with external dose factors for standing on contaminated ground and a shore-width factor of 0.3 (Table A-2, Regulatory Guide 1.109, Rev. 1) allows the determination of maximum expected external dose rates. Water concentrations are calculated for 4 reaches between the nuclear plant site and Tennessee River Mile 400.0. Doses to the population are calculated using estimates for shoreline visits for the respective reaches based on information given in the ODCM multiplied by the predicted population growth factor of 2% per year.

The maximum individual doses due to shoreline activity are assessed for a person on a fictitious beach just below the Sequoyah site 10 hours per week, 50 weeks per year. Calculated hypothetical dose rates from recreational activities are presented in Table 11.2.9-2.

11.2.9.2 Summary of Dose from Radionuclides in Liquid Effluents

Radiation doses calculated for releases of radionuclides in liquid effluents during normal operation of the Sequoyah Nuclear Plant are summarized in Table 11.2.9-2. Liver tissues are expected to receive the greatest doses for both the maximum individual and thyroid tissues receive the highest population dose. These results demonstrate that the releases from the plant are in accordance with the design objectives as outlined in Subsection 11.2.1.

TABLE 11.2.2-1 (Sheet 1)

LIQUID WASTE PROCESSING SYSTEM CALCULATIONAL BASIS

1.0 Tritiated Drain Collection Tank

1.1 Tank activity concentrations are based on the tank activities and liquid volumes given in Table 11.2.2-2.

1.2 TDCT output flow is 5.0 gpm which is directed to the radwaste demineralizer (Rad DI) prior to release to CTBD (cooling tower blowdown).

2.0 Floor Drain Collection Tank

2.1 Tank activity concentrations are based on the tank activities and liquid volumes given in Table 11.2.2-2.

2.2 FDCT output flow is 9.3 gpm which is directed to the Rad DI prior to release to CTBD.

3.0 CVCS Holdup Tank (HUT)

3.1 The HUT is assumed to consist of reactor coolant activity that has been processed through the letdown demineralizer.

3.2 Reactor coolant concentrations are based on ANSI/ANS-18.1-1984, as given in Table 11.1.2-3.

3.3 Decontamination Factors (DFs) for the letdown demineralizer are based on ANSI/ANS-18.1-1984 and are:

1	H-3
100	Anions (Br, I)
50	All other nuclides

3.4 HUT output flow is 0.73 gpm which is directed to the Rad DI prior to release to CTBD.

4.0 Radwaste Demineralizer (Rad DI)

The following DFs for the Rad DI are based on NUREG-0017 and actual operational data:

100	Iodine
1	H-3
50	Cesium
10	Other nuclides

5.0 Chemical Drain Tank (CDT)

5.1 Tank activity concentrations are based on the tank activities and liquid volumes given in Table 11.2.2-2.

5.2 CDT output flow is 1000 gal/yr/unit which is released to CTBD without prior treatment.

TABLE 11.2.2-1 (Sheet 2)

LIQUID WASTE PROCESSING SYSTEM CALCULATIONAL BASIS

6.0 Hot Shower Tank (HST)

6.1 Tank activity concentrations are based on the tank activities and liquid volumes given in Table 11.2.2-2.

6.2 HST output flow is 0.5 gpm which is released to CTBD without prior treatment.

7.0 Condensate Demineralizer System (CDS)

7.1 Nuclide concentrations are based on the values for secondary coolant (steam) given in ANSI/ANS-18.1-1984, adjusted for SQN specific operational parameters.

7.2 CDS output flow is 660 gpm which is released to CTBD without prior treatment.

8.0 Steam Generator Blowdown (SGBD)

8.1 Nuclide concentrations are based on the values for secondary coolant (water) given in ANSI/ANS-18.1-1984, adjusted for SQN specific operational parameters.

8.2 SGBD output flow is 3E+4 lb/h which is released to CTBD without prior treatment.

Table 11.2.2-2

11.3 GASEOUS WASTE SYSTEMS

11.3.1 Design Objectives

The Gaseous Waste Processing System is designed to remove fission product gases from the reactor coolant and to permit operation with periodic discharges of small quantities of fission gases through the monitored plant vent. This is accomplished by internal recirculation of radioactive gases and holdup in the nine gas decay tanks to reduce the concentration of radioisotopes in the released gases.

The offsite exposure to individuals from gaseous effluents released during normal operation of the plant are limited by 10 CFR 50 Appendix I and 40 CFR 190.

Although plant operating procedures, equipment inspection, and preventive maintenance are performed during plant operations to minimize equipment malfunction, overall radioactive release limits have been established as a basis for controlling plant discharges during operation with the occurrence of a combination of equipment faults of moderate frequency. A combination of equipment faults which could occur with moderate frequency include operation with fuel defects in combination with such occurrences as:

1. Steam generator tube leaks.

2. Malfunction in Liquid Waste Processing System.

3. Malfunction of Gaseous Waste Processing System.

4. Excessive leakage in Reactor Coolant System equipment.

5. Excessive leakage in auxiliary system equipment.

The radioactive releases from the plant resulting from equipment faults of moderate frequency are within 10 CFR 20 limits.

11.3.2 System Description

The Gaseous Waste Processing System consists of two waste-gas compressor packages, nine gas decay tanks, and the associated piping, valves and instrumentation. The equipment serves both units. The system is shown on Diagram Figures 11.3.2-1 and 11.3.2-2.

Table 11.3.2-1 gives process parameters for key locations in the system.

The basis used for estimating the process parameters are given in Table 11.3.2-2.

Gaseous wastes can be received from the following: degassing of the reactor coolant and purging of the volume control tank prior to a cold shutdown, displacing of cover gases caused by liquid accumulation in the tanks connected to the vent header, purging of some equipment, sampling and gas analyzer operation, and boron recycle process operation (no longer in service).

Auxiliary Services

The auxiliary services portion of the Gaseous Waste Processing System consists of an online waste gas analyzer (WGA) and its instrumentation, valves, and tubing, a nitrogen and a hydrogen supply manifold and the necessary instrumentation, valves, and piping.

The online gas analyzer determines the quantity of oxygen and hydrogen in the waste gas tank that is in service. The Volume Control Tank, Pressurizer Relief Tank, Holdup Tanks, and Spent Resin Storage Tank may be analyzed by grab sample as plant conditions require.

The nitrogen and hydrogen supply packages are designed to provide a supply of gas to the Nuclear Steam Supply System. Nitrogen (N_2) supply for the Auxiliary and Reactor Buildings has two headers inside the Auxiliary Building, each with its own backup supply of high pressure N_2. Alignment is such that both headers are normally supplied by the liquid nitrogen skid located in the east Auxiliary Building yard. One header is for operation and one is for backup. Twenty-four N_2 cylinders per bank provide the backup N_2 supply or a trailer mounted N_2 tank can be connected near the liquid nitrogen skid. The pressure regulator in the nitrogen backup header is set slightly lower than that in the operating header. When nitrogen from the operating header is exhausted, its discharge pressure falls below the set pressure of the backup header, which comes into service automatically to ensure a continuous supply of nitrogen. An alarm alerts the operator that one header is exhausted. Hydrogen is supplied from two headers up into the reducing station for the Auxiliary Building at which point only one header supplies both units' VCTs. One serves as the operational header and the other serves as the backup header.

Nitrogen is supplied to the spent resin storage tank, reactor coolant drain tank, pressurizer relief tank, volume control tank, gas decay tanks and the holdup tanks. Hydrogen is supplied to the volume control tank.

The design and material of valves and manifolds are the same as for the main Gaseous Waste Processing System.

11.3.3 System Design

11.3.3.1 Component Design

Gaseous waste processing equipment parameters are given in Table 11.3.3-1. For further information on design codes and safety classes see Section 3.2. Design criteria for field run piping is given in Subsection 3.9.2.6.

Waste Gas Compressors

The two waste gas compressors are provided for continuous or batch removal of gases discharging to the vent header. One unit is supplied for normal operation and is capable of handling the gas from a holdup tank which is receiving letdown flow at the maximum rate. The second unit is provided for backup during peak load conditions, such as when degassing the reactor coolant or for service when the first unit is down for maintenance. Operation of either unit can be controlled manually or by vent header pressure. Each unit is sized for 40 cfm.

The compressors are of the liquid piston rotary type. Construction is of cast iron external and bronze internals with a stainless steel shaft.

Waste Gas Decay Tanks

Nine tanks are provided to hold radioactive waste gases for decay. This arrangement is adequate for a plant operating with one percent fuel defects. Nine tanks are provided so that during normal operation, a minimum of 60 days are available for decay.

The tanks are vertical cylindrical type and are constructed of carbon steel.

Valves

The valves handling gases are carbon steel, Saunders patent diaphragm type, which are designed to minimize stem leakage.

Piping

The piping for gaseous waste is carbon steel; all piping joints are welded except where flanged connections are necessary for maintenance.

11.3.3.2 Instrumentation Design

The main system instrumentation is shown on Figures 11.3.2-1 and 11.3.2-2.

The instrumentation readout is located mainly on the Waste Processing System panel in the auxiliary building. Some instruments have local readout at the equipment location.

All alarms are shown separately on the WPS panel.

An online gas analyzer is provided to monitor hydrogen and oxygen concentrations in the waste gas atmosphere. The analyzer indicates the oxygen and hydrogen concentrations and alarms at predetermined explosive levels of hydrogen and oxygen with oxygen the controlling parameter for taking corrective action. The analyzer is normally aligned to the inservice gas decay tank.

11.3.4 Operating Procedure

All equipment installed to reduce radioactive effluents to the minimum practicable level is maintained in good operating order and will be operated to the maximum extent practicable. In order to assure that these conditions are met, administrative controls are exercised on overall operation of the system; preventive maintenance is utilized to maintain equipment in peak condition. The preventive maintenance program is set up on a computer system which indicates preventive maintenance instructions for systems or components in the plant at appropriate intervals (monthly, quarterly, etc.).

Administrative controls are exercised through the use of instructions covering such areas as valve alignment for various operations, equipment operating instructions, and other instructions pertinent to the proper operation of the processing equipment. Discharge permit forms will be

utilized to assure proper procedures are followed and in assuring proper valve alignments and other operating conditions before a release. These forms will be signed and verified by those personnel performing the analysis and approving the release.

Preventive maintenance is carried out on all equipment as described in the preventive maintenance instructions which utilize manufacturers' instruction manuals for reference.

Gaseous wastes consist primarily of hydrogen stripped from the reactor coolant during boron dilution and degassing operations and nitrogen from the closed cover gas system. The components connected to the vent header are limited to those which contain no air or aerated liquids to prevent formation of a combustible mixture of hydrogen and oxygen.

Waste gases discharged to the vent header are pumped to a waste gas decay tank by one of the two waste gas compressors.

The standby compressor is capable of being started automatically when high pressure occurs in the vent header. The standby compressor can be started manually. The compressors may also be used to transfer gas between gas decay tanks. Normal operation of either compressor is in the manual mode.

To compress gas into the gas decay tanks, the operator selects two tanks at the WPS control panel, one to receive gas, and one for standby. The operator then manipulates the isolation valves for these two tanks so they are respectively aligned for service. When the tank in-service is pressurized to 100 psig, flow is automatically switched to the standby tank and an alarm alerts the operator to select/align a new standby tank. Tanks may be manipulated prior to 100 psig, manually, if desired.

The decay tank being filled is normally sampled by the gas analyzer and an alarm alerts the operator to a high oxygen content. On high oxygen signal, the tank must be isolated and operator action is required to direct flow to the standby tank and to select a new standby tank.

If it should become necessary to transfer gas from one decay tank to another, the tank to be emptied is discharged to the holdup tank return line. The tank to receive gas is opened to the inlet header and the return line pressure regulator set-point is raised to above 1.8 psig. The return line isolation valve is closed and the crossover between the return line and the compressor suction is opened. With this arrangement, gas is transferred by the compressor which is in service.

As the Chemical and Volume Control System holdup tanks liquid is withdrawn for processing to the portable radwaste demineralizer system, gas from the gas decay tanks is returned to the holdup tanks. The gas decay tank selected to supply the returning cover gas is aligned to the return header from the WPS control board and by manually opening the appropriate valve.

To maximize residence time for decay in the decay tanks, the last tank filled is the first tank aligned to the cover gas header. A backup supply of gas for the holdup tanks is provided by the nitrogen header.

Before a gas decay tank is discharged to the atmosphere via the plant vent, a gas sample is taken to determine activity concentration of the gas in the tank. The curie content versus

change in tank pressure is used to quantify the activity released along with time to determine the offsite dose for the release.

To release the gas, the appropriate local manual stop valve is opened to the plant vent and the gas discharge modulating valve is opened at the WPS control panel. If there should be a high activity level in the 2 inch discharge line during release, the modulating valve closes.

Refueling

When preparing the plant for a cold shutdown prior to refueling, it is necessary to degas the reactor coolant to reduce the hydrogen concentration to less than 5 cc/kg. At the start of the degassing operation, the volume control tank gas space contains H_2 and traces of fission gases. The operation involves the following steps.

1. Open the tank vent to the vent header
2. Raise the water level, forcing gases out of the tank, then close tank vent to vent header
3. Lower the water level and introduce nitrogen to restore normal gas pressure
4. Repeat steps 1 to 3 as needed until H_2 concentration is at desired level.

Gas evolved from the volume control tank during this operation is pumped by the waste-gas compressors to the gas-decay tanks.

Operation of the Gaseous Waste Processing System is the same during the actual refueling operation as during normal operation.

Auxiliary Services

During normal operation the Gaseous Processing System supplies nitrogen from the liquid nitrogen skid and hydrogen from trailer mounted cylinders to primary plant components. The hydrogen and nitrogen supply services are described in sections 9.5.8 and 9.5.9.

11.3.5 Performance Tests

Initial performance tests are performed to verify the operability of the components, instrumentation and control equipment.

During reactor operation the system is used at all times and hence is under continuous surveillance.

11.3.6 Estimated Releases

11.3.6.1 NRC Requirements

The following documents have been issued by the NRC to provide regulations and guidelines for radioactive releases:

1. 10 CFR 20, Standards for Protection Against Radiation.

2. 10 CFR 50, Domestic Licensing of Production and Utilization Facilities.

The total plant gaseous releases meet these regulations by providing assurance that the exposures to individuals in unrestricted areas are as low as practicable during normal plant operation and during anticipated operational occurrences.

11.3.6.2 Expected Gaseous Waste Processing System Releases

Gaseous Wastes consist primarily of hydrogen stripped from coolant discharged to the Boron Recycle System holdup tanks during boron dilution, nitrogen and hydrogen gases purged from the Chemical Volume and Control System volume control tank when degassing the reactor coolant, and nitrogen from the closed gas blanketing system. During normal gaseous radwaste processing, the gas holdup tank capacity permits at least 60 days decay for waste gases before discharge.

The quantities and isotopic concentration of gases discharged from the Gaseous Waste Processing System have been estimated. The analysis is based on engineering judgment with respect to the operation of the plant and realistic estimation of the input sources to the Gaseous Waste Processing System.

The associated releases in curies per year per nuclide are given in Table 11.3.6-2.

11.3.6.3 Releases from Ventilation Systems

A detailed review of the entire plant has been made to ascertain those items that could possibly contribute to airborne radioactive releases.

During normal plant operations, airborne noble gases and/or iodines can originate from reactor coolant leakage, equipment drains, venting and sampling, primary and/or secondary side leakage, condenser air ejector, gland seal condenser exhausts, Gaseous Waste Processing System leakage and dry cask storage operations inside the auxiliary building.

The assumptions used for this study are given in Table 11.3.6-1. The noble gases and iodines discharged from the various sources are entered in Table 11.3.6-2.

11.3.6.4 Estimated Total Releases

The estimated releases have been used in calculating the unrestricted area boundary doses as shown in Subsection 11.3.9.

The dose calculations, based on the estimated total plant releases, show that the releases are in accordance with the design objectives in Subsection 11.3.1 and meet the regulations as outlined in Paragraph 11.3.6.1. Further, the total plant releases are within the SQN Offsite Dose Calculation Manual (ODCM).

11.3.7 Release Points

Gaseous radioactive wastes are released to the atmosphere through vents located on the shield building, auxiliary building, turbine building, and service building. A brief description, including function and location of each type vent, is presented below.

Shield building vent -- Waste gases from the gas decay tanks are discharged to the environment through a shield building vent. Each shield building has one vent. ABGTS, EGTS, and Containment Purge exhausts to the shield building vents. The vent is of rectangular cross section (dimension - 2 feet by 7 feet 6 inches) and discharges approximately 130 feet above ground level. The location of the shield building vents is shown in the equipment layout drawings, Figure 1.2.3-1. The location of the shield building in relation to the site is shown on the site plot plan, Figure 2.1.2-1. All gases released from the shield building vent except for the air that passes through the containment purge air exhaust monitors are processed through HEPA filters and charcoal adsorbers prior to release. The effluent discharge rate through the vent is variable; occasionally during containment purge, the rate may approach a maximum value of 28,000 cfm in Modes 5 and 6. The flow path for waste gases exhausted through the vent from the gas decay tanks is shown in Figure 11.3.2-1. Also shown in this figure are a HEPA filter and charcoal adsorber which are provided to treat the gas released from the decay tanks.

Auxiliary building vent --Waste gases in the auxiliary building are discharged through the auxiliary building exhaust vent. The vent is of the chimney type having a rectangular cross section of 10 by 30 feet. The top of the vent is located atop the auxiliary building and discharges approximately 106 feet above grade. Under normal operating conditions, gases are continuously discharged through the vent. Effluent flow rates are near 228,000 cfm when two auxiliary building general exhaust fans and one fuel-handling area exhaust fan are operating at full capacity. Under accident conditions the auxiliary building is isolated, and the auxiliary building gas treatment system discharges at a rate of 9000 cfm to the reactor building exhaust vent. The location of the auxiliary building exhaust vent is shown in equipment layout diagram, Figure 1.2.3-1. The auxiliary building is shown on the site plot plan, Figure 2.1.2-1.

Turbine building vents --Ventilation air is exhausted from the turbine building through the turbine building vents. There are 18 vents at the 732-foot level and 20 vents at the 801-foot level (roof level). The effluent flow rates vary for each type of vent. Generally, the flow rates through a typical vent at the 732-foot level will not exceed 23,000 cfm and the flow rates through a typical vent at the 801-foot level will not exceed 36,000 cfm. The general arrangement of vents on the turbine building is shown on Figures 1.2.3-1 and 1.2.3-3. The turbine building is shown on the site plot plan, Figure 2.1.2-1.

Condenser vacuum exhaust vent --Gaseous wastes from the condenser are discharged through the condenser vacuum exhaust vent. The vent, which is a 12-inch diameter pipe, is located on the turbine building roof and discharges approximately 96 feet above grade. Under normal operating conditions the discharge flow rate is less than 20 cfm. Forty-five cfm can be used as the default flow rate for conservatism in the dose rate calculation. The location of the condenser vacuum exhaust on the turbine building is shown on Figure 1.2.3-1.

Service building vent --Potentially radioactive waste gases from the radiochemical laboratory, titration room, and RCA access control area are exhausted to the Service Building vent. This exhausts at a total design flow of approximately 11,200 cfm. The Service Building vent is located on the service building roof. The vent discharges to the atmosphere approximately 24 feet above grade. When exhausting at full capacity from the radiochemical laboratory and the titration room, the combined flow rate is approximately 5,000 cfm. Air from the radiochemical laboratory and titration room is exhausted via fume hoods through HEPA filters. The service building is shown on the site plot plan, Figure 2.1.2-1.

Containment venting --Excess air inside lower containment is exhausted through the reactor building purge vent valves directly into the annulus where the annulus vacuum control system will discharge the effluent through the auxiliary building exhaust vent. See FSAR 9.4.7.2 for additional information.

11.3.8 Atmospheric Dilution

Calculations of atmospheric transport, dispersion, and ground deposition are based on the straight-line airflow model discussed in NRC Regulatory Guide 1.111 (Revision 1, July 1977). All releases are assumed to be continuous. Releases known to be periodic, e.g., those during containment purging and waste gas decay tank venting, are treated as continuous releases.

Releases from the reactor building (RB), turbine building (TB), and auxiliary building (AB) vents are treated as ground level. The joint percentage frequency distributions of 10-meter wind speed and direction, for the pasquill stability classes A through G, that are used in the straight-line model are given in the Tables 2.3.2-23 through 2.3.2-29 for the period 1972-1975. These distributions were used in the calculation of atmospheric dilution factors for a ground level release.

11.3.9 Estimated Doses from Radionuclides in Gaseous Effluents

Individuals are exposed to gaseous effluents via the following pathways: (1) external radiation from radioactivity in the air and on the ground; (2) inhalation; (3) ingestion of beef, vegetables, and milk; and (4) tritium transpiration. No other additional exposure pathway has been identified which would contribute 10 percent or more to either individual or population doses.

11.3.9.1 Assumptions and Calculational Methods

External air exposures are evaluated at points of potential maximum exposure (i.e., points at the unrestricted area boundary). External skin and total body exposures are evaluated at nearby residences. The dose to the target organ from radioiodines and particulates is calculated for real pathways existing at the site. These points of interest are listed in Table 11.3.9-1 and 11.3.9-2.

To evaluate the potential target organ dose, nearest gardens, and milk animals were identified by a detailed survey within five miles of the plant. Information on grazing seasons and feeding patterns are reflected in the feeding factor specified in Table 11.3.9-2 for dairy animals. The feeding factor is the fraction of the year an animal grazes on pasture.

In calculating population doses, TVA assumes that enough fresh vegetables are produced at each residence to supply annual consumption by all members of that household. Also, TVA assumes that enough meat and milk is produced in each sector annually to supply the needs of that region. The projected population distribution within 50 miles of Sequoyah is given in Table 11.3.9-3.

Doses are calculated using the dose factors and methodology contained in NRC Regulatory Guide 1.109, Rev. 1 and NUREG/CR-1004 with certain exceptions as follows:

1. Inhalation doses are based on the average individuals' inhalation rates found in ICRP Publication 23 of 1,400, 5,500, 8,000, and 8,100 m^3/year for infant, child, teen, and adult, respectively.

2. The milk ingestion pathway has been modeled to include specific information on grazing periods for milk animals obtained from a detailed farm survey. A feeding factor (FF) has

been defined as that fraction of total feed intake a dairy animal consumes that is from fresh forage. The remaining portion of feed (1-FF) is assumed to be from stored feed. Doses calculated from milk produced by animals consuming fresh forage are multiplied by these factors. Concentrations of radioactivity in stored feed are adjusted to reflect radioactive decay during the maximum assumed storage period of 180 days by the factor:

$$\frac{1}{180}\int_{o}^{180} \exp(-\lambda_i\, t)dt = \frac{1-\exp(-\lambda_i 180)}{180\,\lambda_i}$$

This factor replaces the factor exp $(-\lambda_i t_h)$ in equation C-5 of Regulatory Guide 1.109.

3. The stored vegetable and beef ingestion pathways have been modeled to reflect more accurately the actual dietary characteristics of individuals. For stored vegetables the assumption is made that home grown stored vegetables are consumed when fresh vegetables are not available, i.e., during the 9 months of fall, winter, and spring. Rather than use a constant storage period of 60 days, radioactive decay is accounted for explicitly during the 275-day consumption period. The radioactive decay correction is calculated by:

$$\frac{1}{275}\int_{o}^{275} \exp\,(\lambda_i\, t)dt = \frac{1-\exp(-\lambda_i\, 275)}{275\,\lambda_i}$$

This replaces the term exp ($-\lambda_i$ th) in equation C-5 of Regulatory Guide 1.109.

4. The beef consumption pathways can be divided into either commercial sales or home use pathways. Dose calculations are made for individuals consuming meat produced for home use. The normal processing route is for an individual to slaughter the beef animal, package and freeze the meat, and then consume the meat during the next 3-month period. Radioactive decay is calculated during the 3-month period by

$$\frac{1}{90}\int_{o}^{90} \exp(\lambda_i\, t)dt = \frac{1-\exp\,(-\lambda_i 90)}{90\,\lambda_i}$$

This term is multiplied into equation C-12 in Regulatory Guide 1.109. If the beef animals are sold commercially, then individuals would not be exposed continuously to meat containing radioactivity from the same farm. It is expected that this pathway will not cause significant individual exposures.

Population doses are based on a U.S. population distribution of:

Category	Ages (A)*	Fraction
Infant	A<1	0.015
Child	1 ≤ A<12	0.168
Teen	12 ≤ A<20	0.153
Adult	20 ≤ A	0.665

*e.g., someone who is 1 year, 11 months is an infant, while someone who is exactly two years old is a child.

Tables 11.3.9-4 and 11.3.9-5 provide the doses estimated for individuals and the population within 50 miles of the plant site.

11.3.9.2 Summary of Annual Population Doses

TVA has estimated the radiological impact to regional population groups in the year 2010 from the normal operation of the Sequoyah Nuclear Plant. Table 11.3.9-5 summarizes these population doses. The total body dose from background to individuals within the United States ranges from approximately 100 mrem to 250 mrem per year. The annual total body dose due to background for a population of about 975,000 persons expected to live within a 50-mile radius of the Sequoyah Nuclear Plant in the year 2010 is calculated to be approximately 141,400 man-rem assuming 145 mrem/year/individual. By comparison, the same population (excluding onsite radiation workers) will receive a total body dose of approximately 7.3 man-rem from effluents released from the Sequoyah Nuclear Plant. Based on these results, TVA concludes that the normal operation of the Sequoyah Nuclear Plant will present minimal risk to the health and safety of the public.

TABLE 11.3.2-2

ASSUMPTION USED IN CALCULATING EXPECTED SYSTEM ACTIVITIES AND RELEASES FROM THE GASEOUS WASTE SYSTEM

1. Containment gaseous source terms are based on a 3%/day (noble gas) and 8.0E-4/day (iodines) release of RCS coolant into the containment airborne atmosphere.

2. Waste gas decay tank releases are based on a 173 ft^3/day (@ standard temperature and pressure) input of RCS coolant offgas to the waste gas disposal system and a waste gas decay tank holdup time of 60 days.

3. Auxiliary Building ventilation noble gas source terms are based on a 160 lb/day release of RCS coolant activity into the Auxiliary Building atmosphere.

4. Auxiliary Building ventilation iodine releases are based on 1.85 Ci/yr per μCi/g of RCS for 300 days and 6.8 Ci/yr per μCi/g for 65 days.

5. Refueling area iodine releases are based on 0.16 Ci/yr per μCi/g of RCS for 300 days and 0.3 Ci/yr per μCi/g for 65 days.

6. Turbine Building ventilation noble gas source terms are based on a 1700 lb/hr release of secondary steam into the Turbine Building atmosphere.

7. Turbine Building ventilation iodine source terms are based on 8500 Ci/yr per μCi/g of secondary steam for 300 days and 1400 Ci/yr per μCi/g for 65 days.

8. Condenser vacuum exhaust vent noble gas source terms are based on a steam flowrate to the condenser of 8.5E6 lb/hr as secondary steam activities.
.
9. Condenser vacuum exhaust vent iodine source terms are based on a 3500 Ci/yr per μCi/g of secondary steam released to the condenser vacuum exhaust vent.

10. Ar-41 releases are 34 Ci/yr.

11. Total tritium releases are based on 0.4 Ci/yr per MWt with 10% of that available for release via gaseous pathways and a power level of 3425 MWt.

12. C-14 releases are 1.6 Ci/yr from containment, 4.5 Ci/yr from the Auxiliary Building, and 1.2 Ci/yr from the WGS for a total of 7.3 Ci/yr.

13. The WGS discharge is filtered with a HEPA (efficiency of 99%) and charcoal (efficiency 70%) filter prior to release.

11.4 PROCESS AND EFFLUENT RADIOLOGICAL MONITORING SYSTEMS

Means are provided for monitoring during normal operations, including anticipated operational occurrences, and during accident conditions various process streams and gaseous and liquid effluent discharge paths. Some of the monitors initiate automatic control actions.

11.4.1 Design Objectives

The Process and Effluent Radiological Monitoring Systems are designed to perform these basic functions:

1. Give warning of a condition which might lead to radioactivity releases that could result in exceeding the limits set forth in 10CFR20 and in 10CFR50.

2. Warn plant personnel of increasing radiation levels which might result in a radiation health hazard.

3. Rapidly provide information on fuel clad and equipment failures or malfunctions.

4. Provide means for detection of leakage of primary coolant to the secondary coolant.

5. Initiate automatic control actions to prevent the unnecessary discharge of excessive radioactivity to the environment.

6. Initiate automatic control actions to prevent the transfer to plant tanks of radioactivity in concentrations above design limits.

7. Perform primary safety functions and postaccident monitoring.

11.4.2 Continuous Monitoring

An instrumentation assembly that includes one or more radiation detectors or radioactive material sample collectors, or both, and all associated instrumentation outside the assembly constitutes a radiation monitor. Each radiation monitor described in this section is composed of one or more of the following channels:

1. gaseous effluent or gaseous process noble gas,
2. gaseous effluent particulate,
3. gaseous effluent iodine,
4. gaseous process exposure rate, and
5. liquid effluent or liquid process.

In the case of two or more monitor channels constituting a single monitor, the monitor channels are considered to share common instrumentation. For example, a three-channel monitor's sampling system is shared among the three channels. Also, part of a sampling system may be shared among two or more monitors.

Most monitor channels have several components. In this section, the unique identification of the detector of any of these monitor channels is used to designate the entire monitor channel.

For monitor channels that do not have uniquely identified components, monitor channel identification requires both the unique identification of the monitor skid assembly which houses the radioactive material sample collectors or channel detectors, or both, and a verbal description sufficient to identify the specific channel of the monitor.

The identification of a monitor channel, monitor skid, and any plant system component that is automatically actuated by a monitor channel begins with one of the character sets, 1-, 2-, or 0-, to denote unit 1, unit 2, or common, respectively. Whenever an identification in this section does not contain one of these character sets, both unit 1 and unit 2 channels, monitor skid assemblies or actuated components exist.

The liquid process and effluent monitors are listed in Table 11.4.2-1. The gaseous process and effluent monitors are listed in Table 11.4.2-2. These tables also list for each monitor channel the electrical safety class, the seismic category, the type of detector, the location of the detector assembly, and the channel range.

Provisions for indication, recording, and alarm annunciation, both locally (i.e., in the vicinity of the detector assembly) and remotely on an MCR panel, are listed in Table 11.4.2-3.

11.4.2.1 Process and Effluent Liquid Monitors

The radiation monitoring system has two basic types of process liquid monitors: (1) off-line monitors and (2) on-line monitors. Each off-line monitor extracts a portion of the process fluid to provide a sample of liquid effluent for real time detection of the effluent radioactivity. The on-line monitors provide real time detection of process liquid radioactivity by means of the detection of dose rates in the vicinity of process liquid piping.

11.4.2.1.1 Waste Disposal System Liquid Discharge Monitor (O-RE-90-122)

Instrument malfunction or detection of radioactivity in excess of the effluent concentration setpoint shall automatically initiate closure of this effluent path to the cooling tower blowdown system by closing RCV-77-43. The setpoint is predetermined by nuclear chemistry Offsite Dose Calculation Manual (ODCM) compliance sampling program prior to each effluent discharge. The sampling program is responsible for determining the acceptability of each release and adherence to 10CFR20 criteria. This monitor provides additional assurance that the effluent releases are consistent with the compliance sampling to preclude potential discharges composed of inconsistent concentrations or piping misalignment.

11.4.2.1.2 Essential Raw Cooling Water Discharge Monitors (O-RE-90-133,140) (O-RE-90-134, 141)

Two monitor channels that share a common sample delivery system are used to continuously monitor each of the two separately trained ERCW discharge headers. Channels O-RE-90-133, 140 monitor discharge header A. Channels O-RE-90-134, 141 monitor discharge header B. The entire sample flow may be routed through either detector channel or divided between each detector channel. These channels provide means for detecting tube leakage in the component cooling heat exchangers or the containment spray heat exchangers, which are served by ERCW.

Channel high radioactivity setpoints are determined in accordance with the ODCM methodology.

11.4.2.1.3 Component Cooling System (CCS) Monitor (O-RE-90-123,1 and 2-RE-90-123)

Each of three off-line channels continuously monitors a CCS line downstream of a CCS heat exchanger pair for activity levels indicative of a reactor coolant leak from either the Reactor Coolant or Residual Heat Removal Systems. On a high radioactivity alarm signal from any of the three channels, discharges from the vent line of the CCS surge tank are stopped by automatic closure of the isolation valve (FCV-70-66) in the vent line. This control action halts the introduction of radioactivity from the surge tank into the building air space. The high radioactivity setpoint is established such that counting rates above normal background will initiate the automatic control action.

11.4.2.1.4 Steam Generator Blowdown Liquid Discharge Monitors (RE-90-120, 121)

The steam generator blowdown liquid discharge monitor channels provide an additional indication to that of the condenser vacuum pump exhaust monitor of primary to secondary leakage by monitoring the steam generator secondary side liquid blowdown. Chemistry sampling is the primary means of identifying which steam generator is experiencing primary to secondary leakage.

The off-line monitor consists of two channels, identified as RE-90-120 and RE-90-121, which share a sampling subsystem. The entire sample flow may be routed through either detector channel or divided between each detector channel. The monitored blowdown discharge is the combined blowdown from the secondary side of all four steam generators. The blowdown is monitored downstream of the steam generator blowdown heat exchangers and downstream of the steam generator drain down flash tank. A sample cooler is provided to establish sample conditions that are within the instrumentation design limits.

Detection of high radioactivity by either monitor channel initiates isolation of the blowdown path to the cooling tower blowdown. Isolation is accomplished by closing valves FCV-15-8 and FCV-15-44. Monitor high radioactivity setpoints are determined in accordance with ODCM methodology.

11.4.2.1.5 Deleted

11.4.2.1.6 Deleted

11.4.2.1.7 Deleted

11.4.2.1.8 Deleted

11.4.2.1.9 Deleted

11.4.2.1.10 Deleted

11.4.2.1.11 Condensate Demineralizer Liquid Monitor (O-RE-90-225)

The condensate demineralizer liquid monitor channel continuously monitors the effluent from the neutralization tank, high crud tanks A and B or the non-reclaimable waste tank prior to discharge of these effluents to the cooling tower blowdown or turbine building sump.

At the channel high radioactivity setpoint, several automatic functions are initiated: (1) effluent lines to the cooling tower blowdown are isolated, (2) recirculation of the contents of the non-reclaimable waste tank is begun, (3) the flow path from the neutralization tank to the non-reclaimable waste tank is closed, and (4) recirculation of the contents of the neutralization tank is begun. The following specific control actions occur to accomplish these functions: (1) valve O-FCV-14-288 closes to isolate effluent from the high crud filter vessel, (2) valve O-FCV-14-360 closes to isolate effluent from the non-reclaimable waste tank, (3) valve O-FCV-14-345 opens to provide recirculation of the contents of the non-reclaimable waste tank, (4) valve O-FCV-14-187 closes to isolate the discharge line of the neutralization tank, and (5) valve O-FCV-14-188 opens to provide recirculation of the contents of the neutralization tank.

The channel high radioactivity setpoint is determined in accordance with the ODCM methodology.

11.4.2.1.12 Station (Turbine Building) Sump Discharge Monitor (O-RE-90-212)

The station sump discharge monitor is an on-line (in close proximity to discharge pipe) channel that monitors the discharge flow from the station sump, located in the Turbine Building, to the yard discharge culvert.

The monitor high radioactivity setpoint is determined in accordance with the ODCM methodology.

11.4.2.2 Process and Effluent Gas Monitors

Three types of effluent gas monitor channels exist in the radiation monitoring system: (1) off-line monitor channels, (2) on-line monitor channels, and (3) an in-line monitor channel.

Off-line channels employ a sampling system, which may be shared, to provide a continuous sample of gaseous effluent for one of five purposes: (1) real-time detection of noble gases or gross radioactivity, (2) collection of particulates on a filter for subsequent laboratory analysis, (3) collection of iodine on an adsorber for subsequent laboratory analysis, (4) collection of particulates for real-time detection of particulate radioactivity, and (5) collection of iodine for real-time detection of iodine radioactivity.

Channels that provide detection of gross radioactivity are called noble gas channels since contributions from other nuclides to the measured gross radioactivity are negligible.

On-line effluent gas monitor channels provide real time detection of effluent noble gas radioactivity by means of the detection of dose rates in the vicinity of the effluent pipe or duct.

An in-line gas monitor channel has its scintillation detector in line with the gas decay tank release piping.

The radiation monitoring system employs three types of process gas monitor channels: (1) in-line monitor channel, (2) off-line monitor channels, and (3) area-type monitors. Each off-line channel employs a sampling system to provide a continuous sample of process gas for real-time detection of noble gas radioactivity. Two area-type monitors that are employed in the system to monitor the fuel pool air space are arbitrarily categorized as process gas monitors since the dose rates that they would measure during a fuel handling accident would be predominantly from noble gas radioactivity.

11.4.2.2.1 Waste Gas Effluent Monitors (O-RE-90-118)

The in-line noble gas channel, O-RE-90-118, continuously monitors the gaseous release from the waste gas decay tanks to the Shield Building vent and initiates isolation of the gas decay tanks by closing valve O-FCV-77-119 on a high radioactivity or instrument malfunction signal.

Gas decay tanks are sampled and analyzed for radioactivity concentrations prior to release. The monitor high radioactivity setpoint for channel O-RE-90-118 is determined in accordance with the ODCM methodology.

11.4.2.2.2 Condenser Vacuum Pump Exhaust Monitors (RE-90-119, 99, 255, 256)

Two low range monitors, RE-90-99 and RE-90-119, and two accident monitors (mid & high range), RE-90-255 & 256, provide detection of noble gases over the entire range of concentrations that could exist during normal operations and during accident conditions. Monitor channel ranges overlap. RE-90-99 or -119 continuously samples the condenser vacuum pump exhaust to monitor noble gas concentrations for indications of primary to secondary leakage and for evaluations of radioactivity released to the environment. The RE-90-99 and -119 monitors cover the same range of concentrations and only one of the two should be sampling the exhaust at a time. The other monitor is a spare/backup monitor to be used during failures or maintenance periods. Both monitors should not be in service at the same time due to flow limitations on the condenser vacuum pump exhaust.

The accident range area type monitor channels RE-90-255, 256 monitor noble gas concentrations over the upper several decades of the design range. These monitor channels, which have overlapping ranges, monitor effluent radioactivity concentrations by detection of dose rates in the vicinity of the condenser vacuum pump exhaust duct.

Each low range channel utilizes a single beta scintillation detector. The mid and high range noble gas area monitor, utilize a G-M tube (255) and ion chamber (256).

Portable samplers can be utilized for laboratory analyses of particulate and iodine radioactivity as required.

Samples for RE-90-99 and RE-90-119 (low range) condenser vacuum pump exhaust monitor channels are obtained with cylindrical sampling manifolds that extend completely across the 12-inch diameter exhaust duct. The sample enters the manifold through four upstream facing openings that are uniformly spaced along the cylindrical surface of the manifold.

The setpoint for the low range monitor channels RE-90-99 and RE-90-119, is established in accordance with the ODCM methodology.

11.4.2.2.3 Fuel Pool Air Space Monitors (O-RE-90-102, 103)

The fuel pool air space channels continuously monitor the air space above the fuel pool. G-M tube detectors are mounted above the fuel pool. A high radioactivity signal initiates Auxiliary Building isolation and startup of the Auxiliary Building Gas Treatment System (ABGTS). These actions would prevent the release to the environment of unfiltered air containing radioactivity from a fuel-handling accident in the Auxiliary Building. The two fuel pool monitors are powered from separate power supplies. Dose rates from a spent fuel assembly in motion will not exceed 2.5 mrem/hr at the detector locations. The setpoint upper value as defined in the Technical Specification allows an ample factor for contributions to the total dose rate from other sources in the spent fuel pit area and takes into account instrument accuracy. These monitors are safety related.

11.4.2.2.4 Building Ventilation Monitors

Containment Building Upper and Lower Compartment Monitors

The containment building upper and lower compartment monitors are principally airborne radioactivity monitors and are therefore described in Section 12.2.4.

Shield Building Vent Monitors

The shield building vent effluents are monitored for particulates, iodine, and noble gases. A primary sample stream for shield building exhaust monitoring originates with a sampling probe assembly fitted into the vent stack with eighteen sample nozzles. The nozzles are provided for taking a representative sample of the stack effluent. See References 11.4.5.1 and 11.4.5.2.

The velocity of the air in the nozzles is automatically controlled over shield building vent flow rates from 7000 SCFM to 14000 SCFM. At flow rates other than this, the sample rate is constant. Automatic flow control is achieved by a stack effluent flow monitoring system. The flow monitoring system is comprised of flow elements and signal processing equipment. A flow element is located in the ABGTS, EGTS, and each of the containment purge exhaust ducts. The outputs of the flow elements are summed to provide total stack flow. Stack total flow and EGTS flow are indicated in the Main Control Room. Total stack flow and ABGTS flow are input to the plant computer system. The flow monitoring system also provides input to RM-90-400 for calculation of radioactive noble gas effluent discharge rate, which is indicated in the main control room and available for trending in the Integrated Computer System.

From the primary sample stream, two secondary streams are drawn: a high flow secondary stream for low range radiation sampling and detection, and a low flow secondary

stream for mid and high range radiation sampling and detection. Both secondary sample streams flow through a sample conditioning skid, RE-90-402. Depending on the radioactivity of the sample, secondary sample may flow through only the low, or through both the low and mid/high, or through only the mid/high range radiation secondary sample streams. The sample conditioning skid filters iodine and particulates from the streams and is the means for normal and accident particulate-iodine sampling. In addition, remotely timed particulate and iodine grab samples can be drawn from RE-90-402 for onsite laboratory analysis.

The filtered secondary streams flow to the radiation detector skid, RE-90-400. The detector skid provides continuous detection of noble gases. The low radiation range stream is monitored by a shielded offline beta detector assembly. The mid and high radiation range stream is monitored by a dual-range beta-gamma sensitive gas detector assembly consisting of two sample chambers, with solid-state CdTe(Cl) detectors encased in six inch thick lead background shielding. These detectors are connected directly to individual charge-sensitive preamplifiers. Sample concentrations are indicated and available to be trended in the main control room.

Accident range monitor channels, RE-90-260 and RE-90-261, provide additional capability for monitoring noble gas concentrations over the upper several decades of the design range. These off-line monitor channels, which have overlapping ranges, monitor effluent radioactivity concentrations by detection of exposure rates in the vicinity of the primary sample line. Channel RE-90-260 uses a G-M tube to monitor the lower end of the range; channel RE-90-261 uses an ion chamber to monitor the upper end of the range.

After being monitored, the primary and secondary sample flow streams are routed back to the ABGTS discharge duct for discharge through the shield building vent.

Effluent setpoints are established in accordance with the ODCM methodology.

Auxiliary Building Vent Monitor

The Auxiliary Building vent is monitored for noble gases by channel 0-RE-90-101B. Particulate radioactivity and radioiodine is collected with a removable filter and analyzed remotely.

Noble gas detection by channel 0-RE-90-101B is accomplished with a beta scintillation detector.

The sample for monitoring is originated with a sampling probe assembly fitted with seventy-two sample nozzles. The nozzles are provided for taking a representative sample of the duct effluent. Since the sample taken from the duct is too large to be routed directly to the particulate and iodine filters, a subsample is taken from the main sample line for monitoring. See References 11.4.5.1 and 11.4.5.2.

The noble gas channel automatically initiates auxiliary building vent isolation and startup of the Auxiliary Building gas treatment system (ABGTS) at the high radioactivity setpoint. The noble gas channel setpoint is determined in accordance with the ODCM. The automatic initiation of control actions by this monitor channel is not a primary safety function; rather, it is provided for ALARA off-site dose purposes.

A Class 1E isolation device between the nonsafety-related circuit and the safety-related Auxiliary Building isolation circuit is provided.

Service Building Vent Monitor

The Service Building vent monitor has channel 0-RE-90-132B to monitor noble gas.

The sample for monitoring is originated with a sampling probe assembly fitted with eight sample nozzles. The nozzles are geometrically arranged to allow taking a representative sample of the duct effluent.

The assembly for 0-RE-90-132B is identical to that for the Auxiliary Building vent channel 0-RE-90-101B.

Channel setpoints are established in accordance with ODCM methodology.

11.4.2.2.5 MCR Normal Intake and Emergency Intake Monitors

Two pairs of monitors are provided to monitor the intake for the MCR. These monitors are an integral part of the design provision for complying with GDC 19. When the MCR ventilation system is operating in the normal mode, the intake air is monitored by the redundant monitors, 0-RE-90-125 and 0-RE-90-126. In the event of high radioactivity level in the intake air, these monitors initiate the emergency mode of operation of the ventilation system. It is possible in the emergency mode to manually switch to a different air intake which is in a location removed from the normal air intake. This is identified as the emergency air intake path and is monitored by the redundant monitors, 0-RE-90-205 and 0-RE-90-206.

Each MCR intake monitor assembly includes a sample pump and a beta scintillation detector. 0-RE-90-125 and 0-RE-90-205 are supplied with train A power while the other two monitors are supplied with train B power.

11.4.2.2.6 Containment Building Purge Exhaust Monitors

The redundant containment building purge air exhaust monitors are identified as RE-90-130 and RE-90-131. Each monitor is supplied with trained power, with RE-90-130 on train A and RE-90-131 on train B. Each monitor assembly includes a sample pump and beta scintillation detector.

The sample for each monitor is taken from one of the containment purge exhaust ducts upstream of the HEPA filter-charcoal absorber filter train.

A high radioactivity signal in either channel initiates containment ventilation isolation. This control action is a safety function. The action prevents the release to the atmosphere of unacceptable quantities of radioactivity should the following set of conditions occur: (1) operation with reactor coolant activity within technical specification limits but unusually high, (2) occurrence of a small LOCA during containment purging, (3) delay caused by pressure relief through the purge exhaust in containment pressure's reaching the setpoint for a containment isolation signal. A containment vent isolation is also identified for a fuel handling accident as discussed in Section 15.5.6.

11.4.2.2.7 Main Steam Line Monitors

The main steam line radiation monitors (RE-90-421, 422, 423, and 424) consist of one monitor per steam line. The detectors are located inside the main steam valve vaults upstream of the branch lines to the relief valve headers. Each main steam line monitor consists of one ion chamber detector, a signal processor, and remote control/display unit and associated hardware. The radiation monitors have area type detectors which are located in the immediate area of the main steam piping. These detectors do not penetrate the main steam pressure boundary. All four monitors provide output to a control room recorder.

The monitors serve as Post Accident Monitors (indication and recording) of steam line specific radioactivity. These measurements can be utilized to determine release rates to the atmosphere. Additionally, the monitors are useful in the identification of the steam generator where a very high primary to secondary coolant leak is occurring.

11.4.3 Sampling

The release points are subject to periodic sampling and are all liquid and gaseous releases which could exceed Appendix I, 10 CFR 50 and 10 CFR 20 limits. The sampling and analysis requirements for these release points are defined in the SQN ODCM controls. The plant discharge meets Regulatory Guide 1.21 Revision 1, 10 CFR 20, and 10 CFR 50 guidelines.

11.4.4 Calibration and Maintenance

Channel checks, channel calibrations, channel operational tests, and channel functional tests are procedurally performed as required by Technical Specifications, ODCM, and plant procedures as appropriate.

Maintenance will be performed if abnormalities are detected during any of the above checks. Unscheduled maintenance will be performed as required.

NOTES FOR TABLE 11.4.2-3

(1) Monitor assembly or channel identifications beginning with the numerals 1, 2, and 0 are for unit 1, unit 2, and common to units 1 and 2, respectively

(2) - denotes that display is not provided.

(3) X denotes that display is provided.

(4) N/A denotes "not applicable."

(5) If vital power is not indicated in this column, power supply is nondivisional (ND).

(6) Panel M-12 is a common panel for unit 1 and 2 components (i.e., 0-M-12).

(7) Unit 1 and Unit 2 channel are entered in their respective Integrated Computer System (ICS) computers.

(8) Entered in both Unit 1 and Unit 2 ICS computers.

11.5 SOLID WASTE MANAGEMENT SYSTEM

11.5.1 Design Objectives

The slurries and solid radwaste[1] produced by Sequoyah Nuclear Plant units 1 and 2 are prepared for shipment or for temporary onsite storage in compliance with the requirements in 10 CFR 61, 10 CFR 71, and 49 CFR 170 through 178. Solid wastes will be processed by the Solid Waste System (SWS).

[(1)]Include resin waste and evaporator concentrates

11.5.2 System Inputs

Waste inputs are divided into two categories: (1) Dry Active Waste (DAW) and (2) Wet Active Waste (WAW). DAW and WAW inputs are products of the plant operation and maintenance. Dry Active Wastes are further subdivided into compactible and noncompactible wastes. Solid compactible wastes include paper, clothing, rags, mop heads, rubber boots, and plastic. Noncompactible wastes include tools, mop handles, lumber, glassware, pumps, motors, valves, and piping.

The wet active wastes are primarily composed of spent resins. The sources for spent resins are spent resin storage tank and the radwaste demineralizer.

A list of inputs and maximum expected yearly volumes of solid wastes are provided in Table 11.5.2-1.

11.5.3 Systems Description

11.5.3.1 Wet Active Waste Processing

Bulk Resin Processing

When sufficient spent resin is accumulated in the spent resin storage tank, the appropriate valves necessary to transfer spent resin to the liner filling area in the railroad access bay are opened except for the liner fill valves. The spent resin tank is then pressurized with N_2. The liner filling valves are then opened and the resin is forced into the liner. Primary water used in the transfer is removed from the liner by a dewatering pump to the liquid waste system. The level in the liner is monitored so that the resin flow can be stopped when the desired level is reached. During transfer, N_2 is forced through the spargers in the tank to slurry and level the resin and maintain tank pressure. When the liner is full the liner filling valves are closed and tank pressure is relieved to the plant waste gas system. The filling valves and the transfer line are then flushed by pumping primary makeup water through the transfer route to both the liner and the tank. Loading is accomplished with the casks mounted on a truck or trailer bed. The truck or trailer is located in the Auxiliary Building railroad bay. The cask with disposable liner is filled from the spent resin tank. The spent resins are dewatered to meet the free-standing water limitations at licensed disposal facilities. Flush connections are provided from the PMW System to flush the resin slurry lines. In the event that the container were to overflow during the filling process, the

initial overflow would be contained in the volume between the cask and liner. In certain cases spent resins will be stabilized (possibly packaged in a high integrity container (HIC) or solidified). Solidification is carried out with an offsite vendor supplied mobile solidification system. A process control program is utilized to conduct the solidification.

The shipping container consists of an inner disposable liner with an outer reusable shield cask. Filter elements are mounted inside the liner and are connected to a hose connection outside the shield to facilitate dewatering operations. The container also has fill and vent connections.

Several types of shipping casks may be used. All casks have been licensed pursuant to the general license provisions of paragraph 71.12(b) of 10 CFR Part 71.

Radwaste Demineralizer Resin Processing

Spent resins from the Radwaste Demineralizer System are sluiced to a transportable liner or HIC inside a shipping container within the Auxiliary Building railroad bay area and dewatered to meet the disposal facilities' free-standing water limitations. The dewatered resins and disposable liners are prepared for shipment or temporary onsite storage.

Condensate Polishing Regeneration Resin Processing

Spent resins from the Condensate Polishing System are transferred directly to a disposal liner (radwaste) or suitable container (non-radwaste) from the resin storage tank. The disposal liner or container is located adjacent to the Condensate Polishing System building. After transfer of the resins is complete, the liner or container is dewatered and prepared for shipment or temporary on-site storage.

11.5.3.2 Dry Active Waste Processing

The waste packaging area is provided for receiving, sorting, and compacting DAW. Bagged and/or boxed DAW collected throughout the plant is brought to the waste packaging area for final packaging into 55-gallon drums or metal boxes. Collected waste may also be sent to a contracted broker/processor for processing, packaging, and/or subsequent disposal.

Compactible DAW Processing

Compactible trash like paper, clothing, rags, plastic, etc., are collected and compacted or maybe transported to a contracted broker/processor for processing, packaging, and/or subsequent disposal. See section 11.5.4.1 for detailed onsite compactor operation.

Noncompactible DAW Processing

Items such as tools, mop handles, valves, motors, piping, lumber and some compactibles are packaged, sealed, and stored until shipped for offsite disposal. Collected waste may also be sent to a contracted broker/processor for processing, packaging, and/or subsequent disposal.

11.5.3.3 Miscellaneous Waste Handling

Air and gas filter and prefilter elements and glassware are packaged, sealed, and stored until shipped for offsite disposal or may be transported to a contracted broker/processor for

processing, packaging, and/or subsequent disposal. Active waste filters are packaged when necessary in high integrity containers.

If the radiation levels of containers are high enough to require shielding, the containers are transported in shielded truck trailers or casks similar to those used to transport liners containing bulk quantities of dewatered resins.

11.5.4 Equipment Operation

11.5.4.1 Compactor Operation

The onsite compactor is used to compress low-level radioactive wastes into drums. Solid wastes are inserted in the open drum, the drum placed in the compactor, and the shroud door closed. The drum is automatically positioned to be coaxial with the compactor ram. An operator initiates the compaction process by pressing the cycle button. The ram will lower, hold upon reaching the rated hydraulic supply pressure, and return to the raised position. The shroud door is opened, the drum is removed and additional wastes are added to the drum. The cycle is repeated until the drum is full, at which time the lid is installed, the clamping ring tightened, and the drum stored pending shipment.

The shroud is ducted to a HEPA filter system in order to remove dust or particulates that may be emitted from the drum during compression of the wastes.

11.5.4.2 Mobile Solidification System (MSS)

The MSS is a portable solidification unit provided under a vendor service contract. The MSS combines and mixes radioactive wastes (concentrates and liquid wastes) with solidification agents and needed additives to solidify the waste. The solidification is done in accordance with a Process Control Program to ensure that each batch of waste is properly solidified. Only solidification agents (such as cement) which have been approved by licensed disposal facilities are used. The waste is solidified in a disposable liner and prepared for shipment or temporary onsite storage. The disposable liners are equipped with internal mixers to provide uniform mixing. The mobile solidification system is located in the Auxiliary Building railroad bay area when the MSS is utilized. Necessary service connections have been provided in the railroad bay to support the mobile solidification system.

11.5.5 Packaging and Storage

Two processes are employed within the facility. One, for use with solid compressible material, is a baling process. The other, for use with chemical drain tank effluents and spent resin, is a bulk packaging system.

Waste will be collected, sorted and packaged for disposal or prepared for shipment to an offsite broker/processor. The onsite sorting process will separate compactible waste from noncompactible waste and segregate wet articles for drying. The waste will be packaged in its appropriate container, and each container will be marked, decontaminated (if necessary), weighed, monitored for radiation dose rate by Radiological Control, and logged for tracking.

Noncompactible trash is packaged in metal boxes which are sealed when full and stored temporarily in the radwaste packaging area. Solid compressible waste of low radiation levels are compressed in standard 55-gallon drums. After compaction, the drum is closed and stored temporarily in the radwaste packaging area. The drums and boxes are loaded into a commercial vehicle for transfer to the disposal site.

For packaging of effluent from the chemical drain tank, a commercial portable solidification contractor at the plant site receives and solidifies these wastes in liners prior to offsite shipment to the disposal site.

Two methods are used to dispose of spent resin. The method used depends on the properties of the waste at any given time. One process involves transfer of the resin to a liner or high integrity container, dewatering, and finally shipment to the commercial disposal site. The second process involves transfer of the resin to a commercial portable solidification unit for solidification and transfer to a commercial disposal site. Radioactive plant filters are usually packaged in high integrity containers or 55-gallon drums. The filter elements are either remotely or manually removed from the filter housing. Inplant transportation shielding is provided as required. Radioactive filter elements are drummed and stored in a shielded transportation cask or drum shield prior to shipment for disposal. The low activity level filter elements may be handled as intermediate activity level elements, or they may be stored prior to shipment for disposal. Further contingency storage is provided in the Auxiliary Building filter decay pit to be used as necessary.

11.5.6 Storage Facilities

11.5.6.1 Inplant Radwaste Storage Area

Waste containers will be stored in a designated storage area until shipment. Designated inplant storage areas include the waste packaging area and the Auxiliary Building railroad bay. Radioactive material and associated shielding may be stored temporarily in the spent fuel pool and cask loading area.

11.5.6.2 Outside Radwaste Storage

Operational considerations makes it necessary to temporarily store containers of low-level radioactive waste in designated areas (such as the northside storage yard beside the DAW building), in trailers, the rear of the Condensate Demineralizer Building, outside the Auxiliary Building railroad bay, behind Power Stores, the DAW building, and the onsite storage facility yard. Liners of resin not dewatered yet will either be stored in shipping casks or in an area which incorporates a temporary retaining system of sufficient volume to contain any accidental spillage of radioactive waste. Liners of dewatered resin will be stored the same as other containers such as drums and boxes. Use of these areas for storage will be continued as necessary to meet short term storage needs. Drums and boxes of radwaste or radioactive material or liners containing solidified or dewatered material may be stored in outside storage areas after being closed in accordance with approved procedures. The storage areas are administratively controlled to minimize employee exposure.

11.5.6.3 <u>Onsite Storage Facility (OSF)</u>

In order to provide storage for low-level radioactive waste (LLRW) which cannot be shipped, an onsite storage facility has been constructed. This facility is located on a 16-acre site within the Sequoyah Nuclear Plant reservation, but outside the existing security fence approximately 2,000 feet east of the Reactor Building on a peninsula between Chickamauga Reservoir and the cooling tower return channel (see Figure 2.1.2-1). The grade elevation is approximately 730 feet, which is above the probable maximum flood elevation. The nearest existing structures to the storage facility are the cooling towers (closest point is 450 feet south) and the Sequoyah Nuclear Plant boat dock (closest point is 250 feet north).

The facility is comprised of individual buildings called modules. Each module is designed to contain packaged radwaste generated at Sequoyah and Watts Bar Unit 1 and is segmented into four compartments. All of the modules are above-ground, safety-related structures constructed of reinforced concrete. Access to each module is provided only from above, and is only used for placing LLRW in or removing LLRW from the module by a crane. The modules are designed to resist loads resulting from extreme environmental events, such as high winds, tornadoes, and seismic events. The structural characteristics of the OSF meet or exceed the criteria applicable to the Sequoyah site.

A storage module's foundation is composed of concrete base slab and walls placed on either in situ soil or compacted fill. To provide shielding, the outer walls of a resin storage module are 42 inches thick, while the outer walls of a trash storage module are 24 inches thick. The removable concrete caps for both module types are 24 inches thick. The resin module design includes support for more shielding, if needed. All of the modules are capable of storing "as-produced" (i.e., not "volume-reduced," but packaged in a form suitable for disposal) or "volume-reduced" LLRW in a retrievable form. Each module compartment is provided with internal liquid drainage and collection capability routed to an external point for sampling and collection. The external collection point is surrounded by a covered concrete sump connected to the module.

The sump in each module will be used as a passive sump by design to collect any liquid (e.g., fire suppression water) and sampled periodically to detect the presence of water and/or radioactive releases in the module. The interior surfaces of each module (excluding the concrete cap) are sealed with a decontaminable coating.

The OSF structures are designed to contain (within each module) all fire suppression water from a design basis fire in a way that will not preclude processing of the water (if determined to be radioactive) using the existing SQNP liquid radioactive waste treatment system.

The entire OSF is enclosed within an access controlled security fence.

11.5.7 <u>Shipment</u>

Waste is shipped to a commercial disposal site according to Federal regulations and disposal site criteria. Waste may also be shipped to a broker/processor for processing and/or disposal to meet Federal regulations and disposal site criteria.

Drums and boxes containing radwaste are transported from the Sequoyah Nuclear Plant to the disposal facility in a sole-use flatbed or van-type truck trailers. Dewatered resins, solidified resins, and chemical sludges are packaged in liners or high integrity containers and transported either by sole-use van type trailer or in a transportation cask (dependent upon dose rates).

All radioactive waste is packaged and transported in accordance with the TVA Radioactive Material Shipment Manual.

TABLE 11.5.2-1

Maximum Anticipated Total Solid
Waste Generated Per Year

Waste Type	Volume (ft^3)
Spent Resins	1,200*
Spent Filter Cartridges	350
Sludge, and Crud	8,400
DAW Trash Compactible	26,000**
Noncompactible Trash	7,500
Contaminated Waste Oil	100
TOTAL	43,550

*Significant primary-to-secondary leaks could cause an increase in the amount of spent condensate cleanup resin.

**This is the as-generated volume before compaction.

11.6 OFFSITE RADIOLOGICAL MONITORING PROGRAM

The preoperational environmental monitoring program has established a baseline of data on the distribution of natural and manmade radioactivity in the environment near the plant site. The preoperational environmental monitoring program was initiated in the spring of 1971. The operational monitoring program initiated in the spring of 1980 reflects the current monitoring philosophy and regulatory guidelines.

Evaluations after plant startup are made on the basis of the baselines established in the preoperational program, considering geography and the time of the year when these factors are applicable, and by comparisons to control stations where the concentrations of station effluents are expected to be negligible. In those cases where a statistically significant increase in the radioactivity level is seen in a particular sampling vector but not in the control station, meteorology and specific nuclide analysis will be used to identify the source of the increase.

The capability of the environmental monitoring program to detect design level releases from plant effluents is uncertain because the concentrations in the environment are very small. The program provides the capability of detecting any significant buildup of radioactive material in the environment above and beyond that which is already present. Those sectors which are most sensitive to reconcentration of specific isotopes are sampled. If any increase in radioactivity levels is detected in these sectors, the program will be evaluated and broadened if deemed necessary.

From the data obtained from the radioanalytical and radiochemical analyses of the sectors sampled, dose estimates can be made for an individual or the population living near the plant site.

11.6.1 Expected Background

For a number of years measurements of background radiation have been made at various locations throughout the Tennessee Valley Region. TVA has conducted environmental monitoring programs in the vicinity of Oak Ridge, Tennessee, Browns Ferry Nuclear Plant near Athens, Alabama, Watts Bar Nuclear Plant near Spring City, Tennessee, and near Sequoyah Nuclear Plant. Over periods of not less than two years, the measurements made in these areas have indicated only very slight variations from location to location. The measurements obtained utilizing film badges or thermoluminescent dosimeters have revealed the following background radiation dose rate: Oak Ridge - 110 mrem/year, Browns Ferry, Sequoyah, and Watts Bar Nuclear Plants - 55 mrem/year.

Measurements have been made in the immediate vicinity of the Sequoyah Nuclear Plant site and provide the baseline data necessary for comparison of background radiation levels prior to and after startup of the plant.

11.6.2 Critical Pathways to Man

Although the amounts of radioactivity added to the environment from plant operation are small, critical exposure pathways to man have been identified to estimate the maximum dose to the

individual and to establish the sampling requirements for the environmental radioactivity monitoring program. The six principal pathways that can result in radiation exposure to man are:

1. External doses to gaseous releases.
2. Drinking water from the Tennessee River and wells in the immediate vicinity of the plant.
3. Swimming, boating, and fishing in the Tennessee River.
4. Eating fish from the Tennessee River.
5. Consuming milk produced near the plant.
6. Internal doses from inhalation and from eating foods grown in areas adjacent to the plant site affected by the gaseous releases.

The environmental monitoring program, as outlined, provides sampling of critical sectors necessary to evaluate the dose received through the critical pathways in items 1 to 6 above. The following items indicate how samples can be used in performing critical pathway-dose correlation:

1. Data from readings of the thermoluminescent dosimeters can be utilized to estimate the total body dose received from the gaseous effluents.
2. Analysis of water samples collected can be used to estimate the dose that might be received from drinking water from the Tennessee River or from wells in the vicinity of the plant.
3. Analysis of water samples can also be used to estimate the dose an individual might receive while swimming, boating, or fishing on the lake in the vicinity of the plant.
4. Analysis of samples of river water, bottom sediment, and fish can be correlated to estimate the dose that might be received by an individual who eats fish from the Tennessee River.
5. Analysis of samples of air particulate matter, vegetation, food crops, and milk can be used to estimate the dose to the surrounding population through inhalation and the consumption of food or dairy products.

The environmental monitoring program to be conducted throughout operation of the plant provides the necessary means of evaluating the dose to man through critical exposure pathways. All samples referenced will be analyzed for the most biologically-significant gamma-emitting radionuclides found in the gaseous and liquid waste stream of the plant.

Environmental concentrations of radioactivity due to releases to unrestricted areas from the Sequoyah Nuclear Plant may be unmeasurable with present techniques. Therefore, methods to calculate the potential exposure to man have been derived for both gaseous and liquid releases. Calculations of potential exposures from measured environmental levels will only be made if significant concentrations are measured in environmental media.

11.6.2.1 Doses from Gaseous Effluents

The following doses to humans living in the vicinity of the Sequoyah Nuclear Plant will be calculated for the releases of radioactive gases:

1. External beta doses to the skin from air submersion.

2. External gamma doses to the total body from air submersion.

3. Inhalation doses to the maximum exposed organ.

4. Ingestion doses to the maximum exposed organ.

The basic assumptions and calculational methods used in computing these doses are described in Subsection 11.3.9.

The data resulting from the offsite monitoring program will be reviewed and the adequacy of the dose models will be evaluated, as appropriate, to ensure that the actual doses received by individuals and the population as a whole remain as low as practicable and within the applicable Federal Regulations.

11.6.2.2 Internal Doses from Liquid Effluents

The following doses will be calculated for exposures to radionuclides routinely released in liquid effluents:

1. Internal doses from the ingestion of water.

2. Internal doses from the consumption of fish.

3. External doses from water sports.

A detailed description of the basic assumptions and calculational methods used in calculating the doses is given in Subsection 11.2.9.

The dose models employed will be reevaluated, as appropriate, to ensure that all significant pathways are included in the calculations and to ensure that the actual doses received by individuals and the population as a whole remain as low as reasonable achievable and within the applicable Federal regulations.

11.6.3 Sampling Media, Locations, and Frequency

The operational environmental radiological monitoring program is presented in the ODCM. The media selected were chosen on two bases: First, those vectors which would readily indicate releases from the plant, and secondly, those vectors which would indicate long-term buildup of radioactivity. Consideration was also given to the pathways which would result in exposure to man, such as milk and food crops. Locations for sampling stations were chosen after considering meteorological factors and population density around the site. Frequencies for

sampling the various vectors were established so that seasonal variation in radioactivity levels might be determined. In addition, samples are collected during the season in which the major growth occurs to ascertain radioactivity uptake by the vectors during their most susceptible period of growth.

11.6.4 Analytical Sensitivity

Samples are collected routinely following established procedures so that uniformity in sampling methods is assured. The samples are transported to a central laboratory facility for preparation and processing. All the radioanalytical and radiochemical analyses are conducted in the central laboratory. In performing the analyses, pulse height analyzers with state of the art equipment such as Ge detectors, low background beta counters, and liquid scintillation systems are utilized.

The detection capabilities for environmental sample analyses given as the nominal lower limits of detection (LLD) are listed in Table 11.6.4-1. The LLDs listed are the maximum values for the LLDs as presented in the ODCM. Actual values will vary with sample size and radionuclide content, counting time, and background.

The LLD is the smallest concentration of radioactive material in a sample that will be detected with 95 percent probability with 5 percent probability of falsely concluding that a blank observation represents a "real" signal.

For a particular measurement system (which may include radiochemical separation):

$$LLD = \frac{4.66\ s_b}{E \cdot V \cdot 2.22 \cdot Y \quad \exp(-\lambda \ \Delta t)}$$

Where

LLD is the "a priori" lower limit of detection as defined above (as picocurie per unit mass or volume),

s_b is the standard deviation of the background counting rate or of the counting rate of a blank sample as appropriate (as counts per minute),

E is the counting efficiency (as counts per transformation),

V is the sample size (in units of mass or volume),

2.22 is the number of transformations per minute per picocurie,

Y is the fractional radiochemical yield (when applicable),

λ is the radioactive decay constant for the particular radionuclide, and

Δt is the elapsed time between sample collection (or end of the sample collection period) and time of counting (for environmental samples, not plant effluent samples).

The value of s_b used in the calculation of the LLD for a detection system shall be based on the actual observed variance of the background counting rate or of the counting rate of the blank samples (as appropriate) rather than on an unverified theoretically predicted variance. In calculating the LLD for a radionuclide determined by gamma-ray spectrometry, the background shall include the typical contributions of other radionuclides normally present in the samples (e.g., potassium-40 in milk samples). Typical values of E, V, Y, and Δt shall be used in the calculations.

11.6.5 Data Analysis and Presentation

TVA participates in an Interlaboratory Comparison Program. This program provides periodic cross-check samples of the type and radionuclide composition normally analyzed in an environmental monitoring program. The results obtained in the monitoring program and the cross-check program are reported annually to the Nuclear Regulatory Commission.

11.6.6 Program Statistical Sensitivity

As previously noted, because of the small quantities of radioactive material which will be released to the environment from the Sequoyah Nuclear Plant, it is uncertain as to what extent the results from the environmental monitoring program can be used to estimate the probable radiation dose to man. Only if the radioactive waste releases from the plant cause statistically-measurable increases of radiation in the environment can dose correlations be made.

Calculations will be performed utilizing the more concentrated effluent release data and the models given in Subsections 11.2.8 and 11.3.8 to estimate the possible dose to man. Because of the conservative assumptions applied in these models, the estimated dose to the population should be higher than that actually received. However, TVA, even using the conservative assumptions, will control the releases of radioactive materials to the environment such that the releases will be less than the limits described in 10 CFR 20 and 10 CFR 50.

[1]If no drinking water pathway exists, a value of 3000 pCi/l may be used.
[2]If a potential exists for the measurable presence of I-131 in drinking water, a value of 1.0 pCi/l shall be used.

APPENDIX 11A

TRITIUM CONTROL

TABLE OF CONTENTS

LIST OF TABLES

APPENDIX 11A

TRITIUM CONTROL

This section discusses the reduced tritium production in the plant as a result of employing zirconium alloy clad fuel and silver-indium-cadmium control rods.

11A.1 SYSTEM SOURCES

There are two principal contributors to tritium production within the PWR System: the ternary fission source and the dissolved boron in the reactor coolant. Additional small contributions are made by Li^6, Li^7, and deuterium in the reactor water. Tritium production from different sources is shown in Table 11A-1.

11A.1.1 The Fission Source

This tritium is formed within the fuel material and may:

1. Remain in the fuel rod uranium matrix,

2. Diffuse into the cladding and become hydrided and fixed there,

3. Diffuse through the clad for release into the primary coolant,

4. Release to the coolant through macroscopic cracks or failures in the fuel cladding.

Previous Westinghouse design has conservatively assumed that the ratio of fission tritium released into the coolant to the total fission tritium formed was approximately 0.30 for zircaloy clad fuel. The operating experience at the R. E. Ginna Plant of the Rochester Gas and Electric Company and at other operating reactors using zircaloy fuel cladding shows that the fraction of tritium released to the coolant is substantially less than the earlier estimates predicted. Consequently, the release fraction may be revised downward from thirty percent to ten percent based on this data (Reference 1).

11A.1.2 Control Rod Source

The full length rods for this plant are silver-indium-cadmium. There are no reactions in these absorber materials which would produce tritium, thus eliminating any contribution from this source.

11A.1.3 Boric Acid Source

A direct contribution to the reactor coolant tritium concentration is made by neutron reaction with the boron in solution. The concentration of boric acid varies with core life and load follow so that this is a steadily decreasing source during core life. The principal boron reaction is the B^{10} $(n,2\alpha)$ H^3 reaction. The Li^7 $(n,n'^{\propto})$ H^3 reaction occurs with lithium added for pH control. This reaction is controlled by limiting the overall lithium concentration to approximately two ppm during operation. Li^6 is essentially excluded from the system by utilizing 99.9 percent Li^7.

11A.1.4 Burnable Shim Rod Source

These rods are in the core only during the first operating cycle and their potential tritium contribution is only during this period.

11A.2 TRITIUM RELEASES

For a leakage from the Primary Coolant System into the containment of fifty pounds per day, with an assumed tritium concentration in the coolant of 2.5 μCi/cc (no containment ventilation purge), the tritium concentration in the atmosphere of the containment would be low enough to permit access without protective equipment by plant maintenance personnel for an average of two hours per week.

Leakage into the containment atmosphere is based on leakage from equipment such as pumps and valves. Abnormal leakage in excess of the design estimate have occurred in operating plants. The leaking components have been identified and corrective measures have been taken. For example, at Sequoyah, bellows and diaphragm valves are being used to limit leakage.

The total activity which would be released from the containment purge during refueling operations would amount to approximately 110 curies. This activity from evaporative losses will be discharged from the plant as gaseous waste. Similarly, any radioactive gases in the containment would be discharged. Evaporation of tritium from the refueling pool has been considered in evaluating the consequences of tritium on both operators and environmental releases. This indicates maximum tritium concentration in the containment consistent with forty hours per week occupancy and total tritium release of about thirty curies per refueling. Since there is no forced mixing between refueling water and the spent fuel pool, and tritium-free water will be used for makeup, evaporative tritium losses from the spent fuel pool should be minimal.

The tritium source terms in the reactor have been reduced to a sufficiently low level that retention within the plant becomes possible for a significant portion of the reactor lifetime. With an expected production rate of approximately 690 curies per cycle, the tritium concentration would not be expected to reach 2.5 μCi/cc until approximately eight years of plant life. The liquid tritium concentration in the Reactor Coolant System will be controlled by discharging to the cooling tower blowdown via the liquid radwaste system.

11A.3 DESIGN BASES

The design intent is to reduce the tritium sources in the Reactor Coolant System to a practical minimum in order to permit longer retention of the reactor coolant within the plant. Reduction of source terms is provided by utilizing silver-indium-cadmium control rods and the determination that the quantity of tritium released from the fuel rods with zirconium alloy cladding is less than originally expected. (Note: The tritium permeability of M5 cladding is the same as the Zircaloy-4 cladding. Therefore, the tritium release from the M5 clad fuel rods is bounded by the assumed tritium release of the zircaloy clad rods.)

11A.4 DESIGN EVALUATION

Table 11A-1 is a comparison of a typical design basis tritium production which is utilized to establish system and operational requirements of the plant (Reference 1). It will be noted that there are two principal contributors to the tritium production: ternary fission source and the dissolved boron in the reactor coolant. Of these sources it will be noted that the thirty-percent release of ternary fission through the cladding was the predominant contributor in past design considerations.

Because of the importance of this source on the operation of the plant, Westinghouse has been closely following operating plant data. Table 11A-2 represents tritium releases during one calendar year for different Westinghouse PWR plants. Further, a program is being conducted at the R. E. Ginna Plant to follow this in detail. The R. E. Ginna Plant has a zircaloy clad core with silver-indium-cadmium control rods. The operating levels of boron concentration during the startup of the Ginna plant were (following initial fuel loading) approximately 1100 to 1200 ppm of boron. In addition, burnable poison rods in the core contain boron which contributed some tritium to the coolant, but only during the first cycle. Data during the operation of the Ginna plant has indicated very clearly that the present design sources were indeed conservative. The tritium released is essentially from the boron dissolved in the coolant and a ternary fission source which is less than one percent. In addition to this data, other operating plants with zircaloy clad cores have also reported very low tritium concentrations in the Reactor Coolant system after considerably longer operation. The use of M5 clad material (Zr-Nb) (Reference 2) will not change the conclusions of this evaluation.

Based on the above, the following conclusions have been reached:

1. The tritium levels in plants operating with zirconium alloy clad cores will be substantially lower than previous design predictions.

2. The tritium source in the plants will be reduced by utilizing silver-indium-cadmium control rods.

3. The tritium in the containment purge and the containment ventilation air during refueling will be discharged.

TABLE OF CONTENTS

LIST OF TABLES

12.0 RADIATION PROTECTION

12.1 SHIELDING

12.1.1 Design Objectives

The design objectives of the plant shielding are the following:

1. During normal operation, including anticipated operational occurrences, to restrict doses to onsite personnel including TVA employees, contractor employees, and visitors such that doses do not exceed applicable limits of 10 CFR 20.

   In addition to the requirements of 10 CFR 20, the following total effective dose equivalent limits shall be observed.

   The annual 5 rem limit would be exceeded only if it is demonstrated that all ALARA considerations have been closely evaluated and the additional exposure of the individual would result in a reduction of collective occupational dose. Exceeding the 5 rem limit requires the initiation of a Planned Special Exposure and subsequent reporting to the NRC.

2. The philosophy of maintaining radiation doses as low as reasonably achievable (ALARA) is integrated into all shielding and design considerations.

3. To restrict offsite doses in accordance with the ALARA provisions in 10 CFR 50.

4. To limit, under accident conditions, the offsite dose from activity in the containment so that the total dose from this source and from airborne radiation will not exceed the 10 CFR 100 dose limits.

5. To satisfy the requirements of 10 CFR 50, Appendix A, Criterion 19. Sufficient radiation protection is provided to permit access and occupancy of the control room under accident conditions without personnel receiving excessive radiation dose. The sum of the doses an operator receives during any such extra-control room visits and those received while gaining access to and occupying the control room will not exceed doses of 5 rem total effective dose equivalent.

12.1.2 Design Description

Plant Shielding

In numerous cases where access requirements are expected to range from almost continuous occupancy to a few hours per week, shielding is required to achieve acceptable dose rate levels. The shielding design level supports the access control area requirements of Table 12.1.2-1. ALARA considerations may warrant further reduction of base level dose rates and thus increased shielding.

Layouts of the containments and surrounding Shield Buildings and of the Auxiliary, Control, and Turbine Buildings are provided in Figures 1.2.3-1 through 1.2.3-13. While generally to scale,

these equipment drawings cannot be scaled to determine accurately the thickness of concrete shield walls. The Turbine Building and Service Building contain only relatively minor radiation sources.

Shield Walls

Presented in this section are the criteria for the erection of the plant shield walls and for penetrations through these walls. The calculational methods used to determine the thickness and other dimensions of the shield walls are given at the end of this subsection.

Many structural walls also serve a shielding requirement which often sets the wall thickness. Some walls serve only a shielding function. Most of these shielding walls are cast in place up to within two inches of the ceiling above. When necessary, this gap between wall and ceiling is filled over part of the wall thickness with grout. Those shield walls or portions of shield walls that are subject to removal for equipment repair or replacement are constructed of solid concrete blocks.

Except for two applications, which are cited in later subsections, the poured concrete shield walls throughout the plant are ordinary concrete with a minimum density of 145.0 lb/ft^3.

In general shield walls are always erected around any plant component or piping if design level activity at any time in plant life can result in dose rates greater than 50 mrem/hr unless they are remote from general access areas. Areas where design deep dose equivalent rates are between 5 and 50 mrem/hr are normally shielded unless they are remote from general access areas or unless the dose rates will exist for very short times. In many cases, particularly when the design dose rates are toward the upper end of this range, shield walls are erected around these areas even though one of the conditions exists that could justify simply designating the unshielded areas as radiation areas and following the area identification and entry requirements given in Table 12.1.2-1.

Access to many equipment enclosures is provided through the sidewalls of the compartments. In these cases, the effectiveness of the shield walls in limiting dose rates outside the equipment enclosures is maintained by providing labyrinth entrances. Access to some equipment enclosures, principally filter, demineralizer, and waste gas decay tank cubicles, is through the floor above. In these cases, the removable concrete floor slab that provides the entrance generally has the same thickness as the cubicle walls.

The design criterion for shield wall penetrations in the Auxiliary Building, such as those for piping and ventilation ducts is to locate them, whenever practical, so that their effect on the deep dose equivalent rates in accessible areas outside the shielded enclosure is minimized. Often this criterion is satisfied by locating the penetrations as nearly as possible to the corners and to the ceiling of the shielded enclosure. In using this technique, however, consideration is given to the increased length of piping sources that may result. If direct or reflected radiation passing through the penetrations of a shield wall creates a radiation area outside the wall, the criteria given for the erection of shield walls are used to establish the necessity for a wall to shield this area.

The following general shielding considerations are employed in the arrangement of Shield Building penetrations:

1. Where practical, most penetrations of the Shield Building, except those that connect the Shield Building to a shielded enclosure in the Auxiliary Building, are opposite unpenetrated

areas of the crane wall. This arrangement adequately shields outside areas and areas inside the Auxiliary Building from sources inside the containment shell during normal operation. When this arrangement is not used, shadow shields are provided to eliminate radiation streaming from major sources inside the containment to areas outside the Shield Building.

2. Radiation sources in the annulus between the containment and the Shield Building are located behind unpenetrated portions of the Shield Building or behind the Shield Building penetrations that connect the Shield Building to shielded enclosures in the Auxiliary Building.

3. Penetrations of crane wall sections that provide necessary shielding for containment areas accessible during power operations are avoided.

4. Shadow shields are provided at Shield Building penetrations that connect the Shield Building to unshielded areas where access cannot be completely controlled during accident conditions.

Valve and Valve-Operating Stations

The following arrangements are used for manually-operated valves that control process equipment functions:

1. Valves are located and operated in the enclosure with the controlled equipment. This arrangement is used only when design level activities in the equipment and piping and anticipated occupancy for valve operation are such that acceptable dose limits will not be exceeded. This arrangement is not used if the deep dose equivalent rate at the valve is greater than 100 mrem/hr. The limit imposed in the case of each valve depends on expected occupancy requirements and is generally much less than 100 mrem/hr. Another requirement for using this arrangement is that sources and piping in the equipment enclosure can be sufficiently removed, without economic penalty, to allow valve maintenance or that design activities are low enough to keep personnel doses under acceptable levels during valve maintenance without source removal. (Source removal can involve pumping or draining a liquid, venting a gas, flushing demineralizer resin, or replacing a filter cartridge.) For this purpose, acceptable deep dose equivalent rate is 6 mrem/hr. To perform maintenance for an 8-hour shift at an average dose rate above this level, an employee needs to work under an approved radiation work permit.

2. Valves are located and operated in a radiation area outside the equipment enclosure. With this arrangement, deep dose equivalent rates at the valve must be less than 100 mrem/hr and generally much lower limits are set.

3. In the third type of arrangement, valves are located in the equipment enclosure but are operated from behind a shield wall. For this arrangement, deep dose equivalent rates at the valve operating station is typically less than 15 mrem/hr. The dose limitations during valve maintenance are the same as those for the first arrangement.

4. Valves are located in a valve gallery. Generally, a number of valves share a valve gallery. Typically, these are most of the valves that serve a few identical or similar plant components. One side of the valve gallery is formed by a shield wall which separates the valves from the process equipment. The opposite side of the gallery is a shield wall which is penetrated by either extension stem arrangements joining valves to handwheel operators or by flexible shaft controls.

The extension stem is solid metal and the annular space between extension stem and shield wall sleeve is grout filled. With this arrangement, the effectiveness of the shield wall between valves and handwheel operators is virtually undisturbed and the deep dose equivalent rates at the handwheels are less than 5 mrem/hr. In some cases, ducts for the shafts follow an oblique or curved path through the wall to prevent direct radiation streaming from high intensity sources. The design deep dose equivalent rate outside the valve gallery for this arrangement is 2.5 mrem/hr.

The first design objective of the valve gallery is to allow valve maintenance without first removing the sources from the process equipment. Some of the design guides to achieve this objective are the following:

a. Penetrations through the shield wall between the equipment enclosures and valve gallery are as near the ceiling and as close to the corner of the equipment enclosures as practical.

b. Piping runs in the gallery, that will contain radioactive fluid when the control valve is isolated for maintenance, are kept as short as practical.

c. Excessive annular spaces between pipe and pipe sleeve in the wall between equipment and valves are avoided.

   With these precautions, it is expected that the design objective of 6 mrem/hr deep dose equivalent rate will be achieved when the process equipment contains up to a significant fraction of design level activity. The design objective should be achieved in most cases even when the process equipment contains design level activity. As an outside limit, the design assures a dose rate of less than 100 mrem/hr in the valve gallery during valve maintenance without removal of the process equipment sources. Even at dose rates of 100 mrem/hr, some valve inspection and maintenance would be possible.

A second objective for locating some of the valves in valve galleries instead of in the equipment enclosures is that even after removal of the process sources, the remaining activity on the inside walls of the equipment and/or high contamination levels in the enclosure may require extensive decontamination work before valve maintenance if the valve is located in the enclosure.

A third objective for locating control valves in valve galleries is that this arrangement provides a second shield between process equipment and general access areas. This is a worthwhile consideration when any unanticipated shielding deficiencies can result in high dose rates.

Another advantage is that, in the unlikely event of valve operator failure, the valve gallery arrangement allows limited direct operation at the valve location until maintenance is performed.

Most of the advantages of locating hand-operated valves in valve galleries also apply to the location of remote-manual (motor-operated or pneumatically-operated) valves in valve galleries.

Manually-operated valves used to isolate, drain, or vent process equipment such as pumps that contain relatively small amounts of activity are generally located and operated in the enclosure with the equipment. As a rule, remoting the valve and/or its operation from the equipment is a design consideration only when one or both of the following conditions can exist: (1) the anticipated dose from the process equipment during valve operation is significant, and (2) the anticipated dose received from the equipment during valve maintenance is significant and large compared with that which could be received if a remote valve station were used.

A valve is not normally used to isolate, drain, or vent process equipment located and operated in the enclosure with the equipment if the deep dose equivalent rate is greater than 100 mrem/hr. The limit selected for each valve depends on the expected occupancy time at the valve station and is generally much less than 100 mrem/hr. If anticipated dose rates are too high to allow location and manual operation of the valve in the enclosure with the equipment, one of the following procedures is used: (1) the operation of the valve is from behind a shield wall which limits the deep dose equivalent rate at the operating location to less than 15 mrem/hr, or (2) the valve is located in a valve gallery and operation of the valve is from behind the valve gallery wall which restricts the deep dose equivalent rate at the valve operating location to 2.5 mrem/hr. Typically, these valves share a valve gallery with the equipment control valves.

Motor-operated or pneumatic valves that isolate, drain, or vent process equipment are located in valve galleries if process equipment activity levels could be high enough to prohibit emergency access to the valves.

Primary and Secondary Shielding

The primary shield consists of the following parts:

1. Shield elements inside the reactor pressure vessel. These elements, which are the core baffle, the core barrel, the thermal shield, and water annuli, provide a water shield and a steel shield, each several inches thick.

2. The reactor pressure vessel.

3. A concrete structure surrounding the reactor vessel from the floor at the 679.78 elevation to the floor at the 702.12 elevation. The concrete thickness is 5 feet 9 inches on the radius through each of eight out-of-core neutron detector slots. On all other radii, the concrete thickness opposite the active fuel is 8 feet 6 inches. There is an opening in the shield at each of the eight primary coolant pipes. Four of the openings start at the vessel flange surface elevation of 702.12 and go down to elevation 689.71. The other four openings extend from the vessel flange surface to elevation 692.0.

That part of the opening above each pipe is covered with a permanently installed plate. Removal of the plates during shutdown allows inspection of the weld joints between the primary coolant pipes and the reactor vessel nozzles. Inspection time available will be very limited since dose rates levels under pressure vessel equilibrium Co-60 and Fe-59 activity conditions will be on the order of 10 rem/hr at the bottom of the opening and 1 rem/hr at the top.

Except across the refueling canal, the primary concrete structure extends upward at reduced thickness (minimum is 2 feet 6 inches) from the 702.12 elevation to the operating floor

(elevation 733.63). (The blowout panels in this upper structure are located just under the floor at elevation 733.63. The panels extend from elevation 731.13 down to elevation 726.63. With this arrangement, radiation from the reactor vessel that penetrates the blowout panel area is attenuated by at least one reflection off concrete before it reaches accessible plant areas outside the primary concrete.) The upper part of the primary concrete shielding is completed by the walls of the refueling canal which extend upward from elevation 686.23, by the control rod drive missile shield and by a gate which spans the refueling canal from elevation 733.63 down to elevation 702.12. The control rod drive missile shield and the gate are removed during refueling. The primary shielding makes possible necessary access inside the crane wall during shutdown.

The secondary shield consists principally of the crane wall, the Shield Building, the concrete operating floor at elevation 733.63, and the concrete structures which combine with the crane wall to enclose those sections of the steam generators and the portion of the pressurizer that extend above elevation 733.63.

In addition to their providing biological radiation protection, the primary and secondary shielding are arranged and structured to provide additional shielding functions such as:

1. The primary shielding elements inside the vessel attenuate neutron flux sufficiently to prevent excessive radiation damage to the reactor vessel.

2. The primary shielding prevents excessive radiation damage to plant components from neutron and gamma radiations, and the secondary shielding prevents excessive radiation damage to plant components from gamma radiation.

3. The metal and water inside the pressure vessel and the pressure vessel itself serve to reduce the heat flux from neutron and gamma radiation at the vessel outer surface. Cooling necessary to avoid high temperatures and possible dehydration in the surrounding concrete is, thus, an easier task.

4. Parts of the primary and secondary shields serve as portions of the divider, necessary for the ice condenser containment, between lower and upper containment compartments.

5. The Shield Building, which is part of the secondary shielding, is also part of the double containment.

Personnel enter and leave the containment vessel through either of two personnel airlocks. To protect (from primary coolant system radiation) personnel entering the containment through the airlock from the platform at elevation 693.0, heavy concrete with density 218.0 lb/ft^3 is used in a section of the crane wall. With the reactor at significant power levels, personnel access to the lower compartment, as defined in FSAR Reference 15.5.8.17, will be prohibited except under cases of critical need. During full power operation, the upper compartment and the ice condenser upper plenum will be entered infrequently but as necessary for upper compartment inspection and ice bed and ice condenser inspection and maintenance. The seal table and instrument room will be entered as necessary during full power operation. The accumulator rooms, ventilation equipment rooms, and tunnel area outside the crane wall will be entered from the seal table and instrument room only as needed and as radiation and airborne contamination permit. Access to the annulus between the containment vessel and the Shield Building is not normally required during power operation; however, access, if necessary, is through an airlock.

Auxiliary Building Shielding

Shielding in the fuel-handling area of the Auxiliary Building is discussed in a following subsection. The balance of the shielding in the Auxiliary Building protects personnel during normal operation, including anticipated operational occurrences, from the components and piping of the following systems and facilities:

1. Chemical and Volume Control System (CVCS).

2. Waste Disposal Systems (WDS).

3. Residual Heat Removal System (RHR).

4. Spent Fuel Pit Cooling System (SFPCS).

5. Sampling System collection and analysis facilities.

The hot instrument shop and decontamination area enclosures furnish some minimal shielding, but their main function is to minimize the spread of contamination.

The Auxiliary Building shielding is designed to limit deep dose equivalent rates in accessible corridors and open spaces in the building to 1.0 mrem/hr; however, exceptions occur at certain shield wall penetrations. If the dose rate at a penetration exceeds 5.0 mrem/hr, the procedures in Table 12.1.2-1 for designating radiation areas apply. Auxiliary Building shielding is also designed so that equipment areas may be entered for maintenance without shutdown of adjacent operating systems or system equipment. Satisfying this requirement results in a high degree of compartmentalization in the building.

Most piping carrying fluid of high specific activity is routed through shielded pipe chases. The pipe chase walls have a minimum thickness of 27 inches of concrete. Pipe chases run along the A5 line (Unit 1) and A11 line (Unit 2) on elevations 653.0 to 734.0. (See Figures 1.2.3-3 through 1.2.3-7.) The pipe chase areas are enlarged at one end between the floors at elevations 690.0 and 714.0 to form Shield Building penetration areas. Most radioactive fluid-carrying pipes running from the containments to the Auxiliary Building pass through these pipe chase sectors which extend from approximately Az 270 to Az 300 degrees. Another pipe chase runs along the fuel transfer canal and adjoins the A5 and A11 line pipe chases between the floors at elevations 690.0 and 714.0. A concrete partition in this pipe chase along the A8 line, between units, inhibits the spread of contamination from one unit to the other should a pipe rupture occur.

Fuel Transfer Shielding

During fuel transfer operations, the fuel transfer canal, spent fuel pit, refueling canal, and the region above the open reactor vessel are filled with borated water to approximately elevation 726.12. The bottom of the refueling canal is at elevation 686.23 in the fuel assembly tilting device area. A fuel assembly is transferred from the reactor vessel through the refueling canal toward the Auxiliary Building. It travels in a fuel transfer tube from the containment to the fuel transfer canal in the Auxiliary Building, and it is then moved into a storage location in the adjacent spent fuel pit.

After the fuel transfer has begun, the principal radioactive sources in the proximity of the fuel assembly transfer path are the following: (1) activity in the water which is a mixture of reactor coolant and water from the refueling water storage tank, and (2) the fission product inventory in the fuel assembly being transferred. During nuclear fuel transfer activities, personnel are in the immediate area of the fuel transfer canal. Radiation dose exposures are maintained ALARA by various means including the minimization of stay time and controlling source terms.

The minimum water shield above the active fuel region of a spent fuel assembly as it moves from the reactor vessel to the storage position in the spent fuel pit is approximately 10 feet (approximately 9 feet above the fuel assembly). The design of the transfer equipment incorporates restraints to ensure that this water shield is maintained which keeps radiation levels within acceptable limits. Except for an emergency passageway under the fuel assembly tilting device in the refueling canal, the transfer of spent fuel assemblies does not generate any high-radiation areas in accessible plant areas. The minimum shielding between the fuel assembly and the emergency passageway is three feet of heavy concrete (density = 218 lb/ft^3). The deep dose equivalent in the passageway is less than 37 mrem/hr. The minimum shielding inside the primary containment between fuel assembly and personnel on the floor at elevation 693.0 is one foot of water and over 5 feet 6 inches of ordinary concrete. The corresponding maximum deep dose equivalent rate is less than 5 mrem/hr. During fuel assembly transfer, the region in the annulus between the steel containment and the Shield Building is protected from the fuel assembly by concrete and water equivalent to more than six feet of concrete. A radiation streaming gap between the steel containment and the concrete on each side of it in the vicinity of the fuel transfer tube is avoided by offsetting the concrete and attaching to each side of the steel containment a steel ring. Similarly, offsets in the Shield Building concrete and in the Auxiliary Building wall in the vicinity of the transfer tube are used to avoid a direct streaming path between these two structures. The above radiation analyses are summarized in SQN-DC-V-21-0, FSAR Reference 15.5.8.17.

When the spent fuel assembly is outside the Shield Building, during passage through the Auxiliary Building wall and fuel transfer canal to the spent fuel pit, it is shielded by a minimum of six feet of concrete or by a minimum of 10 feet of water. Spent fuel pit concrete walls which separate spent fuel assemblies in their storage locations from the Auxiliary Building access area at elevation 669.0 are seven feet thick.

For dry cask storage operations, the minimum water shield above the active fuel region of a spent fuel assembly as it moves from the spent fuel pit to the cask loading area is approximately 10 feet (approximately 9 feet above the fuel assembly). The design of the transfer equipment incorporates restraints to ensure that this water shield is maintained which keeps radiation levels within acceptable limits. Refer to the HI-STORM FSARs (Holtec Reports HI-2002444 and HI-2114830) for radiation doses affiliated with the HI-STORM 100 Cask System and the HI-STORM FW Storage System.

<u>Turbine Building and Service Building</u>

Activity in the Turbine Building occurs only in the event of steam generator primary-to-secondary leakage. Almost the entire Turbine Building is an unlimited access area. For an extreme case of primary-to- secondary leakage of 1 gal/min per unit (2 gal/min per plant), some accessible areas immediately adjacent to the Condenser Vacuum Exhaust System, including the optional use of HEPA filters and charcoal absorber train, could become Radiation Areas.

There are several areas of low activity level in the Service Building such as the hot machine shop, radiological control laboratory, and radiochemical laboratory. A water retention system is provided to prevent the possible release of contaminated water after the fire protection sprinkler system actuates.

Enclosures about these areas furnish necessary shielding, but their principal purpose is to minimize the spread of contamination.

Outside Areas

Except for the following, all areas outside the plant buildings are unlimited access areas as defined in Table 12.1.2-1 during normal operation including anticipated operational occurrences.

1. For short periods of time when solid waste shipping is imminent, the casks will be outside. The number of casks allowed outside at any one time is controlled and depends on the dose rates from each. The maximum dose rate from each cask satisfies the provisions of 49 CFR 173. Access to the outside region where these casks are located during the short preshipment periods is controlled. The type of control required depends on the designated access type which, in turn, is established by the dose rate.

2. During solid waste and spent fuel shipment, the area immediately adjacent to the transport vehicle may be reevaluated.

3. There are six outside tanks that contain radioactive liquids: two refueling water storage tanks, two primary water storage tanks, and two condensate storage tanks. The activity in each is low level, and no shielding is required. Maximum deep dose equivalent rates at the exclusion area boundary from these tanks is 2.0E-4 mrem/hr for all tanks total. The radiation analysis is summarized in SQN-DC-V-21.0, FSAR Reference 15.5.8.17.

4. Guidance for the cumulative radiation dose to the public is provided in 10 CFR 20.1301 and 10 CFR 72.104. SQN is a dual NRC licensed facility that will [1] produce nuclear power with Unit 1 and Unit 2 in accordance with 10 CFR Part 50 and [2] will store spent fuel utilizing up to 90 fuel-loaded overpacks (the HI-STORM 100 Cask System and the HI-STORM FW System overpacks) in accordance with 10 CFR Part 72.210. Therefore, the radiation doses affiliated with the operations of SQN Unit 1 and Unit 2 reactor power facilities must be summed with the dose from 90 fuel-loaded overpacks (the HI-STORM 100 Cask System and the HI-STORM FW System overpacks) and yield a total value less than the limitation provided by 10 CFR 20.1301 and 10 CFR 72.104. This summation is provided in SQN's Independent Spent Fuel Storage Installation (ISFSI) Section 9.1.5 (Reference calculations SQN-TI-534, SQS2-0171, and SQS2-0234).

5. The Unit 1 and Unit 2 Old Steam Generator Storage Faciilities (OSGSFs) are non-quality related, non-seismic, reinforced concrete structures that provide interim storage for the Old Steam Generators (OSGs) that were removed from the Unit 1 and Unit 2 reactor buildings as a result of the steam generator replacements during the Unit 1 Cycle 12 outage and the Unit 2 Cycle 18 outage. The OSGSFs are located north of the plant, outside the protected area, but within the exclusion area and site boundary. The general locations of the OSGSFs are shown on Figure 2.1.1-1.

   The reinforced concrete walls and roof (minimum density of 150 lb/cft) of the Unit 1 and Unit 2 OSGSFs and their access vestibules have been designed to ensure that the dose rates outside the facilities are within the limits of 10 CFR 20 and 40 CFR 190 (See References 9 and 10). The interior of each OSGSF is classified as a “high radiation area (controlled)” and the vestibule entrance is classified as a “regulated access” area as defined in UFSAR Table 12.1.2-1.

   The radiation dose assessment was accomplished using the SHIELD-SG and Multigroup Oak Ridge Stochastic Experiment (MORSE) computer codes. SHIELD-SG is a point-kernel program used to calculate direct doses at various distances from the source. MORSE is a Monte-Carlo program that calculates direct and skyshine doses. See Reference 9.

Shielding For Accident Conditions

Some shielding provided for normal operation also has a function during accident conditions. However, other shielding has a function during accident conditions only. This accident shielding is required to serve two functions: (1) it must restrict the dose at the exclusion area boundary from activity in the containment to a small fraction of 10 CFR 100 limits, and (2) it must attenuate dose rates at interior and other onsite locations from activity in the containment to levels which will allow required access. Requirements are the following:

1. Continuous control room occupancy is required.

2. Visits of several minutes duration into the shutdown board rooms to operate breakers and switches must be possible. For these visits, which may occur at any time after the start of accident conditions, the operator will wear appropriate protective equipment.

3. Since a single crew cannot remain in the control room for the duration of the accident, it must be possible to make the trip from the exclusion area boundary to the control room sometime after 24 hours without receiving an excessive dose.

4. The diesel fuel will have to be replenished during the course of the accident. The onsite storage allows about seven days of operation.

The Shield Building is the principal structure that limits dose at the exclusion area boundary and at site exterior locations from activity in the containment. The Shield Building also, in concert with other shields, limits dose rates at interior and other onsite locations. The accident shielding functions of the Shield Building are shared by the structures that shield its penetrations, such as the steam line penetrations, the personnel hatches, the equipment hatch, ventilation ducts, and the many smaller penetrations. Some of the structures that shield the Shield Building penetrations are Auxiliary Building internal walls. These and other Auxiliary Building walls and the Auxiliary Building ceilings further attenuate radiation from sources within the containment to improve accessibility during accident conditions.

The ESF equipment compartment shielding provides for emergency maintenance. To make possible this maintenance, the equipment will be drained before the maintenance begins and the operator will wear appropriate protective equipment. In the case of ESF equipment, such as the RHR pumps which also operate during normal operation, the shielding required for normal operation is controlling.

The control room is shielded so that the total effective dose equivalent from external sources (activity inside the primary containment, in the passing cloud, and in surrounding rooms) obtained during occupancy following a LOCA is less than 5.0 rem. The remainder of the total effective dose equivalent will come from the airborne activity within the control room. (The dose from this airborne activity which is more difficult to limit than that from the external sources is discussed in Subsection 15.5.3, which considers integrated doses in the control room under accident conditions from all sources.)

In the control room shielding design, sufficiently thick walls, ceiling, and floor are provided. In addition, special attention is given to the doorways. Radiation shielding is provided at the entrances from the Turbine Building to attenuate radiation from the radioactive cloud which is assumed to occupy the Turbine Building. The door shielding shall have a radiation attenuation coefficient greater than or equal to the Main Control Room C36 pressurization door including the security bullet plate barrier.

Analysis shows that shield doors at the small entrances from the control room to the Auxiliary Building are not necessary.

A control room layout drawing is included as Figure 1.2.3-3.

Shielding Calculations

Shielding required to reduce the dose rates, from conservative source strengths in known source geometries as design objective values, are determined with hand calculations and/or with computer codes. Both the hand calculations and the computer codes employ the point-to-point kernel integration method. The PATH code and the QAD-P5Z code integrate the basic exponential attenuation point kernel over the various geometries to provide the uncollided gamma-ray flux. Many of the integrations found in the Reactor Shielding Design Manual (Reference 2) are utilized. Dose rates are obtained by multiplying the uncollided flux by the product of the flux weighted buildup factor and a dose-conversion factor. The computer program COROD is used to solve the equations for the beta and gamma dose rates from airborne activity in the control room. COROD also provides the gamma dose rate after attenuation by a shield. The equations solved are given in Subsection 15.5.3.

The computer codes addressed above are utilized in radiation analyses to demonstrate compliance to 10 CFR 20, 10 CFR 50.49, 10 CFR 50 Appendix AGDC-19, and 10 CFR 100 requirements. These analyses are summarized in SQN-DC-V-21.0, FSAR Reference15.5.8.17.

12.1.3 Source Terms

Radiation analyses utilized for normal plant operations and post accident conditions are described in FSAR Chapters 11.1 and 15.5, respectively. These radiation analyses are summarized in SQN-DC-V-21.0, FSAR Reference 15.5.8.17.

12.1.4 Low Range Area Monitoring

12.1.4.1 Objectives and Design Basis

Area radiation monitors are provided to assist in compliance with 10 CFR 50, Appendix A, General Design Criteria 19, 63, and 64, and with 10 CFR 20.

Monitors are provided to monitor exposure rates and warn plant personnel of increasing radiation levels in the general area of the monitors.

12.1.4.2 Operational Characteristics

Table 12.1.4-1 lists the physical location of each area monitor, type of detector, and detector range. The area Radiation Monitoring System has the following operational characteristics.

12.1.4.2.1 Area Monitor Detector

Detectors are Geiger-Mueller type gamma detectors. Each detector has its own independent high-voltage power supply located in the Main Control Room (MCR) and has a remote-operated check source mechanism with actuation from its rate meter in the MCR.

12.1.4.2.2 Deleted

12.1.4.2.3 Local Indicating Ratemeter

With the exception of the MCR monitor, each monitor has a local indicator, high radiation light and audible alarm, and a power-on light.

12.1.4.2.4 Trending

The area monitors are trended on multi-point recorders or on the plant computer in the main control room.

12.1.4.2.5 Range and Setpoints

The ranges of the instrumentation are provided in Table 12.1.4-1. The area monitor's setpoints are adjustable over the entire range.

12.1.4.3 Calibration and Maintenance

Periodic calibrations will be performed on each monitor. The calibration procedure may be performed by means of sequential, overlapping, or total channel steps including:

1. Calibration check of each monitor using a portable radiation calibration source.

2. Electronic calibration of all ratemeters and recorders.

3. Verification for all monitors that "Instrument Malfunction" annunciation is initiated on downscale ratemeter trip or loss of power.

4. Verification that "High Radiation" annunciation is initiated on upscale ratemeter trip.

5. Each detector is checked using its built-in check source.

Maintenance will be performed if any of the above checks indicate a malfunction. Unscheduled maintenance will be performed as required.

12.1.5 Operating Procedures

Radiation protection systems and administrative controls are designed to maintain radiation doses within the site ALARA goals and within the criteria specified in 10 CFR 20 during normal operations. Plant areas are classified into zones with varying degrees of administrative control. Allowable dose rates are based on anticipated frequencies and duration of occupancy. Dose rates and occupancy times are controlled. Table 12.1.2-1 summarizes these general classifications of plant areas.

The entrance to all zones are marked in accordance with the regulations of 10 CFR 20. To prevent inadvertent entry by personnel into high and very high radiation areas (controlled or prohibited classifications) rigid access control is maintained, including locked or barricaded doors, interlocks, and a system of local and remote alarms. Administrative control includes the use of radiation work permits, radiological control surveys, and a high or very high radiation key issued at the site radiological control (RADCON) or Shift Manager’s Supervisors' office. All other less hazardous areas are properly identified in accordance with Table 12.1.2-1 with radiation work permits required when plant working guidelines for radiation dose may be approached.

A radiation work permit (RWP) is required for all work where employee doses are anticipated to exceed 50 mrem/day (deep dose equivalent). RWP's are required for contamination zones, airborne radioactivity areas, and when radiation systems are being breached. Personnel doses are tracked and each supervisor routinely informed. Personnel will be scheduled by their supervisor so that doses are in accordance with the ALARA objective.

RADCON coverage at the plant is provided as necessary in an effort to maintain radiation doses ALARA.

The general procedures have been formulated from various successful programs in use at other power reactor facilities and radioactive materials-handling facilities.

The working guidelines applied at the plant will result in radiation doses below 10 CFR 20 criteria and as such provide for a conservative approach toward assuring ALARA radiation doses.

The radiation monitors are used to enhance the radiological control program. The following statements describe the monitors and their intended use.

1. Portal monitors - The portal monitor is a radiation monitoring device for providing a visual and audible warning when radioactive contamination is detected on an individual. The monitor scans the entire body.

   The portal monitors are located at the exit from the Access Control Portal and in the plant at the exit from the auxiliary building.

2. Local rate meter radiation monitors (friskers) - The local ratemeter is a small compact count rate meter operated by ac line or by a rechargeable battery. Trickle charging occurs while the unit is plugged into the line. Battery condition may be checked on the control panel.

12.1.6 Estimates of Doses

Peak External Dose Rates

Peak external gamma dose rates for various access types during power operations are given in Table 12.1.6-1. Peak rates given are based on operation with 1.0 percent failed fuel.

Annual Doses

Personnel dose estimates are calculated annually for each fiscal year to establish site ALARA goals consistent with current industry practices and standards.

The following method is used to establish the annual personnel dose estimates. First, the work scope and the number of man-hours to be performed in each area of the plant is determined. Then by projecting radiation dose rates for these involved plant areas, an estimate is calculated by multiplying the number of hours in the area by the area dose rates. Historical dose data for similar work activities is also reviewed. By comparing the calculated and historical values, the personnel radiation dose for the upcoming fiscal year is estimated.

Non-emergency radiation doses to plant personnel are controlled by the requirements imposed by 10 CFR 20.

The remaining sections of FSAR subsection 12.1.6 describe personnel radiation dose estimates for plant maintenance and operational activities as calculated prior to plant operation, and are included for historical purposes only.

Estimates of yearly doses to plant nonmaintenance personnel are made by estimating the total time per year that plant personnel occupy access control areas as defined in Table 12.1.2-1. For this analysis, occupancy (man-hours/yr) in each type zone is multiplied by the estimated average dose rate (rem/hr) within the type zone to obtain the estimated man-rem/yr for occupancy in that type zone. The sum over all zone types is the estimated man-rem/yr for the Sequoyah Plant.

The estimates are based on a working time of 2000 hours per year for each person considered and as such includes the dose to these persons during one refueling and during minor maintenance that they may perform during the year. The estimates follow.

Access Type*	Occupancy (man-hours/yr)	Dose Rate, mrem/hr	Plant Dose man-rem/yr
Unlimited access - continuous occupancy	56,700 operators 20,000 others 76,700 total	0.1	5.67 operators 2.00 others 7.67 total
Unlimited access - intermittent occupancy	19,600 operators 23,775 others 43,375 total	1.0	19.60 operators 23.80 others 43.40 total
Regulated access - Radiation area	5,700 operators 2,225 others 7,925 total	15.0	85.50 operators 33.80 others 119.30 total
High radiation area (controlled)	120 operators 330 others 450 total	200	24 operators 66 others 90 total
High radiation area (restricted)	10 operators 20 others 30 total	1000	10 operators 20 others 30 total
Subtotal Subtotal	82,130 operators 46,350 others	All	144.77 operators 145.60 others
Grand Total	128,480 total		290.37 total

*Definitions are provided in Table 12.1.2-1.

As used in the above table, the category, "Operators," includes only the approximately 164 persons directly involved in plant operation. These persons are the manager supervisors, unit supervisors, unit operators, and assistant unit operators. The personnel category, "Others," are the other plant nonmaintenance personnel who will experience some radiation dose as a result of plant operation. These approximately 210 persons are radiological control, radiochemistry, and other technical support personnel.

As determined from the above table, the dose per year for "Operators" is 0.88 rem/yr per man and for "Others" is 0.69 rem/yr per man. If the total man-rem dose is averaged over the total nonmaintenance

staff of approximately 600 ("Operators," "Others," and "Administrative"), the average dose is 0.48 rem/yr per man. The doses given in the table are not expected during the early years of plant operation since they are based partly on the extreme condition of operation throughout the year with 1.0 percent failed fuel. However, they could be approached after a few years as plant activated corrosion product inventory increases.

Doses to the plant employees (approximately 700), whose primary duties are maintenance activities, are explained below. There is experience available from operating plants to serve as a guide for making such predictions. The experience available does suggest that such doses (to maintenance personnel) will be a significant fraction of 10 CFR 20 limits. A value of 0.5 rem/yr to 1.0 rem/yr per maintenance man is a reasonable expectation. With increasing plant age, this dose will increase due to accumulation of corrosion product activities on process surfaces and due to increasing plant maintenance requirements.

The estimates made for yearly man-rem dose are consistent with data reported from operating PWR power plants.

Table 12.1.2-1

ACCESS CONTROL AREAS

Area Type	Exposure** Rate, mrem/hr at 30 cm	Identification and Entry Requirements
Unlimited	<2.0	None
Regulated access	***	Note 1
Radiation area	5.0-100	Note 2
High radiation area (controlled)	100-1000	Note 3
High radiation area (restricted)	>1000	Note 4
Very High radiation area (restricted)	>500 rad/hr*	Note 5

*At very high doses received at high dose rates, units of absorbed dose (rad) are appropriate, rather than units of dose equivalent (rem).

** As specified in 10 CFR 20 and TECH SPEC 5.7.

*** Not defined by Exposure Rate. This area includes all areas where any type of radiological control is implemented.

Notes:

1. Access is under administrative control. The area is conspicuously posted with a sign or signs bearing the radiation symbol and the words CAUTION, RADIOLOGICALLY CONTROLLED AREA.

2. Access is under administrative control. The area is conspicuously posted with a sign or signs bearing the radiation symbol and the words CAUTION, RADIATION AREA. Radiation Work Permit (RWP) required if expected dose is ≥50 mem/day.

3. Access is under administrative control. The area is conspicuously posted with a sign or signs bearing the radiation symbol and the words DANGER, HIGH RADIATION AREA or CAUTION, HIGH RADIATION AREA. RWP is required. Radcon surveillance or radiation monitoring device is required.

4. Same as Note 3 above. Additionally, each entry will have a solid or wire mesh door which is maintained locked except when access to the area is required. The door can always be opened from the inside.

5. Entry will generally be forbidden unless there is a sound operational or safety reason for such an entry. The area is conspicuously posted with a sign or signs bearing the radiation symbol and the words GRAVE DANGER, VERY HIGH RADIATION AREA.

TABLE 12.1.6-1

PEAK EXTERNAL DOSE RATES

Typical Areas	Peak External Dose Rate, mrem/hr
Exclusion boundary	Natural background
Control room	0.1
Turbine building (most areas)	0.1
Auxiliary building (most general passageways)	1.0
Some valve operating locations	5.0
Floor above spent fuel pool during refueling	2.5
Sample rooms	50
Containment instrumentation rooms	25
Containment (outside primary coolant system shielding except opposite penetrations in this shielding)	100
Inside some process equipment shielded	1000

There are numerous shielded plant areas where dose rates can be over 1.0 rem/hr. Although there are no absolute limits on peak dose rates where personnel are permitted (Subsection 12.1.1), administrative dose controls limit such access. Entry into areas such as those inside the primary coolant system shielding, where dose rates are as high as 30 rad/hr* to 50 rad/hr*, can be permitted to perform critical maintenance activities or in emergencies.

* At very high doses received at high dose rates, units of absorbed dose (rad) are appropriate, rather than units of dose equivalent (rem).

12.2 VENTILATION

The plant ventilation systems maintain a suitable environment for personnel and equipment during normal operation, including anticipated operational occurrences. Several of the plant ventilation systems perform safety-related functions.

12.2.1 Design Objectives

The design objectives of the plant ventilation systems with respect to the requirements of 10 CFR parts, 20, 50, and 100 are the following:

1. During normal operation, including anticipated operational occurrences, control airborne activity concentrations so that the average concentrations to which any plant staff individual is exposed will not exceed the maximum airborne radioactive material concentrations given in 10 CFR 20.

2. During accident conditions, reduce released airborne activity to limit the offsite dose from airborne activity and all other sources to within the requirements in 10 CFR 100.

3. Prevent doses from airborne activity in the control room and penetrating radiations through walls under accident conditions from exceeding the limits of 10 CFR 50, Appendix A, Criterion 19.

12.2.2 Design Description

The following subsections present descriptions of the Containment, Auxiliary, Control, and Turbine Buildings ventilation systems expected to contain radioactive material or which may become contaminated with radioactive material (see Section 11.3.7 for other areas with radioactive material). The descriptions include the design criteria and pertinent ventilation system and building parameters. Additional description is provided in Section 9.4.

12.2.2.1 Containment Ventilation Systems

The Containment Ventilation Systems are described in detail in Subsection 9.4.7, 9.4.8 and Subsection 6.2.3. These systems are:

1. Containment Purge Supply and Exhaust Systems.

2. Instrument Room Purge Supply and Exhaust Systems.

3. Emergency Gas Treatment System.

4. Containment Cooling Systems.

The containment volumes, in cubic feet are:

a. Lower compartment: 367,600

b. Upper compartment: 716,000

c. Total volume: 1,083,600

The Containment Purge Supply and Exhaust System provides the capability with only one of two trains, to purge the containment lower compartment, upper compartment, instrumentation room, and annulus individually. The purge exhaust is routed through particulate filters and the charcoal adsorbers of the Containment Purge Air Exhaust-Filtration System located in the Auxiliary Building. The system contains two 50 percent capacity exhaust fans and filter trains. In addition, an exhaust fan, 100 percent capacity, is connected to one of the filter trains for operation of the Instrumentation Room Purge System. A separate supply fan is also provided for the independent purge of the instrumentation room.

The upper and lower compartments of the containment are also provided with air coolers. These coolers will remove moisture from containment air including any radioactivity which has adhered to or dissolved in the water vapor in the containment atmosphere.

12.2.2.2 Auxiliary Building Ventilation System

The Auxiliary Building Ventilation System is described in detail in Subsection 9.4.2. The Auxiliary Building services the two reactor units with identical sets of equipment arranged symmetrically within the building. The spent fuel area is common to both units. Air supply fans are located on each end of the building. Those at each end supply half of the required general building ventilation air. Each air intake also delivers nominally half of the air supply to the fuel handling area. The auxiliary shutdown board rooms, located in the Auxiliary Building, are separated from the remainder of the building and have independent cooling systems.

The building ventilation system is designed to maintain a low level of airborne activity in most general areas within the building. The building supply air is delivered to relatively cleaner areas and exhausted from areas of potentially higher airborne radioactivity levels. When high radiation is detected by monitors in the exhaust vent or an Auxiliary Building isolation signal is obtained, the normal ventilating system is automatically stopped and the building is automatically isolated. A negative pressure is then created by the Auxiliary Building Gas Treatment System. Air exhausted in this mode is equivalent to the building in-leakage. Before this air mass is released through one of the Shield Building exhaust vents, it is passed through HEPA filters and charcoal adsorbers.

The Auxiliary Building general volume is 3,480,000 cubic feet. The fuel handling and radwaste packaging area volume is 1,012,900 cubic feet.

12.2.2.3 Turbine Building Ventilation System

The Turbine Building Ventilation Systems are described in detail in Subsection 9.4.4. No radioactive particulate or halogen cleanup systems are included in the ventilation system design, since airborne radioactive contamination can occur only when secondary system leakage occurs simultaneously with steam generator tube leaks.

The Ventilation System supplies air from several locations. Most of the air is supplied through air-intake hoods on the building roof at elevation 797. In addition, an air supply housing at

elevation 732 on the west side of the building supplies some of the air. The Turbine Building volume is approximately 8,000,000 cubic feet.

12.2.2.4 Control Room Ventilation System

The Control Room Ventilation System is provided with equipment for a normal and an emergency mode of operation. The Ventilation System is fully described in Subsection 9.4.1.

Under the normal mode of operation fresh make-up air is mixed with the return air, filtered, and supplied to the control room by air cooling units. All of the air is filtered before going through the coolers.

The equipment for emergency operation consists of isolation dampers on the normal control room supply and exhaust ducts, and two 100 percent capacity emergency pressurizing fans which provide outside air for maintaining a slight positive pressure to two 100 percent capacity filter and fan trains for filtration of the small amount of outside air mixed with the return air for cleanup of control room air. The air cleanup filter trains consist of a bank of four HEPA filters mounted in series with a bank of adsorber modules. For rated efficiency of the filters and adsorbers, see Subsection 9.4.1.3.

In the event of a safety injection signal and/or high radiation signal from either of the two beta radiation monitors located in the common intake duct, the control room supply and exhaust isolation dampers will be automatically closed and a portion of the recirculated air together with the small flow of outside air will be automatically routed to the fully redundant emergency air cleanup fans and filter trains.

The Control Room volume is 260,000 cubic feet.

The capability of the Control Room Ventilation System to meet NRC General Design Criterion 19 and the inhalation dose limit has been evaluated and is presented in Chapter 15.

12.2.3 Source Terms

Radiation analyses utilized for normal plant operations and post-accident conditions are described in FSAR Chapters 11-1 and 15.5, respectively. These radiation analyses are summarized in SQN-DC-V-21.0, FSAR Reference 15.5.8.17.

12.2.4 Airborne Radioactivity Monitoring

12.2.4.1 Fixed Airborne Radioactivity Monitoring Systems

12.2.4.1.1 Design Basis

The airborne radioactivity monitoring systems are one of the plant features provided to comply with 10 CFR 50, Appendix A, General Design Criteria 64, 10 CFR 20, and with 10CFR100.

The fixed airborne radioactivity monitoring system is supplemented by portable radiological control instrumentation that qualitatively responds to airborne radioactivity.

12.2.4.1.2 Airborne Monitoring Channels

Normal Conditions

The Containment Building upper and lower compartment monitors indicate, record, and annunciate airborne radioactivity levels in the MCR (See Table 12.2.4-3). The normal range particulate monitor utilizes a beta scintillation detector with a filter collector to collect the particles from the air. The noble gas channel also uses a beta scintillation detector. These normal range monitor assemblies consist of sample pumps, detector assemblies with preamplifiers, indicators, and other instrumentation. The upper compartment monitors are identified as RE-90-112A, B for the particulate and noble gas channels while the lower compartment is identified as RE-90-106A, B respectively. Redundant isolation valves are provided on the intake and discharge lines for containment isolation. Additionally, these monitors serve as leakage detection devices (see Section 5.2.7). Details on these monitors are listed in Table 12.2.4-1 and Table 12.2.4-3. The filter transport mechanism can be operated in the continuous advance mode or programmed for step advance.

As described in Section 11.4, the safety function of containment ventilation isolation on detection of high radiation is served by the containment purge exhaust monitors.

Accident Conditions

The accident range monitors for the upper compartment are designated as RE-90-271, 272 on trains A and B, respectively. The accident range monitors for the lower compartment are designated as RE-90-273, 274, on trains A, and B, respectively. These are area (type) monitors and are listed in Table 12.2.4-2 and Table 12.2.4-3.

12.2.4.1.3 Component Descriptions

Detectors

The non-area type detector units employ scintillation detectors and built-in preamplifiers (RE-90-106 and -112).

Area type monitors employ ion chambers (RE-90-271 through -274).

Alarms

Alarms are provided for high radiation, signal failure, flow failure, and power failure as applicable. The alarms are both visual and audible in main control room on high radiation and instrument malfunction. One annunciator window for high radiation and one window for instrument malfunction are provided for the area type monitors (RE-90-271 through -274). One annunicator window for particulate channel instrument malfunction, one window for gas channel instrument malfunction, and one common window for particulate/gas channel high radiation are provided for the non-area type monitors (RE-90-106 and -112).

Multipoint Recorder (0-M-12 and M-31)

The monitor outputs are recorded on multi-point recorders located in the main control room. See Table 12.2.4-3.

Pumping System

For those airborne monitors using a pumping system, the pump is a positive displacement, dry vane type. A flow indicator is also provided.

Visual flow alarms are provided at the enclosure.

12.2.4.1.4 Sensitivity, Range, and Set Point

Tables 12.2.4-1 and 12.2.4-2 provide sensitivity range information. Monitor channel setpoints are determined in accordance with plant procedures.

12.2.4.1.5 Calibration and Maintenance

Channel checks, channel operational tests, and channel calibrations of the airborne monitors are performed in accordance with Technical Specifications or maintenance instructions as appropriate.

Maintenance will be performed if any of the above checks indicate a malfunction. Unscheduled maintenance will be performed as required.

12.2.4.2 Airborne Radioactivity Measurements by Laboratory Analysis of Collected Samples

The program for monitoring airborne radioactivity concentrations in plant air spaces with the real time detection devices described in Subsection 12.2.4.1 is supplemented with the use of a low volume portable sampler. A charcoal cartridge or charcoal impregnated paper can be used with the sampler to collect iodine. Collected samples are analyzed in the laboratory.

12.2.5 Operating Procedures

Plant instructions and administrative controls are designed to maintain inhalation doses resulting from airborne radioactivity within site ALARA goals and within the limits of 10 CFR 20 during normal operation. An airborne radioactivity area is posted and access controlled in accordance with 10 CFR 20. Entry into these areas requires the issuance of a radiation work permit. Air samples are analyzed to determine radionuclide concentrations to assure that appropriate respiratory protection equipment is specified on the radiation work permit.

Entry and exit are made through specified portals and all personnel and equipment are monitored for radioactive contamination upon exit from the area.

The respiratory protection program is organized to conform to the standards of 10 CFR 20 to assure the effectiveness of respiratory protection equipment. Training of personnel in respiratory fit tests and maintenance of equipment is an integral part of this program.

In order to evaluate the effectiveness of the respiratory protection program, whole body counting and bioassay analysis will be performed on a routine or requested basis.

These general procedures have been formulated from various successful programs in use at other power reactor and radioactive materials-handling facilities. The 10 CFR 20 airborne radioactivity limit routinely applied within the plant is based on "unidentified" radionuclides commonly present in the reactor environment, thus establishing the respiratory protection program on a conservative basis. This approach is an effort toward maintaining inhalation doses ALARA.

12.2.6 Estimates of Doses

The estimated average dose rates are given in Table 12.2.6-1. The table also considers maximum expected dose rates.

TABLE 12.2.6-1

ESTIMATED DOSES FOR EXPECTED ACTIVITY LEVELS

IN VARIOUS BUILDINGS(1)

Area	Dose Rate(2) (mrem/hr)*
Containment Lower Compartment(3)	18.2
Instrumentation Room(4)	9.8
Auxiliary Building(5)	.035
Turbine Building	4×10^{-5}

Notes:

(1) Doses from maximum activity levels will be higher by approximately a factor of 40 based on an increase in failed fuel from 0.25 percent to 1 percent, and leakage rate increase factor of 10.

(2) All dose rates based on an equivalent 5 rem/2000 hours at MPC.

(3) After 90 day operation, 16 hours cleanup, 2 hours purge.

(4) Based on concentration in containment lower compartment prior to cleanup or purge, and P.F. = 100 due to purge prior to entry.

(5) Average MPC shown in Table 12.2.2-1 reduced by a factor of 10 to account for nonuniformity of concentration due to air flow from regions of lower contamination to regions of higher contamination.

*Calculated values shown are based on 10 CFR 20 concentrations prior to January 1, 1994.

12.3 RADIOLOGICAL CONTROL PROGRAM

12.3.1 Program Objectives

The Radiological Control (RADCON) Program policy is described in the TVA Nuclear Radiation Protection Plan (RPP). The Sequoyah Nuclear Plant site is responsible for implementing the site portion of the RPP.

The site Senior Manager Radiation Protection is responsible for direction of the radiological control surveillance program for plant operations involving potential radiation hazards. He keeps the plant manager informed of radiation hazards and conditions related to potential dose, contamination of the plant and its equipment, or contamination of site and environs. His duties include training and supervising RADCON technicians; planning and scheduling monitoring and surveillance services; implementation of the site personnel dosimetry programs; scheduling technicians to ensure around-the-clock shift coverage as required; maintaining current data files on radiation levels, contamination levels, personnel doses; and work restrictions. The site RADCON section monitors plant operations to ensure that the provisions of developed RADCON standards and procedures are not violated. The site Senior Manager Radiation Protection provides assistance and advice to the plant manager during radiological emergencies.

12.3.2 Facilities and Equipment

The Site RADCON facilities consist of space in the Office Building for the site Senior Manager Radiation Protection. The RADCON laboratory is located at the main boundary between the clean and controlled access areas in the Service Building at elevation 690 near the Auxiliary Building entrance. Portable and laboratory radiation monitoring instruments, respiratory protection, and other supplies including signs, personnel decontamination supplies, air sampling equipment, etc., will be kept in designated areas.

The portable and laboratory equipment will allow the RADCON personnel to measure dose rates and contamination levels throughout the plant in routine and emergency situations.

Each portable survey instrument will be calibrated and checked with standard radioactive sources at least annually (including instruments used exclusively for training purposes). Accurate records on the performance of each instrument during each calibration will be maintained at the appropriate laboratory. Calibration and maintenance procedures specific for each instrument are written and routinely used. Each laboratory counting system is checked at regular intervals with standard radioactive sources for proper counting efficiencies, background count rates, and high-voltage settings by RADCON personnel at the plant.

Personnel decontamination facilities are located on elevation 690.0. This facility is equipped with a shower, sink, and the necessary radiation monitoring instruments to adequately detect very low levels of radioactive contamination. The floor drain from the facility is piped to the Liquid Radwaste System for processing.

TVA will provide protective clothing and equipment for personnel working in radiological areas. Clothing required for a particular instance shall be prescribed by RADCON based upon the actual or potential radiological conditions.

12.3.3 Personnel Dosimetry

National Voluntary Laboratory Accreditation Program (NVLAP) accredited external dosimetry service is provided by TVA for personnel exposed to ionizing radiation in accordance with the requirements of 10 CFR 20. Dosimetry processing and evaluation is performed by an organization currently accredited by the NVLAP of the National Institute of Standards and Technology for the type or types of radiation that most closely approximates the type of radiation or radiations for which the individual wearing the dosimeter is monitored.

The Radiation Protection section has whole body counters to determine internal deposition of gamma-emitting radionuclides. The frequency of the counts will be determined for each individual, and it will be dependent upon the work environment for this individual. The counters will be calibrated with standard radioisotope solutions in configurations approximating the human body.

Data obtained from the whole body counter may be supplemented by in-vitro sampling. The necessity of in-vitro sampling will be dependent upon the work environment for that individual. In-vitro analyses and whole body counter data will be maintained as a part of the employee's permanent dose record.

12.4 LEAKAGE REDUCTION PROGRAM

In response to NUREG-0578, paragraph 2.1.6.a, a program has been implemented to identify and reduce leakage from systems outside containment which would or could contain highly radioactive fluids during a serious transient or accident to as-low-as practical levels.

12.4.1 Waste Gas System

The waste gas system was pressurized, leak tested, and all external leaks repaired as of June 1980. Identification of gaseous leakage during operation is accomplished in response to any alarm from area radiation detectors and/or the waste gas effluent radiation monitor.

12.4.2 Liquid Systems

The following liquid systems are checked periodically to determine if any leakage to the auxiliary building exists:

1) Safety Injection
2) Containment Spray
3) Residual Heat Removal
4) Chemical and Volume Control
5) Liquid Post Accident Sampling System

Each train of each system is tested individually. A general description of the test is given below.

The boundaries of the system to be tested are identified by marked drawings, and the system is aligned to utilize system pumps for pressurizing the areas to be tested. A visual inspection is performed on the piping, valves, pumps, flanges, and fittings for any signs of external leakage. Table 12.4.2-1 contains some general items of inspection and inspection guidelines used. Items to be inspected are not limited to these general items. Each identified leak is quantified and its location specified and documented on data sheets. Steps are taken to repair any external leakage found. All data sheets from the most current test on each system are kept on file in the Main Control Room and are readily available during an emergency.

Each system, initially tested quarterly, will be tested at intervals not to exceed each refueling cycle.

Table 12.4.2-1

INSPECTIONS

1. Drain Valves, Vent Valves, and Root Valves

   a. Inspect blind flange (if required) for leakage. Initiate maintenance request if leakage is present. Estimate any leakage.

   b. If no blind flange is installed but a flange is required, initiate maintenance request.

   c. If no blind flange is provided for, estimate leakage, if any, and initiate maintenance request if leakage is present.

   d. Inspect valve for bonnet leakage, packing leakage, etc. Initiate maintenance request if leakage is present. Estimate leakage.

2. Orifice Flow Element

   a. Inspect flanges for leakage. Initiate maintenance request if leakage is present. Estimate any leakage.

   b. Inspect root valves if present, per (1).

3. Heat Exchangers and Tanks

   a. Inspect shell for possible leakage, particularly at welded sections. Initiate maintenance request if leakage is present. Estimate leakage.

   b. Inspect any bolted joints such as heads, inlet and outlet nozzles, manhole covers, vents, drains, etc. for leakage. Initiate maintenance request if leakage is present. Estimate leakage.

   c. Inspect floor around HX for any water accumulation. Initiate maintenance request if found. Estimate accumulation.

4. Large Valves (3" and up)

   a. Inspect for packing leakage, flange leakage, bonnet to body joints or body to bonnet pressure seal leakage. Initiate maintenance request if leakage present. Estimate leakage.

5. Pumps

   a. Inspect for excessive packing leakage. Initiate maintenance request if leakage is excessive. Estimate leakage. Note: Mechanical seals should have <u>NO</u> leakage)

   b. Inspect bolted joints such as casing flange, inlet and outlet, etc., for leakage. Initiate maintenance request if leakage is present. Estimate leakage.

6. Flanged Piping Connections

   a. Inspect for leakage. Initiate maintenance request if leakage is present. Estimate leakage.

TABLE OF CONTENTS

TABLE OF CONTENTS

LIST OF FIGURES

13.0 CONDUCT OF OPERATIONS

13.1 ORGANIZATIONAL STRUCTURE

13.1.1 Corporate Organization

The organization of the Tennessee Valley Authority's Nuclear Power Organization including the Sequoyah Nuclear Plant is presented in Tennessee Valley Authority Topical Report TVA-NPOD89-A, Nuclear Power Organization Description.

13.1.1.1 Functions, Responsibilities, and Authorities

Sequoyah Nuclear Plant's two nuclear steam supply systems were supplied by Westinghouse Electric Corporation. The TVA Nuclear Engineering organization served as the plant architect, engineer, and principal contractor for the balance of plant equipment and was responsible for ensuring that the technical requirements of the nuclear steam supply system contracts were met. The TVA Nuclear Construction organization was responsible for constructing the plant in accordance with design specifications supplied by the Nuclear Engineering organization.

TVA Nuclear Power is responsible for the safe operation and maintenance of the plant in compliance with the operating licenses, technical specifications, and other applicable requirements.

Nuclear Power is responsible for preoperational and startup testing programs as discussed in Chapter 14.

Chapter 17 and the TVA Nuclear Quality Assurance Plan, TVA-NQA-PLN89-A, describes the quality assurance plan developed for the design, construction, and operation of Sequoyah for both TVA and Westinghouse. Quality assurance of components that were built and supplied by Westinghouse is the responsibility of Westinghouse. Quality assurance for TVA supplied components and designs is the responsibility of TVA. Quality assurance programs for plant operations are also the responsibility of TVA and are audited by the Nuclear Assurance organization.

13.1.1.2 Interrelationships With Contractors and Suppliers

TVA had overall responsibility for planning, scheduling, carrying out, and documenting the plant startup programs. All aspects of plant startup conform to the requirements of the Nuclear quality assurance program. Initial tests and operations are discussed in detail in Chapter 14.

Westinghouse assisted by providing technical guidance in support of the following operations:

1. The storage, protection, installation, cleaning, initial calibration, testing, and operation of the nuclear system equipment, instrumentation and material supplied by Westinghouse.

2. The preoperational testing of the nuclear plant systems in which Westinghouse supplied equipment as installed. This includes the right of review and comment on the preoperational testing of all plant systems that are related to the safety and performance of the nuclear system.

3. All operational checkouts and startup testing of the nuclear system, the initial fuel loading and startup to the completion of the warranty demonstration test.

4. The onsite training of TVA personnel during the nuclear systems preoperational testing, initial fuel loading, and startup activities.

5. Fuel management services as part of the initial long-term fuel contact.

13.1.2 Nuclear Power

Nuclear Power (NP) is responsible for the safe design, construction, operation, and modification of TVA nuclear plants; for compliance with TVA policy on safety and quality; and for compliance with regulatory requirements as applicable to all activities. Nuclear Power plans and manages the nuclear energy supply programs to meet the requirements of the TVA power program consistent with safety, environmental, quality and economic objectives. It develops and implements policies, programs and plans for the nuclear power program.

13.1.2.1 Offsite Organizations

The Nuclear Power Organization is presented in Tennessee Valley Authority Topical Report, TVA-NPOD89-A, Nuclear Power Organization Description.

Qualification requirements for positions providing corporate technical support, specifying required education and experience are maintained in approved position descriptions on file at the site and central office by the Nuclear Human Resources organization. Numbers of positions are contained in approved staffing plans also maintained by the Nuclear Human Resources organization.

13.1.2.2 Onsite Organization

The Sequoyah Nuclear Plant organization is presented in Tennessee Valley Authority Topical Report, TVA-NPOD89-A Nuclear Power Organization Description.

13.1.2.3 Personnel Functions, Responsibilities, and Authorities

During normal plant operations, the plant manager is responsible for all plant activities. In the event of absence, incapacitation of personnel, or other emergencies, the plant manager shall delegate in writing the succession to this responsibility in accordance with Technical Specification 5.1.1.

13.1.3 Qualification Requirements for Nuclear Facility Personnel

Nuclear Power (NP) personnel at the Sequoyah Nuclear Plant are required to meet or exceed the minimum qualifications referenced for comparable positions in Regulatory Guide 1.8, Revision 2 (April 1987), as stipulated in the TVA Nuclear Quality Assurance plan (TVA-NQA-PLN89-A). Regulatory Guide 1.8, Revision 2, endorses ANSI N18.1-1971 and ANSI/ANS 3.1-1981. Minimum qualification requirements are detailed in Site Administrative Procedures.

Below are various onsite and offsite positions correlated to ANSI N18.1.1971 and ANSI/ANS 3.1-1981 positions as appropriate. Site positions will meet or exceed these requirements at a minimum.

TVA Position Title	ANSI N18.1-1971 Position Titles
Plant Manager	Plant Managers
Director Maintenance	Maintenance Manager
Director Site Engineering	Engineer in charge
Senior Manager Systems Engineering	Technical Manager
Superintendent Operations	Operations Manager

TVA Position Title	ANSI N18.1-1971 Position Titles
Senior Manager Chemistry	Radiochemistry
Director Work Management	Maintenance Manager (Need not have non-destructive testing familiarity, craft knowledge, or complete understanding of electrical, pressure vessel, and piping codes and standards)
Assistant Unit Operator	Operators (Unlicensed)
Manager Reactor Engineering	Reactor Engineering & Physics
Superintendent Instrument & Controls Manager	Instrumentation & Control
Instrument Mechanics, Chemistry & Radiological Techicians, Health PhysicsTechnicians	Technicians
Craftsman (Mechanist, Electrician, Steamfitter, Boilermaker)	Repairmen
Offsite Supervisory Personnel	Staff Specialists
	ANSI/ANS 3.1-1981
Senior Manager Radiation Protection	Radiation Protection
Shift Technical Advisor*	Shift Technical Advisor
Shift Manager	Shift Supervisor
Unit Supervisor	Senior Operator
Unit Operator	Licensed Operator

13.1.4 Qualification Records of Plant Personnel

The qualifications of key plant personnel are maintained on site and are available for NRC inspection.

* An on-duty SRO, as required by 10CFR50.54(M)(2)(i), may serve as the individual that will provide the technical expertise on shift. The on-duty SRO shall meet the qualifications specified by the Commission Policy Statement on engineering expertise on shift.

13.2 TRAINING PROGRAMS

13.2.1 Accredited Training Programs

The Sequoyah Nuclear Plant (SNP) training programs have been developed in accordance with the Systems Approach to Training as described by the Institute for Nuclear Power Operations (INPO). The National Academy for Nuclear Training, through a formal accreditation process, verifies that SNP training programs meet the established criteria. SNP is a branch of the National Academy and has achieved accreditation of the following programs:

Non-licensed operator
Reactor operator
Senior reactor operator
Continuing training for licensed personnel
Shift manager
Shift technical advisor
Instrument and control mechanics
Electrical maintenance craftsmen
Mechanical maintenance personnel and supervisor
Radiological protection technician
Chemistry technician
Engineering support personnel

The training programs are periodically evaluated and revised as appropriate, and reviewed by management for effectiveness. Revisions are made as appropriate. Records are retained as necessary to support management information needs and to provide historical data.

13.2.2 General Employee Training Program

All persons regularly employed at SNP are trained in the following areas commensurate with their job duties:

Fitness for duty
General plant description
Job related procedures and instructions
Radiological protection
Emergency preparedness
Industrial safety
Fire protection
Security
Quality assurance

13.2.3 Other Training Programs

Responsible managers ensure that personnel performing quality-related activities receive indoctrination and training as necessary to ensure that adequate proficiency is achieved and maintained.

13.2.4 References

1. 10 CFR Part 55, Operator's Licenses
2. 10 CFR 50.120, Training and qualification of nuclear power plant personnel
3. Nuclear Quality Assurance Plan, TVA-NQA-PLN89-A

13.3 EMERGENCY PLANNING

The Radiological Emergency Plan (REP) has been developed to provide protective measures for TVA personnel and to protect the health and safety of the public in the event of a radiological emergency resulting from an accident at Sequoyah Nuclear Plant. This plan fulfills the requirements set forth in Part 50, Title 10 of the Code of Federal Regulations. The REP provides for the following:

1. Adequate measures to protect employees and the public.

2. Proper training for individuals having responsibilities during an accident.

3. Procedures to provide the capability to cope with a spectrum of accidents ranging from those of little consequence to major core melt.

4. Reference to equipment to detect, assess, and mitigate the consequences of such occurrences.

5. Emergency action levels and procedures to assist in making decisions.

The SQN emergency organization is such that broad functional areas are controlled from emergency centers located near the normal work areas. This is to ensure that the working staffs have the needed resources and are immediately available.

Specific information on TVA emergency centers is included in the REP and a site specific appendix. The appendix details facility features, capabilities, equipment, and responsibilities.

13.4 REVIEW AND AUDIT

13.4.1 Onsite Review

A continuing review of operational activities is a normal function of the plant staff. Two plant organizations, the Plant Operations Review Committee and the Nuclear Assurance (NA) Organization have specific responsibilities in the area of review of plant operation. A description of the NA Organization including their responsibility and authority is contained in Reference 2. In addition, the quorum requirements, meeting frequency, responsibility, authority, and record requirements of the Plant Operations Review Committee are contained in Reference 2.

13.4.2 Independent Review

Independent review of operational activities is the function of the TVA Nuclear Safety Review Board (NSRB). The NSRB reviews nuclear safety-related activities, programs, and events, including those required by plant technical specifications, to independently evaluate the safety of licensed TVA nuclear plants. Audits of activities identified in Reference 2 are performed under the cognizance of the NSRB. They advise the Chief Nuclear Officer on the nuclear safety significance of these reviews and audits and on the adequacy and implementation of TVA nuclear safety policies and programs. The NSRB consists of a chairman and members appointed by the Chief Nuclear Officer.

TVA internal procedures define the responsibility, authority, and method of operation of the NSRB. These procedures comply with the requirements of Reference 1.

13.4.3 Audit Program

The NA Organization is responsible for a system of planned and periodic audits of the nuclear plants and supporting organizations. Reference 2 describes the audit program and specific NA responsibilities. The audit program complies with the requirements of Reference 1 with the alternatives described by Reference 2.

13.4.4 References

1. "Administrative Controls and Quality Assurance for the Operational Phase of Nuclear Power Plants," ANSI-18.7-1976.

2. "Nuclear Quality Assurance Plan," TVA-NQA-PLN89-A.

13.5 SITE INSTRUCTIONS AND PROCEDURES

Instruction or procedure may be used interchangeably in 13.5.1.

13.5.1 System of Site Instructions and Procedures

Day-to-day operations are carried out by the various site sections. Each section, within its assigned area of responsibility, operates with some degree of independence and freedom from close supervision; yet their actions are closely coordinated to best achieve the common purpose. Written procedures are established, implemented, and maintained covering site activities as identified in Section 5.4 of the SQN Technical Specifications.

The Site Vice President or Plant Manager issues, in the form of administrative procedures, instructions governing employee actions and established standards for site or plant operation. Additionally, standard TVAN administrative procedures are issued by the Vice President Nuclear Support, which are applicable to all TVA plants. These instructions, written in accordance with ANSI N18.7-1976, contain administrative restrictions and station requirements established to ensure safe operation of the plant within the limits set by the facility licenses and technical specifications. They provide that plant activities will be conducted in a manner to protect the general public, site personnel, and equipment.

The formalized system of written instructions onsite conforms to the requirements of the TVA Nuclear Quality Assurance Plan. Figure 13.5.1-1 shows the organizational structure of these various instructions.

Instructions and procedures covering plant operations, maintenance work, tests, equipment changes, and other activities which might affect nuclear safety are put into effect only after being reviewed by a independent qualified reviewer(s), the Plant Operations Review Committee when required, and approved by a responsible manager who is designated by the Plant Manager. It is the Site Vice President's or Plant Manager's responsibility to ensure that required reviews and approvals are completed before instructions are authorized to be issued.

The Plant Operations Review Committee is responsible for reviewing proposed instructions and changes to plant instructions that would require NRC approval before implementation or prepared tests or experiments that affect nuclear safety. On the basis of the recommendations received from this group, the Plant Manager is responsible for determining whether further review is required before approving a new instruction or a change to an existing instruction.

13.5.1.1 Administrative Procedures

Instructions, standards, programs, and processes are prepared to govern employee actions and site and plant operation. These instructions contain administrative restrictions and station requirements established to ensure safe operation of the plant within the limits set by the facility licenses and technical specifications. They provide that plant activities will be conducted in a manner to protect the general public, plant personnel, and equipment.

13.5.1.2 Operating Instructions and Procedures

Operating instructions are prepared for integrated plant operations such as plant startup, power operation, etc., where such instructions are required to ensure safety and reliability. ANSI

N.18.7-1976, and Regulatory Guide 1.33, Rev. 2 are used as guidelines in the preparation of operating instructions.

13.5.1.2.1 System Operating Instructions

Operating instructions are prepared for system operations and equipment operations to ensure safety and reliability. Most instructions must be followed step-by-step and documented. These requirements are identified within the instruction.

The instructions contain mode of operation of the system such as startup, shutdown, energizing, filling and venting, and standby operation as applicable, conditions for operation, precautions to be observed, and technical specifications.

13.5.1.2.2 Abnormal Operating Instructions/Procedures

Abnormal operating instructions/procedures exist for abnormal operation of the unit. Operation of the system or equipment in this mode could degrade into an emergency condition. Symptoms of the abnormality and operator actions are given.

13.5.1.2.3 Emergency Operating Instructions/Procedures

Emergency Instructions are prepared for conditions which may possibly lead to injury of plant personnel or to the public or conditions which may possibly lead to the release of radioactivity in excess of established operating limits. These instructions provide symptoms of the postulated emergency and immediate (if applicable) and subsequent operator actions.

13.5.1.2.4 General Operating Instructions

General operating instructions are developed to ensure safe unit startup, shutdown, and load changes.

13.5.1.2.5 Fuel Handling Instructions

Detailed fuel handling instructions are used to ensure safe and orderly refueling operations. The instructions specify or make reference to other system operation documents that specify periodic shutdown margin checks, fuel handling techniques, and other precautionary steps to assure that the facility license and technical specifications are not violated. Licensed operators will supervise the operations when fuel is received, initially inventoried, stored, removed, or rearranged in the core or when control rods are being installed, removed, or manipulated. Technical personnel will provide guidance when necessary and will verify that all fuel has the proper orientation and is in the correct location.

13.5.1.2.6 Annunciator Response Instructions

Annunciator Response instructions are written to guide operator response to conditions that result in annunciation of plant conditions.

13.5.1.3 Maintenance Instructions

13.5.1.3.1 Equipment Maintenance Instructions

Written maintenance instructions are prepared for critical equipment and for special jobs on safety related systems and 10CFR50.49 equipment as the need arises, or systems and equipment expected to require frequent or systematic maintenance. These instructions covering mechanical and electrical maintenance provide information to assure proper coordination of operating and maintenance employees as well as step-by-step actions with allowance for "skill of the craft" to be followed by the craftsmen doing the work. As operating and maintenance experience is acquired, maintenance instructions are revised and/or new instructions are written to improve the quality of the maintenance program.

13.5.1.3.2 Instrumentation Maintenance Instructions

Instrument Maintenance instructions are written for performing periodic calibration and testing of safety-related plant instrumentation. These instructions will ensure measurement accuracies adequate to maintain plant safety parameters within operational and safety limits according to technical specification requirements.

13.5.1.3.3 Special Maintenance Instructions

Special Maintenance Instructions are developed for special maintenance activities. These instructions are not routinely performed, however, results from these performances may generate routinely performed instructions covered by one of the other types of instructions addressed in Section 13.5.1.

13.5.1.4 Surveillance Instructions

Instructions are prepared covering the conduct of all periodic surveillance tests and inspections designated in the plant technical specifications. These instructions as a minimum specify requirements, precautions, acceptance criteria, necessary step-by-step actions for conduct of the test and return to normal, data sheets, and signatures of those conducting and reviewing the tests or inspections. Detailed test schedules and records are maintained to assure that all scheduled surveillance requirements are conducted in a timely manner and the results are properly documented.

13.5.1.5 Technical Instructions

Instructions are prepared covering routine technical evolutions for tests, inspections, examinations, and special processes as required. Examples of these evolutions are chemical instructions, and calibration of vital instrumentation.

Fuel accountability instructions delineating the requirements, responsibilities, and methods of nuclear material control from the time new fuel is received until it is shipped from the plant as spent fuel are utilized. They provide detailed steps for physical safeguards, inventory, accounting, and for preparing records and reports.

13.5.1.6 Radiation Control Instructions

Radiation control instructions are maintained and made available to all site personnel. These instructions are written to implement the requirements of 10 CFR 20, applicable codes and standards, and commitments to outside agencies (American Nuclear Insurers, Institute of Nuclear Plant Operations, etc).

13.5.1.7 Special Test Instructions

Instructions are prepared for special test and experiments. These instructions are normally one time performances, however, results from these tests may generate routinely performed instructions covered by one of the other types of instructions addressed in section 13.5.1.

13.5.1.8 Radiological Emergency Plan (REP) Implementing Procedures

Procedures are prepared covering the site implementation of the REP. See Subsection 13.3.

13.5.1.9 Vendor or Contractor Instructions

Instructions are prepared to convert vendor or contractor instructions into plant instructions, as applicable. These instructions will meet TVA quality assurance program and site administrative requirements.

13.5.1.10 Radwaste Handling & Shipping

Instructions are prepared covering compacting trash, packing and shipping of radioactive waste and materials or equipment, and the process control program for the radwaste system.

13.5.1.11 Flood Preparation Instructions

Instructions are prepared covering plant activities for flood conditions. These instructions provide directions of activities affecting important equipment or systems that would require extra protection to maintain their operability during a flood.

13.5.1.12 Restart Test Instructions

Instructions are prepared covering restart sequence, core reloading, initial criticality, flux mapping, and power ascension.

13.5.1.13 Modifications and Additions Instructions

Instructions are prepared covering modifications and additions to plant systems and equipment. Processes covered by these instructions include welding; pulling, splicing, and installation of cables; conduit and junction boxes; bolted connections; supports; grouting; conax connectors; coatings; and concrete.

13.5.1.14 Physical Security Instructions/Standard Programs and Processes

Instructions are prepared covering plant access, badging, vehicles, searches, physical security of vital areas of plant, security events, security degradation, and reporting and security inspections.

13.5.1.15 Periodic Instructions

Instructions are prepared covering periodic tests and inspections which are not designated in the plant technical specifications. These include but are not limited to tests designated by applicable FSAR sections, the NPDES permit, and augmented QA/test programs.

13.5.2 Safety and Health Manual

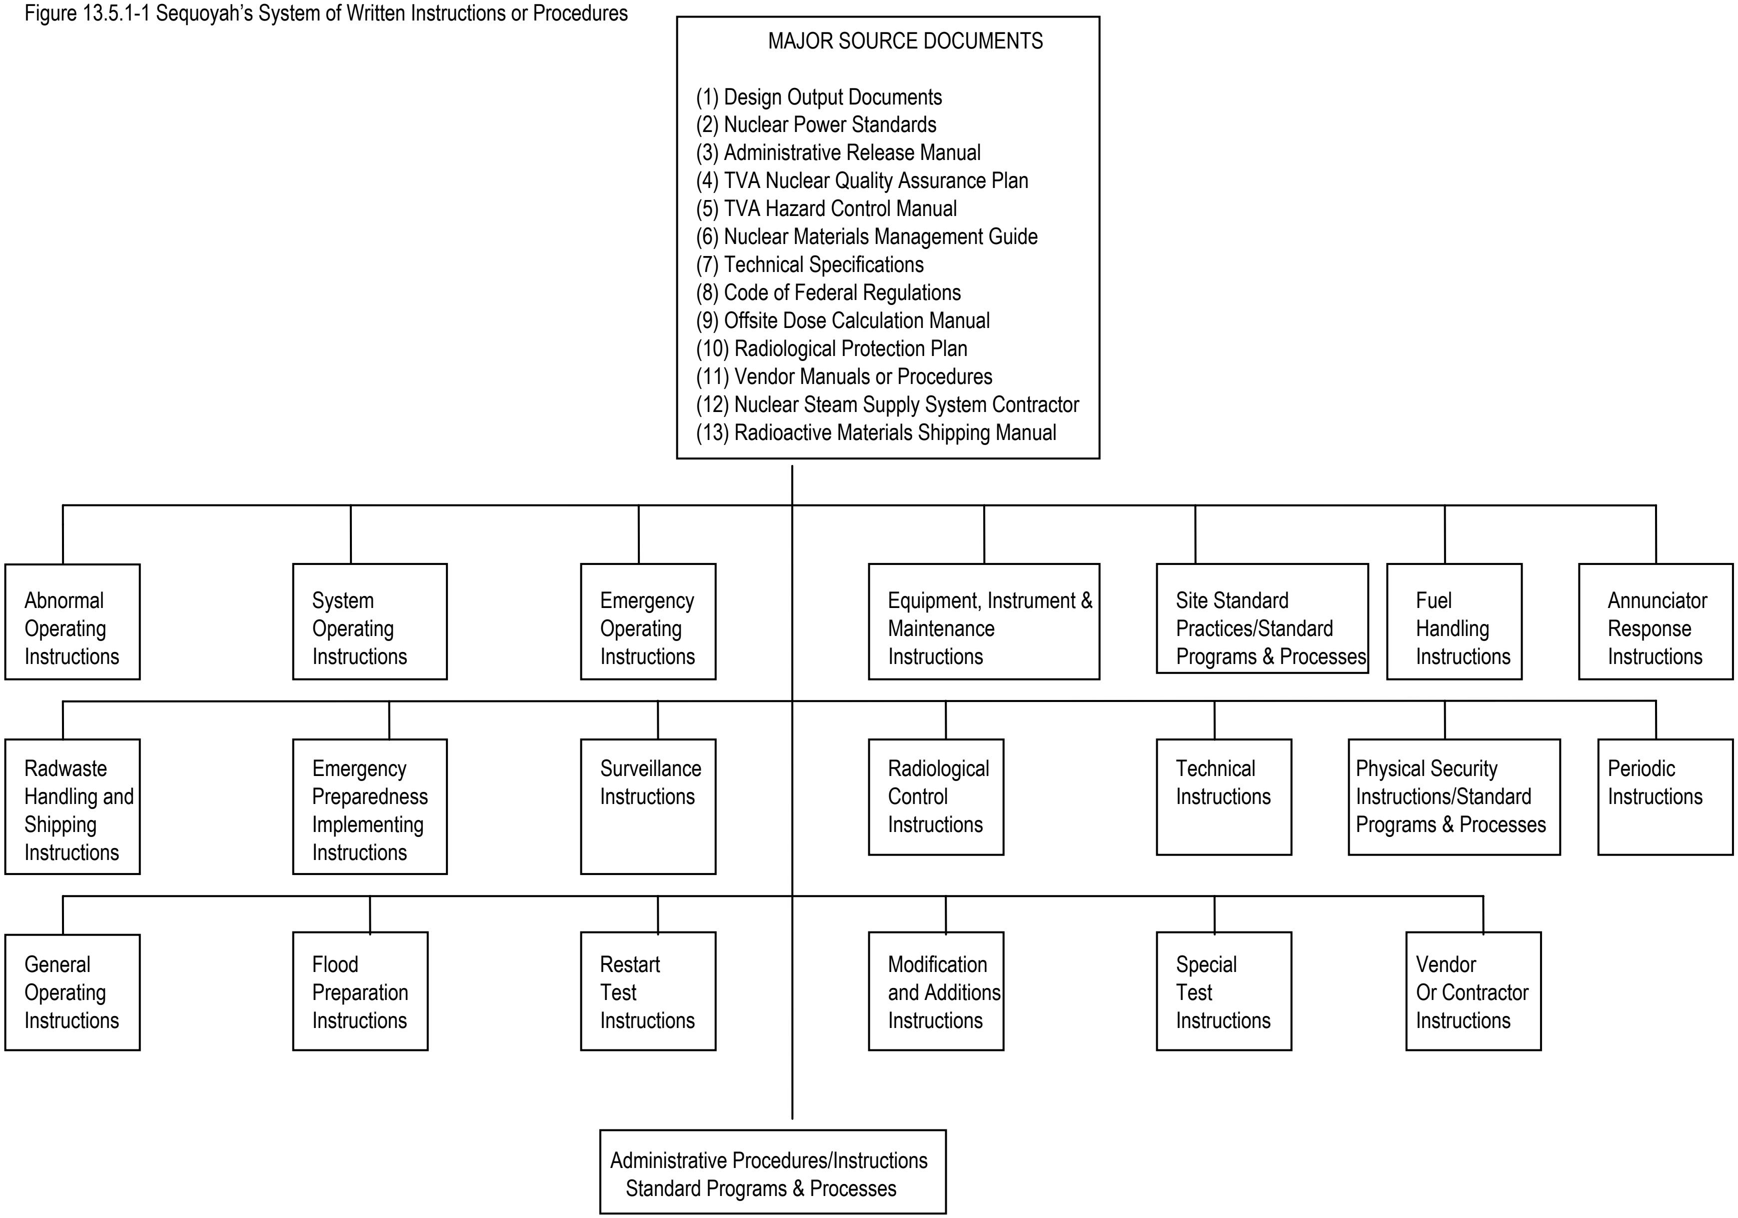
Instructions are prepared covering safety measures to be taken by personnel when handling certain types of portable mechanical or electrical equipment and protective measures which inspecting electrical equipment.

13.5.3 Section Instruction, Manuals or Equivalent

Each section supervisor may prepare, as the need arises, instructions pertaining to administrative routines, responsibilities, and methods to be followed by members of his/her section in areas of activity that does not involve nuclear safety and/or the implementation of the technical specifications.

SQN

Figure 13.5.1-1 Sequoyah’s System of Written Instructions or Procedures



13.6 PLANT RECORDS

13.6.1 Plant History

TVA's records program observes all acts of Congress, executive orders, and regulations of Federal agencies having jurisdiction in records administration (for the particular case of nuclear plants, this includes 10 CFR 50, Appendix B, Section XVII). TVA complies with Department of Energy regulations concerning the preservation and disposal of records of public utilities and licensees, insofar as these regulations apply to TVA records relating to the generating, transmission, and sale of electric energy.

The site Management Services (MS) Manager has responsibility for 1) developing, implementing, and maintaining an integrated site program to ensure that documents are properly processed up-to-date, and readily available for use, 2) managing a program for storing, updating, and retrieving plant documents.

13.6.2 Operating Records

Records reflecting plant or equipment performance and records of tests and inspections which support compliance with the plant licenses, including records of radioactivity release to the environs, are routed to site MS for retention. These records are originated by all plant sections.

Operators maintain unit operating logs which are a chronological record of significant plant events and conditions containing details pertinent to the operation of each unit. The unit logs are retained in the Site MS. Operators also maintain operating data which ensure their frequent observations of equipment condition and operating values. These records are examined by the plant operations supervisor and are support documents for performance analysis.

The station computer printouts and the operations data serve as the normal source of operating data and statistics. To ensure continuity of information, provision is made for supplementary data to be maintained if the computer becomes inoperative. In addition, this information is supported by installed recording and data logging instrumentation. These records are sent to Site MS on a regular basis for retention.

The Maintenance and Engineering sections initiate equipment history and inventory files. The history files are maintained and updated by Site MS. These records contain complete information on all repairs, modifications, tests, derangements, and other data as considered necessary to provide a comprehensive material history of the item concerned.

Specific records and their retention periods are specified in the TVA Nuclear Quality Assurance Plan, TVA NQA-PLN89-A.

13.6.3 Event Records

Records of individual radiation exposure and plant and environs radiation levels are retained by Radiological Control.

Records of results of all surveillance and maintenance requirements are retained by Site MS. Records of radioactive effluent discharges and quantities of radioactive wastes shipped for offsite disposal are also retained by Site MS.

13.7 NUCLEAR SECURITY

TVA's plan for protection of the Sequoyah Nuclear Plant is contained in separate controlled documents. These documents require submission as separate submittals to ensure compliance with the applicable regulatory requirements indicated below. These separate submittals provide a comprehensive description of the physical security program for the plant site which include physical barriers and means of detecting unauthorized intrusions; provisions for monitoring vital equipment and access control; provisions for selection and training of personnel for security purposes; communication systems for security; provisions for maintenance and testing of security systems; arrangements for law enforcement assistance; provisions for responding to security threats; and required organizational charts and drawings that depict the site layout. These documents are identified and controlled as follows:

A. The Physical Security/Contingency plan as specified by 10 CFR Parts 50.34(c), 50.34(d), and 73.55(a), and the Security Personnel Training and Qualification Plan as specified by 10 CFR 73.55(b) are controlled in accordance with 10 CFR 73.21.

13.7.1 Personnel and Plant Design

TVA's Nuclear Power organization is responsible for protection of power properties with functional responsibility delegated to the Senior Vice President of Nuclear Power.

The Manager, Corporate Nuclear Security, represents Nuclear Power on all security matters and is responsible for developing policy for TVA's nuclear security program.

The Sequoyah Security Program is evaluated in accordance with 10 CFR 73.55(g)(4) by individual(s) who are knowledgeable of security requirements and independent of both security management and supervision. The review is conducted to determine the effectiveness of security procedures and personnel practices as they relate to the implementation of licensed security documents. Based on the review, a detailed report is submitted to appropriate management recommending corrective action and improvements, if any, to ensure the successful implementation of the security program.

13.8 Technical Requirements Manual (TRM)

The TRM is maintained in one volume for Units 1 and 2. The TRM provides an appropriate location for relocated technical specification requirements that have an action that could require a unit shutdown. The change control process for the TRM is provided in the TRM.

13.9 LICENSE RENEWAL PROGRAM

13.9.1 License Renewal -Appendix A

Appendix A represents the Updated Final Safety Analysis Report (UFSAR) Supplement as required by 10 CFR 54.21(d) for the Sequoyah Nuclear Plant (SQN) License Renewal Application (LRA).

The information presented in Appendix A is being incorporated into the UFSAR following issuance of the renewed operating license (Reference 5). Future changes to the descriptions of the programs and activities will be made in accordance with 10 CFR 50.59.

APPENDIX A

A.0 AGING MANAGEMENT PROGRAMS AND ACTIVITIES

The SQN license renewal application (Reference A.3-1) and information in subsequent related correspondence provided sufficient basis for the NRC to make the findings required by 10 CFR 54.29 (Final Safety Evaluation Reports) (Reference A.3-2). As required by 10 CFR 54.21(d), this UFSAR supplement contains a summary description of the programs and activities for managing the effects of aging (Section A.1) and a description of the evaluation of time-limited aging analyses for the period of extended operation (Section A.2). The period of extended operation is the 20 years after the expiration dates of the original operating licenses for SQN Unit 1 and Unit 2.

A.1 AGING MANAGEMENT PROGRAMS

The integrated plant assessment for license renewal identified aging management programs (AMPs) necessary to provide reasonable assurance that components within the scope of license renewal will continue to perform their intended functions consistent with the current licensing basis (CLB) for the period of extended operation (PEO). This section describes the AMPs and activities required during the PEO.

The phrase “prior to entering the PEO” means the SQN AMPs will be implemented six months prior to the PEO (for SQN1: prior to 03/17/20; for SQN2: prior to 03/15/21) or the end of the last refueling outage prior to each unit entering the PEO, whichever occurs later. The specific implementation date is provided in the commitment list for each individual commitment.

The corrective action, confirmation process, and administrative controls of the SQN (10 CFR Part 50, Appendix B) Quality Assurance Program are applicable to all aging management programs and activities during the PEO. SQN quality assurance (QA) procedures, review and approval processes, and administrative controls are implemented in accordance with the requirements of 10 CFR 50, Appendix B. The SQN Quality Assurance Program applies to safety-related and important-to-safety structures and components. Corrective actions and administrative (document) control for both safety-related and nonsafety-related structures and components are accomplished in accordance with the established SQN corrective action program (CAP) and document control program and are applicable to all aging management programs and activities during the period of extended operation. The confirmation process is part of the corrective action program and includes reviews to assure adequacy of corrective actions, tracking and reporting of open corrective actions, and review of corrective action effectiveness. Any follow-up inspection required by the confirmation process is documented in accordance with the corrective action program.

Operating experience (OE) from plant-specific and industry sources is captured and systematically reviewed on an ongoing basis in accordance with the quality assurance program, which meets the requirements of 10 CFR Part 50, Appendix B, and the operating experience program, which meets the requirements of NUREG-0737, "Clarification of TMI Action Plan Requirements," Item I.C.5, "Procedures for Feedback of Operating Experience to Plant Staff."

The OE Program includes the review of current and future revisions to NUREG-1801, “Generic Aging Lessons Learned (GALL) Report,” as a source of industry OE. The evaluation of age-related OE items is based on consideration of affected plant systems, structures, and components; materials; environments; aging effects, aging mechanisms; aging management programs; and the

activities, criteria, and evaluations integral to the elements of the aging management programs.

Codes are used in the corrective action program that provide for the comprehensive identification and categorization of aging-specific issues for plant systems, structures, and components within the scope of license renewal.

The operating experience program includes active participation in the Institute of Nuclear Power Operations' operating experience program, as endorsed by the NRC.

In accordance with these programs, all incoming operating experience items are screened to determine whether they may involve age-related degradation or impact to aging management programs (AMPs). Items so identified are further evaluated, and affected AMPs are either enhanced or new AMPs are developed, as appropriate, when it is determined through these evaluations that the effects of aging may not be adequately managed.

Assessments of AMP effectiveness are performed periodically, regardless of whether the AMP acceptance criteria are met. If an assessment concludes that the effects of aging may not be adequately managed, then a corrective action is entered into the corrective action program to either enhance the AMP or develop and implement new AMPs.

Training will be provided on aged-related topics for personnel responsible for submitting, screening, assigning, evaluating, or otherwise processing plant-specific and industry operating experience, as well as for personnel responsible for implementing AMPs, is based on the complexity of the job performance requirements and assigned responsibilities. Training is scheduled on a recurring basis, which accommodates the turnover of plant personnel and allows for incorporation of new training content.

Plant-specific operating experience associated with aging management and age-related degradation is reported to the industry in accordance with guidelines established in the operating experience review program.

The following enhancements have been implemented.

- Revise OE Program Procedure to include current and future revisions to NUREG-1801, “Generic Aging Lessons Learned (GALL) Report,” as a source of industry OE, and unanticipated age-related degradation or impacts to aging management activities as a screening attribute.
- Revise the CAP Procedure to provide a screening process of corrective action documents for aging management items, the assignment of aging corrective actions to appropriate AMP owners, and consideration of the aging management trend code.
- Revise AMP procedures as needed to provide for review and evaluation by AMP owners of data from inspections, tests, analyses or AMP OEs.

- Revise the OE Program Procedure to provide guidance for reporting plant-specific operating experience on unanticipated age-related degradation or impact to aging management activities to the TVA fleet and/or INPO.Revise the OE, CAP, Initial and Continuing Engineering Support Personnel Training to address age-related topics, the unanticipated degradation or impacts to the aging management activities; including periodic refresher/update training and provisions to accommodate the turnover of plant personnel, and recent AMP-related OE from INPO, the NRC, Scientech, and nuclear industry-initiated guidance documents and standards.
- A comprehensive and holistic AMP training topic list will be developed before the date the SQN renewed operating license is scheduled to be issued.
- TVA AMP OE Process, AMP adverse trending & evaluation in CAP, AMP Initial and Refresher Training will be fully implemented by the date the SQN renewed operating license is scheduled to be issued.

A.1.1 Aboveground Metallic Tanks Program

The Aboveground Metallic Tanks Program includes outdoor tanks on soil or concrete and indoor large volume water tanks (excluding the fire water storage tanks) situated on concrete that are designed for internal pressures approximating atmospheric pressure. This program includes the Refueling Water Storage Tanks and the Condensate Storage Tanks. Periodic external visual and surface examinations are sufficient to monitor degradation. Internal visual and surface examinations are conducted in conjunction with measuring the thickness of the tank bottoms to ensure that significant degradation is not occurring and that the component's intended function is maintained during the PEO. Internal inspections are conducted whenever the tank is drained, with a minimum frequency of at least once every 10 years, beginning in the appropriate interval (5-years for one time inspections, 10-years for periodic inspections) prior to the PEO. The program is consistent with NRC guidance contained in Appendix E of LR-ISG-2012-02 "Aging Management of Internal Surfaces, Fire Water Systems, Atmospheric Storage Tanks, and Corrosion Under Insulation" which represents an acceptable deviation from the requirements of the GALL Report for the Aboveground Metallic Tanks Program.

APPENDIX A

The following table provides tank inspection details:

Tank Inspection Recommendations[1, 2]				
Material	Environment	AERM	Inspection Technique[3]	Inspection Frequency
Inspections to identify degradation of inside surfaces of tank shell, roof[4], and bottom Inside Surface (IS), Outside Surface (OS)[5, 6]				
Steel	Raw water Waste water	Loss of material	Visual from IS or Volumetric from OS[7]	Each 10-year period starting 10 years before the period of extended operation
Steel	Treated water	Loss of material	Visual from IS or Volumetric from OS[7]	One-time inspection conducted in accordance with AMP XI.M32[8]
Stainless steel	Treated water	Loss of Material	Visual from IS or Volumetric from OS[7]	One-time inspection conducted in accordance with AMP XI.M32[8]
Aluminum	Treated water	Loss of Material	Visual from IS or Volumetric from OS[7]	One-time inspection conducted in accordance with AMP XI.M32[8]
Inspections to identify degradation of external surfaces of tank roof, tank shell, and bottom not exposed to soil or concrete[9]				
Steel	Air – indoor uncontrolled Air – outdoor	Loss of material	Visual from OS	Each refueling outage interval
Stainless steel	Air – indoor uncontrolled	Cracking	Surface [10, 11]	Each 10-year period starting 10 years before the period of extended operation
Stainless steel	Air-outdoor	Loss of material	Visual from OS	Each refueling outage interval
		Cracking	Surface[10, 11]	Each 10-year period starting 10 years before the period of extended operation
Aluminum	Air – indoor uncontrolled	Cracking	Surface[10, 11]	Each 10-year period starting 10 years before the period of extended operation
Aluminum	Air-outdoor	Loss of material	Visual from OS	Each refueling outage interval
		Cracking	Surface[10, 11]	Each 10-year period starting 10 years before the period of extended operation
Inspections to identify degradation of external surfaces of tank bottoms and tank shells exposed to soil or concrete				
Steel	Soil or concrete	Loss of material	Volumetric from IS[12]	Each 10-year period starting 10 years before the period of extended operation[13]
Stainless steel	Soil or concrete	Loss of material	Volumetric from IS[12]	Each 10-year period starting 10 years before the period of extended operation[13]
Aluminum	Soil or concrete	Loss of Material	Volumetric from IS[12]	Each 10-year period starting 10 years before the period of extended operation[13]

APPENDIX A

1. GALL Report AMP XI.M30, “Fuel Oil Chemistry,” is used to manage loss of material on the internal surfaces of fuel oil storage tanks. However, for outdoor fuel oil storage tanks, inspections to identify aging of the external surfaces of tank bottoms and tank shells exposed to soil or concrete are conducted in accordance with GALL Report AMP XI.M29. GALL Report AMP XI.M41 is used to manage loss of material and cracking for the external surfaces of buried tanks.
2. When one-time internal inspections in accordance with these footnotes are used in lieu of periodic inspections, the one-time inspection must occur within the 5-year period before the start of the PEO.
3. Alternative inspection methods may be used to inspect both surfaces (i.e., internal, external) or the opposite surface (e.g., inspecting the internal surfaces for loss of material from the external surface, inspecting for corrosion under external insulation from the internal surfaces of the tank) as long as the method has been demonstrated to be effective at detecting the AERM and a sufficient amount of the surface is inspected to ensure that localized aging effects are detected. For example, in some cases, subject to being demonstrated effective by the applicant, the low frequency electromagnetic technique (LFET) can be used to scan an entire surface of a tank. If follow-up ultrasonic examinations are conducted in any areas where the wall thickness is below nominal, an LFET inspection can effectively detect loss of material in the tank shell, roof, or bottom.
4. Non-wetted surfaces on the inside of a tank (e.g., roof, surfaces above the normal waterline) are inspected in the same manner as the wetted surfaces based on the material, environment, and AERM.
5. Visual inspections to identify degradation of the inside surfaces of tank shell, roof, and bottom should cover all the inside surfaces. Where this is not possible because of the tank’s configuration (e.g., tanks with floating covers or bladders), the LRA should include a justification for how aging effects will be detected before the loss of the tank’s intended function.
6. For tank configurations in which deleterious materials could accumulate on the tank bottom (e.g., sediment, silt), the internal inspections of the tank’s bottom should include inspections of the side wall of the tank up to the top of the sludge-affected region.
7. At least 25 percent of the tank’s internal surface is to be inspected using a method capable of precisely determining wall thickness. The inspection method should be capable of detecting both general and pitting corrosion and be demonstrated effective by the applicant.
8. At least one tank for each material and environment combination should be inspected at each site. The tank inspection can be credited towards the sample population for GALL Report AMP XI.M32.

9. For insulated tanks, the external inspections of tank surfaces that are insulated are conducted in accordance with the sampling recommendations in this AMP. If the initial inspections meet the criteria described in the preceding “Alternatives to Removing Insulation” portion of this AMP, subsequent inspections may consist of external visual inspections of the jacketing in lieu of surface examinations. Tanks with tightly adhering insulation may use the “Alternatives to Removing Insulation” portion of this AMP for initial and all follow-on inspections.
10. A one-time inspection conducted in accordance with GALL Report AMP XI.M32 may be conducted in lieu of periodic inspections if an evaluation conducted before the PEO and during each 10-year period during the PEO demonstrates the absence of environmental impacts in the vicinity of the plant due to: (a) the plant being located within approximately 5 miles of a saltwater coastline, or within 1/2 mile of a highway that is treated with salt in the wintertime, or in areas in which the soil contains more than trace amounts of chlorides, (b) cooling towers where the water is treated with chlorine or chlorine compounds, and (c) chloride contamination from other agricultural or industrial sources. The evaluation should include soil sampling in the vicinity of the tank (because soil results indicate atmospheric fallout accumulating in the soil and potentially affecting tank surfaces) and sampling of residue on the top and sides of the tank to ensure that chlorides or other deleterious compounds are not present at sufficient levels to cause pitting corrosion, crevice corrosion, or cracking.
11. A minimum of either 25 sections of the tank’s surface (e.g., 1-square-foot sections for tank surfaces, 1-linear-foot sections of weld length) or 20 percent of the tank’s surface are examined. The sample inspection points are distributed in such a way that inspections occur in those areas most susceptible to degradation (e.g., areas where contaminants could collect, inlet and outlet nozzles, welds).
12. When volumetric examinations of the tank bottom cannot be conducted because the tank is coated, an exception should be stated, and the accompanying justification for not conducting inspections should include the considerations in footnote 13, below, or propose an alternative examination methodology.

13. A one-time inspection conducted in accordance with GALL Report AMP XI.M32 may be conducted in lieu of periodic inspections if an evaluation conducted before the PEO and during each 10-year period during the PEO demonstrates that the soil under the tank is not corrosive using actual soil samples that are analyzed for each individual parameter (e.g., resistivity, pH, redox potential, sulfides, sulfates, moisture) and overall soil corrosivity. The evaluation should include soil sampling from underneath the tank. Alternatively, a one-time inspection conducted in accordance with GALL Report AMP XI.M32 may be conducted in lieu of periodic inspections if the bottom of the tank has been cathodically protected in such a way that the availability and effectiveness criteria of LR-ISG-2011-03, “Changes to the Generic Aging Lessons Learned (GALL) Report Revision 2 Aging Management Program (AMP) XI.M41, ‘Buried and Underground Piping and Tanks’,” Table 4c., “Inspections of Buried Tanks for all Inspection Periods,” have been met beginning 5 years prior to the PEO, and the criteria continue to be met throughout the PEO.

A.1.2 Bolting Integrity Program

The Bolting Integrity Program manages loss of preload, cracking, and loss of material for closure bolting for safety-related and nonsafety-related pressure-retaining components using preventive and inspection activities. This program does not include the reactor head closure studs or structural bolting. Preventive measures include material selection (e.g., use of materials with an actual yield strength of less than 150 kilo-pounds per square inch [ksi]), lubricant selection (e.g., restricting the use of molybdenum disulfide), applying the appropriate preload (torque), and checking for uniformity of gasket compression where appropriate to preclude loss of preload, loss of material, and cracking. This program supplements the inspection activities required by ASME Section XI for ASME Class 1, 2 and 3 bolting. For ASME Code Class 1, 2, and 3, and non-ASME Code class bolts, periodic system walkdowns and inspection (at least once per refueling cycle) ensure identification of indications of loss of preload (leakage), cracking, and loss of material before leakage becomes excessive. A representative sample of submerged bolts in the ERCW system are visually inspected for degradation at least once every five years. The representative sample for ERCW system submerged bolts will be 20% of the population, with a maximum of 25, during each five year inspection interval. The inspection of ERCW system submerged bolts focuses on the bounding or lead components most susceptible to aging due to time in service and severity of operating conditions. Visual inspection methods are effective in detecting the applicable aging effects and the frequency of inspection is adequate to prevent significant age-related degradation. No high-strength bolting has been identified at SQN. Identified leaking bolted connections will be monitored at an increased frequency in accordance with the corrective action process. Applicable industry standards and guidance documents, including NUREG-1339, EPRI NP-5769, and EPRI TR-104213, are used to delineate the program.

The Bolting Integrity Program has been enhanced as follows.

- Revise Bolting Integrity Program procedures to ensure the actual yield strength of replacement or newly procured bolts will be less than 150 ksi.

- Revise Bolting Integrity Program procedures to include the additional guidance and recommendations of EPRI NP-5769 for replacement of ASME pressure-retaining bolts and the guidance provided in EPRI TR-104213 for the replacement of other pressure-retaining bolts.

- Revise Bolting Integrity Program procedures to specify a corrosion inspection and a check-off for the transfer tube isolation valve flange bolts."

- Revise Bolting Integrity Program procedures to visually inspect a representative sample of normally submerged ERCW system bolts at least once every five years."

A.1.3 Boric Acid Corrosion Program

The Boric Acid Corrosion Program manages loss of material and increase in connection resistance for components on which borated reactor water may leak. The program consists of (a) visual inspection of external surfaces that are potentially exposed to borated water leakage, (b) timely discovery of leak path and removal of boric acid residues, (c) assessment of the damage, and (d) follow-up inspection for adequacy. This program was implemented in response to NRC Generic Letter (GL) 88-05 and industry operating experience.

The program provides systematic measures to ensure that corrosion caused by leaking borated coolant does not lead to degradation of the leakage source, adjacent structures, or electrical components and provides reasonsable assurance that the reactor coolant pressure boundary will have an extremely low probability of abnormal leakage, rapidly propagating failure, or gross rupture. Visual inspections are performed for boric acid deposits, discoloration, staining, and moisture on insulated surfaces. If evidence of leakage is identified, insulation is required to be removed to determine the exact location and cause of the leakage. The Boric Acid Corrosion Program includes provisions for triggering evaluations and assessments when leakage is discovered by other activities (normal plant walkdowns, maintenance, etc.) to identify and correct boric acid leakage before loss of intended function of affected components. Corrective actions may include modifications to existing design or operating procedures to reduce the probability of boric acid leakage at locations where such leaks may cause corrosion damange.

A.1.4 Buried and Underground Piping and Tanks Inspection Program

The Buried and Underground Piping and Tanks Inspection Program manages loss of material and cracking for the external surfaces of buried and underground piping fabricated from carbon steel and stainless steel through preventive measures (i.e., coatings, backfill, and compaction), mitigative measures (e.g., electrical isolation between piping and supports of dissimilar metals), and periodic inspection activities (i.e., direct visual inspection of external surfaces, protective coatings, wrappings, and quality of backfill) during opportunistic or directed excavations. There are no underground or buried tanks at SQN for which aging effects are managed by the Buried and Underground Piping and Tanks Inspection Program.

Based on the guidance of NUREG-1801 Rev. 2, Section XI.M41, as modified by LR-ISG-2015-01, cathodic protection will be provided at SQN prior to the period of extended operation of Unit 1.

Based on the guidance of NUREG-1801 Rev. 2, Section XI.M41, as modified by LR-ISG-2015-01, buried high pressure fire protection (HPFP) piping will be managed by periodic flow testing in accordance with NFPA 25. The cathodic protection system will not be credited for protecting the buried high pressure fire protection piping.

A.1.5 Compressed Air Monitoring Program

The Compressed Air Monitoring Program manages loss of material in compressed air systems by periodically monitoring air samples for moisture and contaminants and by opportunistically

inspecting internal surfaces within compressed air systems. Inspection frequency and acceptance criteria are based on the SQN response to NRC GL 88-14 and SOER 88-01 along with applicable industry standards and documents such as ASME OMa-S/G-1998, Part 17 and ISA-S7.0.1-1996 for guidance on testing and monitoring air quality.

The Compressed Air Monitoring Program has been enhanced as follows.

- Revise Compressed Air Monitoring Program procedures to include the standby diesel generator (DG) starting air subsystem.
- Revise Compressed Air Monitoring Program procedures to include maintaining moisture and other contaminants below specified limits in the standby DG starting air subsystem.

- Revise Compressed Air Monitoring Program procedures to apply a consideration of the guidance of ASME OMa-S/G-1998, Part 17; EPRI NP-7079; and EPRI TR-108147 to the limits specified for the air system contaminants.

- Revise Compressed Air Monitoring Program procedures to maintain moisture, particulate size, and particulate quantity below acceptable limits in the standby DG starting air subsystem to mitigate loss of material.

- Revise Compressed Air Monitoring Program procedures to include periodic and opportunistic visual or nondestructive examination (NDE) inspections consistent with frequencies described in ASME OMa-S/G-1998, Part 17 of accessible internal surfaces such as compressors, dryers, after-coolers, and filter boxes of the following compressed air systems:

    - Diesel starting air subsystem

    - Auxiliary controlled air subsystem

    - Nonsafety-related controlled air subsystem

- Revise Compressed Air Monitoring Program procedures to monitor and trend moisture content in the standby DG starting air subsystem.

- Revise Compressed Air Monitoring Program procedures to include consideration of the guidance for acceptance criteria in ASME OMa-S/G-1998, Part 17; EPRI NP-7079; and EPRI TR-108147.

A.1.6 <u>Containment Inservice Inspection – IWE Program</u>

The Containment Inservice Inspection (CII) – IWE Program implements the requirements of 10 CFR 50.55a. The regulations in 10 CFR 50.55a impose the inservice inspection (ISI) requirements of the American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel (B&PV) Code, Section XI, Subsection IWE, for steel containments (Class MC) and steel liners for concrete containments (Class CC). The SQN containment design is a low-leakage, free-standing steel containment founded on the circular concrete foundation slab of the shield building. The portion of SQN's containment that is classified as Class CC equivalent is the circular concrete foundation slab of the shield building. The bottom steel liner plate of the steel containment vessel was erected on top of the circular concrete foundation slab with a two-foot thick concrete slab poured on top of the liner plate. Since the Class CC equivalent concrete foundation slab and the bottom steel liner plate are inaccessible, they are exempted from examination in accordance with IWL-1220(b) and IWE-1220(b). There are no tendons associated with SQN's steel containment vessel. The code of record for the examination of the SQN containment, Class MC and Class CC components is ASME Code Section XI, Subsections IWE and IWL, 2001 Edition with the 2003 Addenda, as mandated and modified by 10 CFR 50.55a.

The CII-IWE Program is augmented by plant procedures that use the guidance of EPRI TR-104213, NUREG-1339, and EPRI NP-5769 to ensure proper specification of bolting material, lubricant and sealants, and installation torque. .

A.1.7 Containment Leak Rate Program

The Containment Leak Rate Program consists of tests performed in accordance with the regulations and guidance provided in 10 CFR Part 50, Appendix J, "Primary Reactor Containment Leakage Testing for Water-Cooled Power Reactors," Option B; NEI 94-01, "Industry Guideline for Implementing Performance-Based Options of 10 CFR Part 50, Appendix J"; Revision 3-A and Revision 2-A; and ANSI/ANS 56.8, "Containment System Leakage Testing Requirements," 2002 Edition. The Containment Leak Rate Program provides for detection of pressure boundary degradation due to aging effects such as loss of leakage tightness, loss of material, cracking, loss of sealing, or loss of preload in various systems penetrating containment. The program also provides for detection of age-related degradation in material properties of gaskets, O-rings, and packing materials for the containment pressure boundary access points.

Three types of tests are performed under Option B. Type A tests are performed to determine the overall primary containment integrated leakage rate at the loss of coolant accident peak containment pressure. Performance of the integrated leakage rate test (ILRT) per 10 CFR Part 50, Appendix J, Option B, demonstrates the leak-tightness and structural integrity of the containment. Type B containment leakage rate tests (LRT) are intended to detect local leaks and to measure leakage across each pressure-containing or leakage-limiting boundary of containment penetrations. Type C tests are intended to detect local leaks and to measure leakage across containment isolation valves installed in containment penetrations or lines penetrating containment. Containment leakage rate tests are performed at frequencies that comply with the requirements of 10 CFR Part 50, Appendix J, Option B.

“The Containment Leak Rate Program has been enhanced as follows.

- Revise Containment Leak Rate Program procedures to require venting the SCV bottom liner plate weld leak test channels to the containment atmosphere prior to the CILRT and resealing the vent path after the CILRT to prevent moisture intrusion during plant operation.”

A.1.8 Diesel Fuel Monitoring Program

The Diesel Fuel Monitoring Program manages loss of material in piping, tanks, and components exposed to an environment of diesel fuel oil by verifying quality of the fuel oil source before allowing it to enter the fuel oil storage tanks, as well as periodic draining, cleaning, and inspection of the fuel oil storage tanks. Applicable industry standards and guidance documents are used to establish inspection frequency. Acceptance criteria for fuel oil quality parameters are specified in the SQN technical specifications.

The One-Time Inspection Program (Section A.1.29) describes inspections planned to verify that the Diesel Fuel Monitoring Program has been effective at managing aging effects.

The Diesel Fuel Monitoring Program has been enhanced as follows.

- Revise Diesel Fuel Monitoring Program procedures to monitor and trend sediment and particulates in the standby DG day tanks.

- Revise Diesel Fuel Monitoring Program procedures to monitor and trend levels of microbiological organisms in the seven-day storage tanks.

- Revise Diesel Fuel Monitoring Program procedures to include a ten-year periodic inspection of the standby DG diesel fuel oil day tanks and high pressure fire protection (HPFP) diesel fuel oil storage tank. These inspections will be performed at least once during the ten-year period prior to the period of extended operation and at succeeding ten-year intervals. If a visual inspection is not possible, a volumetric inspection will be performed. The HPFP diesel fuel oil storage tank inspections will be supplemented by cleaning, if necessary based on inspection results, to remove any accumulated sediment. The standby DG diesel fuel oil day tank inspections will be supplemented by cleaning, to remove sediment, if warranted based on the results of a) periodic cleaning of the yard fuel oil storage tanks and seven-day tanks, b) periodic cleaning of the fuel pump suction strainers and filters, and c) day tank sediment and particulate monitoring.

- Revise Diesel Fuel Monitoring Program procedures to include a volumetric examination of affected areas of the diesel fuel oil tanks, if evidence of degradation is observed during visual inspection. The scope of this enhancement includes the standby DG seven-day fuel oil storage tanks, standby DG fuel oil day tanks, and HPFP diesel fuel oil storage tank and is applicable to the inspections performed during the ten-year period prior to the period of extended operation and succeeding ten-year intervals.

A.1.9 Environmental Qualification (EQ) of Electric Components Program

The Environmental Qualification (EQ) of Electric Components Program manages the effects of thermal, radiation, and cyclic aging through the use of aging evaluations based on 10 CFR 50.49(f) qualification methods. As required by 10 CFR 50.49, EQ components are refurbished, replaced, or their qualification is extended prior to reaching the aging limits established in the evaluation. Reanalysis of an aging evaluation addresses attributes of analytical methods, data collection and reduction methods, underlying assumptions, acceptance criteria, and corrective actions. Some aging evaluations for EQ components are time-limited aging analyses (TLAAs) for license renewal.

A.1.10 External Surfaces Monitoring Program

The External Surfaces Monitoring Program manages aging effects of components fabricated from metallic and polymeric materials through periodic visual inspection of external surfaces during system inspections and walkdowns for evidence of leakage, loss of material (including loss of material due to wear), cracking, and change in material properties. When appropriate for the component and material, physical manipulation is used to augment visual inspections to confirm the absence of elastomer hardening and loss of strength. Inspections will be performed by personal qualified through plant-specific programs, and deficiencies are documented and evaluated under the corrective action program. Surfaces that are not readily visible during plant operations and refueling outages are inspected when they are made accessible and at such intervals that would ensure the components' intended functions are maintained.

APPENDIX A

For a representative sample of outdoor insulated components and indoor insulated components operated below the dew point, which have been identified with more than nominal degradation on the exterior of the component, insulation is removed for inspection of the component surface. For a representative sample of indoor insulated components operated below the dew point, which have not been identified with more than nominal degradation on the exterior of the component, the insulation exterior surface is inspected. These inspections will be conducted during each 10-year period during the PEO.

The External Surfaces Monitoring Program has been enhanced as follows.

- Revise External Surfaces Monitoring Program procedures to clarify that periodic inspections of systems in scope and subject to aging management review for license renewal in accordance with 10 CFR 54.4(a)(1) and (a)(3) will be performed. Inspections shall include areas surrounding the subject systems to identify hazards to those systems. Inspections of nearby systems that could impact the subject systems will include SSCs that are in scope and subject to aging management review for license renewal in accordance with 10 CFR 54.4(a)(2).
- Revise External Surfaces Monitoring Program procedures to include instructions to look for the following related to metallic components:
    - Corrosion and material wastage (loss of material).
    - Leakage from or onto external surfaces (loss of material).
    - Worn, flaking, or oxide-coated surfaces (loss of material).
    - Corrosion stains on thermal insulation (loss of material).
    - Protective coating degradation (cracking, flaking, and blistering).
    - Leakage for detection of cracks on the external surfaces of stainless steel components exposed to an air environment containing halides.
- Revise External Surfaces Monitoring Program procedures to include instructions for monitoring aging effects for flexible polymeric components through physical manipulations of the material, with a sample size for manipulation of at least ten percent of the available surface area. The inspection parameters for polymers shall include the following:
    - Surface cracking, crazing, scuffing, dimensional changes (e.g., ballooning and necking).
    - Discoloration.
    - Exposure of internal reinforcement for reinforced elastomers (loss of material).
    - Hardening as evidenced by loss of suppleness during manipulation where the component and material can be manipulated

- Revise External Surfaces Monitoring Program procedures to specify the following for insulated components.
    - Periodic representative inspections are conducted during each 10-year period during the PEO.
    - For a representative sample of outdoor components, except tanks, and indoor components, except tanks, identified with more than nominal degradation on the exterior of the component, insulation is removed for visual inspection of the component surface. Inspections include a minimum of 20 percent of the in-scope piping length for each material type (e.g., steel, stainless steel, copper alloy, aluminum). For components with a configuration which does not conform to a 1-foot axial length determination (e.g., valve, accumulator), 20 percent of the surface area is inspected. Inspected components are 20% of the population of each material type with a maximum of 25. Alternatively, insulation is removed and component inspections performed for any combination of a minimum of 25 1-foot axial length sections and individual components for each material type (e.g., steel, stainless steel, copper alloy, aluminum.)
    - For a representative sample of indoor components, except tanks, operated below the dew point, which have not been identified with more than nominal degradation on the exterior of the component, the insulation exterior surface or jacketing is inspected. These visual inspections verify that the jacketing and insulation is in good condition. The number of representative jacketing inspections will be at least 50 during each 10-year period.

    If the inspection determines there are gaps in the insulation or damage to the jacketing that would allow moisture to get behind the insulation, then removal of the insulation is required to inspect the component surface for degradation.

    - For a representative sample of indoor insulated tanks operated below the dew point and all insulated outdoor tanks, insulation is removed from either 25 1-square foot sections or 20 percent of the surface area for inspections of the exterior surface of each tank. The sample inspection points are distributed so that inspections occur on the tank dome, sides, near the bottom, at points where structural supports or instrument nozzles penetrate the insulation, and where water collects (for example on top of stiffening rings).
    - Inspection locations are based on the likelihood of corrosion under insulation (CUI). For example, CUI is more likely for components experiencing alternate wetting and drying in environments where trace contaminants could be present and for components that operate for long periods of time below the dew point.
    - If tightly adhering insulation is installed, this insulation should be impermeable to moisture and there should be no evidence of damage to the moisture barrier. Given that the likelihood of CUI is low for tightly adhering insulation, a minimal number of inspections of the external moisture barrier of this type of insulation, although not zero, will be credited toward the sample population.
    - Subsequent inspections will consist of an examination of the exterior surface of the insulation for indications of damage to the jacketing or protective outer layer of the insulation, if the following conditions are verified in the initial inspection.

- No loss of material due to general, pitting or crevice corrosion, beyond that which could have been present during initial construction
- No evidence of cracking

Nominal degradation is defined as no loss of material due to general, pitting, or crevice corrosion, beyond that which could have been present during initial construction, and no evidence of cracking. If the external visual inspections of the insulation reveal damage to the exterior surface of the insulation or there is evidence of water intrusion through the insulation (e.g. water seepage through insulation seams/joints), periodic inspections under the insulation will continue as described above.

- Revise External Surfaces Monitoring Program procedures to include acceptance criteria. Examples include the following:

  - Stainless steel should have a clean shiny surface with no discoloration.
  - Other metals should not have any abnormal surface indications.
  - Flexible polymers should have a uniform surface texture and color with no cracks and no unanticipated dimensional change, no abnormal surface with the material in an as-new condition with respect to hardness, flexibility, physical dimensions, and color.
  - Rigid polymers should have no erosion, cracking, checking or chalks.
  - Specific, measurable, actionable/attainable and relevant acceptance criteria are established in the maintenance and surveillance procedures or are established during engineering evaluation of the degraded condition.

A.1.11 **Fatigue Monitoring Program**

The Fatigue Monitoring Program ensures that fatigue usage remains within allowable limits by (a) tracking the number of critical thermal and pressure transients for selected components, (b) verifying that the severity of monitored transients are bounded by the design transient definitions for which they are classified, (c) assessing the impact of the reactor coolant environment on a set of sample critical components, and (d) addressing applicable fatigue exemptions.

The Fatigue Monitoring Program has been enhanced as follows.

- Revise Fatigue Monitoring Program procedures to monitor and track critical thermal and pressure transients for components that have been identified to have a fatigue TLAA.
- Fatigue usage calculations that consider the effects of the reactor water environment will be developed for a set of sample reactor coolant system components. This sample set will include the locations identified in NUREG/CR-6260 and additional plant-specific component locations in the reactor coolant pressure boundary if they are found to be more limiting than those considered in NUREG/CR-6260. In addition, fatigue usage calculations for reactor vessel internals (lower core plate and control rod drive (CRD) guide tube pins) will be

evaluated for the effects of the reactor water environment. F_{en} factors will be determined as described in Section A.2.2.3.

- Fatigue usage factors for the reactor coolant system pressure boundary components will be adjusted as necessary to to incorporate the effects of the Cold Overpressure Mitigation System (COMS) event (i.e., low temperature overpressurization event) and the effects of the structural weld overlays.

- Revise Fatigue Monitoring Program procedures to provide updates of the fatigue usage calculations and cycle-based fatigue waiver evaluations on an as-needed basis if an allowable cycle limit is approached, or in a case where a transient definition has been changed, unanticipated new thermal events are discovered, or the geometry of components has been modified.

- Revise Fatigue Monitoring Program procedures to track the tensioning cycles for the reactor coolant pump hydraulic studs.

A.1.12 Fire Protection Program

The Fire Protection Program manages cracking, loss of material, delamination, separation, and change in material properties through periodic visual inspection of components and structures with a fire barrier intended function. It also performs functional testing of fire doors and inspections and testing of the CO_2 fire suppression system. The program includes visual inspections of not less than ten percent of each type of penetration seal at least once per refueling cycle and visual inspections of the fire barrier walls, ceilings and floors in structures within the scope of license renewal at a frequency of at least once per refueling cycle. Inspections of fire barriers include inspections of coatings and wraps. Periodic visual and functional tests are used to manage the aging effects of fire doors. The visual inspection frequency for fire doors is at least once per refueling cycle, and functional tests of closing mechanisms and latches for required doors is at least once per refueling cycle. The Fire Protection Program performs visual inspections of the CO_2 system every 18 months to identify conditions of corrosion. A functional test of the CO_2 system is performed every 18 months, which is consistent with the standards of NFPA 12A.

The Fire Protection Program has been enhanced as follows.

- Revise Fire Protection Program procedures to include an inspection of fire barrier walls, ceilings, and floors for any signs of degradation such as cracking, spalling, or loss of material caused by freeze thaw, chemical attack, or reaction with aggregates.
- Revise Fire Protection Program procedures to provide acceptance criteria of no significant indications of concrete cracking, spalling, and loss of material of fire barrier walls, ceilings, and floors and in other fire barrier materials.

A.1.13 Fire Water System Program

The Fire Water System Program (FWSP) manages loss of material and fouling for components in fire protection systems (including the fire water storage tanks). The program includes periodic flushing and system performance testing in accordance with the applicable National Fire Protection Association (NFPA) commitments as described in the Fire Protection Report. System pressure is monitored such that loss of pressure is immediately detected and corrective action initiated. Portions of the system exposed to water are internally visually inspected. Sprinkler heads that have been in place for 50 years are tested in accordance with NFPA 25 Section 5.3.1 if not replaced.

The Fire Water System Program has been enhanced as follows.

- Revise (FWSP) procedures to periodically remove a representative sample of components such as sprinkler heads or couplings, within five years prior to the PEO and every five years during the PEO, to perform a visual internal inspection of the dry fire water system piping for evidence of corrosion, loss of wall thickness, and foreign material that may result in flow blockage using the methodology described in NFPA-25 Section 14.2.1.

- Revise FWSP procedures to perform one of the following inspection methods for those sections of dry piping described in NRC Information Notice (IN) 2013-06, where drainage is not occurring, to ensure there is no flow blockage in each five-year interval beginning with the five-year period before the PEO:

  (a) Perform a flow test or flush sufficient to detect potential flow blockage.
  (b) Remove sprinkler heads or couplings in the areas that do not drain and perform a 100% visual internal inspection to verify there are no signs of abnormal corrosion (wall thickness loss) or blockage.

  If option (a) is chosen, controls will be established to ensure potential blockage is not moved to another part of the system where it may be undetected.

  In each five-year interval during the PEO, 20% of the length of piping segments that cannot be drained or piping segments that allow water to collect will be subjected to UT wall thickness examination.

  The piping examined during each inspection interval will be piping that was not previously examined.

  If the results of a 100% internal visual inspection are acceptable, and the segment is not subsequently wetted, no further augmented tests or inspections will be performed.

- Revise FWSP procedures to ensure sprinkler heads are tested .in accordance with NFPA -25 (2011 Edition), Section 5.3.1.

- Revise Fire Water System Program procedures to include acceptance criteria for periodic visual inspection of fire water system internals for corrosion, minimum wall thickness, and the absence of biofouling in the sprinkler system that could cause corrosion in the sprinklers.

- Revise FWSP procedures to perform an obstruction evaluation in accordance with NFPA-25 (2011 Edition), Section 14.3.1.

APPENDIX A

- Revise FWSP Program procedures to conduct follow-up volumetric examinations if internal visual inspections detect surface irregularities that could be indicative of wall loss below nominal pipe wall thickness.

- Revise FWSP procedures to annually inspect the fire water storage tank exterior painted surface for signs of degradation. If degradation is identified, conduct follow-up volumetric examinations to ensure wall thickness is equal to or exceeds nominal wall thickness. The fire water storage tanks will be inspected in accordance with NFPA-25 (2011 Edition) requirements.

- Revise FWSP procedures to include a fire water storage tank interior inspection every five years that includes inspections for signs of pitting, spalling, rot, waste material and debris, and aquatic growth. Include in the revision direction to perform fire water storage tank interior coating testing, if any degradation is identified, in accordance with ASTM D 3359 or equivalent, a dry film thickness test at random locations to determine overall coating thickness; and a wet sponge test to detect pinholes, cracks or other compromises of the coating. If there is evidence of pitting or corrosion ensure the Fire Water System Program procedures direct performance of an examination to determine wall and bottom thickness.

- Revise FWSP procedures to perform annual spray head discharge pattern tests from all open spray nozzles to ensure that patterns are not impeded by plugged nozzles, to ensure that nozzles are correctly positioned, and to ensure that obstructions do not prevent discharge patterns from wetting surfaces to be protected. Where the nature of the protected critical equipment or property is such that water cannot be discharged, the nozzles shall be inspected for proper orientation and the system tested with smoke or some other medium to ensure that the nozzles are not obstructed.

- Revise FWSP procedures to ensure that the dry piping is unobstructed downstream of deluge valves protecting indoor areas containing critical equipment by flow testing with air, smoke, or other medium from deludge valve through the sprinkler heads. Based on the trip testing of the deluge valves without flow through the downstream piping and sprinkler heads, additional testing in the RCA or areas containing critical equipment is not warranted due to the addition of a risk-significant activities and the production of additional radwaste.
- Revise FWSP procedures to perform an internal inspection of the accessible piping associated with the strainer inspections for corrosion and foreign material that may cause blockage. Document any abnormal corrosion or foreign material in the CAP.
- Revise FWSP procedures to perform 25 main drain tests every 18 months (for three 18-month intervals). At least one main drain test is performed in each of the following buildings: (1) control building, (2) auxiliary building, (3) turbine building, and (4) diesel generator building.

  The results of the main drain tests from the three 18-month inspection intervals will be evaluated to determine if the NFPA 25 (2014 Edition) main drain test guidance can be applied to the number of main drain tests performed (.i.e., Section 13.2.5, "A main drain test shall be conducted annually for each water supply lead-in to a building water-based fire protection system to determine whether there has been a change in the condition of the water supply" and Section 13.2.5.1 "Where the lead-in to a building supplies a header or manifold serving multiple systems, a single main drain test shall be performed.")

APPENDIX A

Any flow blockage or abnormal discharge identified during flow testing or any change in delta pressure during the main drain testing greater than 10% at a specific location is entered into the CAP.

Flow or main drain testing increases risk due to the potential for water contacting critical equipment in the area, and main drain testing in the RCAs increase the amount of liquid radwaste. Therefore, SQN will not perform main drain tests on every standpipe with an automatic water supply and every system riser.

- Revise FWSP procedures to include acceptance criteria equivalent to “no debris” (i.e., no corrosion products that could impede flow or cause downstream components to become clogged). Any signs of abnormal corrosion or blockage will be removed, its source determined and corrected, and entered into the CAP.

A.1.14 Flow-Accelerated Corrosion Program

The Flow-Accelerated Corrosion (FAC) Program manages loss of material due to wall thinning caused by FAC for carbon steel piping and components by (a) performing an analysis to determine systems subject to FAC, (b) conducting appropriate analysis to predict wall thinning, (c) performing wall thickness measurements based on wall thinning predictions, and (d) evaluating measurement results to determine the remaining service life and the need for replacement or repair of components. Measurement results are also used to confirm predictions and to plan long-term corrective action. The program relies on implementation of guidelines published by the latest revision available of EPRI in NSAC-202L, and internal and external operating experience. The program uses a predictive code for portions of susceptible systems with design and operating conditions that are amenable to computer modeling. Inspections are performed using ultrasonic or other approved testing techniques capable of determining wall thickness. Components predicted to reach the minimum allowed wall thickness before the next scheduled outage are isolated, repaired, replaced, or reevaluated under the corrective action program.

Where applicable, the FAC Program also manages loss of material due to erosion mechanisms of cavitation, flashing, liquid droplet impingement and solid particle erosion for any material in moving fluid environments.

The Flow-Accelerated Corrosion Program has been enhanced as follows.

- Revise Flow-Accelerated Corrosion Program procedures to implement NSAC-202L guidance for examination of components upstream of piping surfaces where significant wear is detected.

- Revise Flow-Accelerated Corrosion Program procedures to implement the guidance in LR-ISG-2012-01, which will include a susceptibility review based on internal operating experience, external operating experience, EPRI TR-1011231, Recommendations for Controlling Cavitation, Flashing, Liquid Droplet Impingement, and Solid Particle Erosion in Nuclear Power Plant Piping, and NUREG/CR-6031, Cavitation Guide for Control Valves. In addition, revise the FAC program procedures to include portions of the Essential Raw Cooling Water (ERCW) piping where Belzona coating is applied. These inspections are to be performed prior to the PEO, and pending results of the inspections, future inspections should be planned as part of the FAC program.

A.1.15 Flux Thimble Tube Inspection Program

The Flux Thimble Tube Inspection Program manages loss of material due to wear of the flux thimble tube walls from the reactor vessel instrument nozzles to the fuel assembly instrument guide tubes. Nondestructive examination methodology such as eddy current testing or other NRC-accepted inspection methods are used. This program implements the recommendations of NRC Bulletin 88-09, "Thimble Tube Thinning in Westinghouse Reactors," in regards to nondestructive examinations such as eddy current testing or other justified and NRC-approved method used to monitor flux thimble tube wear.

The Flux Thimble Tube Inspection Program has been enhanced as follows.

- Revise Flux Thimble Tube Inspection Program procedures to include a requirement to address if the predictive trending projects that a tube will exceed 80 percent wall wear prior to the next planned inspection, then initiate a service request to define actions (i.e., plugging, repositioning, replacement, evaluations, etc.) required to ensure that the projected wall wear does not exceed 80 percent. If any tube is found to be greater than 80 percent through-wall wear, then initiate a service request to evaluate the predictive methodology used and modify as required to define corrective actions (i.e., plugging, repositioning, replacement, etc.).

A.1.16 <u>Inservice Inspection Program</u>

The Inservice Inspection Program manages loss of material, cracking, thermal embrittlement, flaw growth, and reduction in fracture toughness for ASME Class 1, 2, and 3 pressure-retaining components, including welds, pump casings, valve bodies, integral attachments, and pressure-retaining bolting using volumetric, surface, and/or visual examination and leakage testing of ASME Class 1, 2 and 3 component as specified in ASME Section XI code, 2001 Edition 2003 addendum. Additional limitations, modifications, and augmentations described in 10 CFR 50.55a are included as a part of this program. Every ten years this program is updated to the latest ASME Section XI code edition and addendum approved by the NRC in 10 CFR 50.55a. Repair and replacement activities for these components are covered in Subsection IWA of the ASME code edition of record.

The Inservice Inspection Program has been enhanced as follows.

- Revise Inservice Inspection Program procedures to include a supplemental inspection to monitor cracking of Class 1 CASS piping components that do not meet the materials selection criteria of NUREG-0313, Revision 2 with regard to ferrite and carbon content when an inspection technique has been qualified by ASME or EPRI. If an inspection technique has not been qualified by ASME or EPRI prior to the commitment due date, revise program procedures to continue monitoring the development of a qualified inspection technique. Once an ASME or EPRI inspection technique is qualified, revise Inservice Inspection Program procedures to perform the supplemental inspections.

- Inspections will be conducted on a sampling basis. The extent of sampling will be based on the established method of inspection and industry operating experience and practices when the program is implemented, and will include components determined to be limiting from the standpoint of applied stress, operating time and environmental considerations.

- Revise Inservice Inspection Program procedure to monitor the wear of the accessible CRDM housing penetrations in weld examination volume.

- Revise Inservice Inspection Program procedure to perform an examination of the accessible CRDM housing penetration to determine the amount of wear in the area of the thermal sleeve centering pads for Units 1 and 2. The accessible locations consist of the centermost CRDM housing penetrations 1 through 5 on Unit 1 and penetrations 2 through 5 on Unit 2.

- Revise Inservice Inspection Program procedure to estimate the wall thickness of the accessible CRDM housingpenetration wear in the area of the thermal sleeve centering tabs at the end of the next RVH inspection interval and compare this projected wall thickness to the thickness used in Sequoyah design basis analyses to demonstrate validity of the analyses.

- Revise the Inservice Inspection Program procedures to perform an augmented visual inspection of the Unit 1 and Unit 2 CRDM thermal sleeves and a wall thickness measurement of the six thermal sleeves exhibiting the greatest amount of wear. The results of the augmented inspection should be used to project if there is sufficient wall thickness for the PEO, or until the next inspection.

- The ASME Section XI Program procedure which defines the Class 1 components subject to examination will be revised to specifically require a visual examination method VT-3 of the clevis bolts, dowel pins and tack welds as well as the 6 core support pads.

- Evaluate industry operating experience related to CRDM housing penetration wear and initiatives to measure CRDM housing penetration wear and resulting wall thickness. Upon successful demonstration of a wear depth measurement process, SQN will revise Inservice Inspection Program procedures to use the demonstrated process at accessible locations to measure depth of wear on the CRDM housing penetration wall associated with contact with the CRDM thermal sleeve centering pads.

A.1.17 <u>Inservice Inspection – IWF Program</u>

The Inservice Inspection (ISI) – IWF Program performs periodic visual examinations of ASME Class 1, 2, and 3 piping and component supports to determine general mechanical and structural condition or degradation of component supports such as verification of clearances, settings, physical displacements, loose or missing parts, debris, corrosion, wear, erosion, or the loss of integrity at welded or bolted connections. The ISI-IWF Program is implemented through plant procedures which provide administrative controls for the conduct of activities that are necessary to fulfill the requirements of ASME Section XI, as mandated by 10 CFR 50.55a. The monitoring methods are effective in detecting the applicable aging effects, and the frequency of monitoring is adequate to prevent significant degradation.

The ISI-IWF Program is augmented by plant procedures to ensure that the selection of bolting material, installation torque or tension, and the use of lubricants and sealants are appropriate for the intended purpose. These procedures include the guidance of EPRI TR-104213, NUREG-1339, and EPRI NP-5769 to ensure proper specification of bolting material, lubricant, and installation torque.

The ISI-IWF Program has been enhanced as follows.

- Revise ISI-IWF Program procedures to clarify that detection of aging effects will include monitoring anchor bolts for loss of material, loose or missing nuts, and cracking of concrete around the anchor bolts.

- Revise ISI - IWF Program procedures to include the following corrective action guidance.

  When an indication is identified on acomponent support exceeding the acceptance criteria of IWF-3400, but an evaluation concludes the support is acceptable for service, the program shall require examination of additional similar/adjacent supports per IWF-2430 unless the evaluation of the identified condition against similar/adjacent supports concludes that it would not adversely affect the design function of similar adjacent supports. This evaluation will be performed regardless of whether the program owner chooses to perform corrective measures to restore the component to its original design condition, per IWF-3112.3(b) or IWF-3122.3(b).

A.1.18 <u>Inspection of Overhead Heavy Load and Light Load (Related to Refueling) Handling Systems Program</u>

The Inspection of Overhead Heavy Load and Light Load (Related to Refueling) Handling Systems Program performs periodic visual examinations and preventive maintenance to manage loss of material due to corrosion, loose bolting or rivets, and crane rail wear of cranes and hoists, based on industry standards and guidance documents. The program includes structural components, including structural bolting, that make up the bridge, the trolley, lifting devices, and rails in the rail system and includes cranes and hoists that meet the provisions of 10 CFR 54.4(a)(1) and (a)(2) as well as NUREG-0612, "Control of Heavy Loads at Nuclear Power Plants." The activities rely on visual examinations and functional testing to ensure that cranes and hoists are capable of sustaining their rated loads, thus ensuring their intended function is maintained during the period of extended operation.

The Inspection of Overhead Heavy Load and Light Load (Related to Refueling) Handling Systems Program has been enhanced as follows.

- Revise program procedures to specify the inspection scope will include monitoring of rails in the rail system for wear; monitoring structural components of the bridge, trolley and hoists for the aging effect of deformation, cracking, and loss of material due to corrosion; and monitoring structural connections/bolting for loose or missing bolts, nuts, pins or rivets and any other conditions indicative of loss of bolting integrity.

- Revise program procedures to include the inspection requirements of ASME B30.2.

- Revise program procedures to include the inspection frequency requirements of ASME B30.2.

- Revise program procedures to clarify that the acceptance criteria will include requirements for evaluation in accordance with ASME B30.2 of significant loss of material for structural components and structural bolts and significant wear of rail in the rail system.

- Revise program procedures to clarify that the acceptance criteria and maintenance and repair activities use the guidance provided in ASME B30.2.

A.1.19 Internal Surfaces in Miscellaneous Piping and Ducting Components Program

The Internal Surfaces in Miscellaneous Piping and Ducting Components Program manages fouling, cracking, loss of material, and change in material properties using opportunistic visual inspections of the internal surfaces of piping and components during periodic surveillances or maintenance activities when the surfaces are accessible for visual inspection.

This opportunistic approach is supplemented with the following sampling approach.

- In each 10-year period during the period of extended operation (PEO), an assessment will be made of the opportunistic inspections completed during that period for each material-environment-aging effect combination within the scope of this program.
- Directed inspections will be conducted to ensure that an inspection sample size of 20 percent, with a maximum sample size of 25 inspections, is completed for each of these material-environment-aging effect combinations during the 10-year period under review.
- Where practical, inspections shall be conducted at locations that are most susceptible to the effects of aging because of time in service, severity of operating conditions (e.g., low or stagnant flow), and lowest design margin.
- An inspection conducted of a material in a more severe environment may also be credited as an inspection of the same material in a less severe environment.

For metallic components, visual inspection of surface conditions will be used to detect loss of material, fouling and cracking. For elastomeric components, visual inspections and physical manipulation will be used to detect cracking and change in material properties. The program monitors surface condition for visible evidence of loss of material in metallic components and changes in material properties for elastomeric components, including possible evidence of surface discontinuities. Visual examinations of elastomeric components are accompanied by physical manipulation such that changes in material properties are readily observable. The sample size for physical manipulation is at least ten percent of available surface area, including visually identified suspect areas.

Specific acceptance criteria are as follows:

- Stainless steel: clean surfaces, shiny, no abnormal surface condition.
- Metals: no abnormal surface condition.
- Flexible polymers: a uniform surface texture and color with no cracks, no unanticipated dimensional change, and no abnormal surface conditions.
- Rigid polymers: no surface changes affecting performance such as erosion and cracking.
- Specific, measurable, actionable/attainable and relevant acceptance criteria are established in the maintenance and surveillance procedures or are established during engineering evaluation of the degraded condition.

Conditions that do not meet the acceptance criteria are entered into the corrective action program for evaluation. Any indications of relevant degradation will be evaluated using design standards, procedural requirements, current licensing basis, and industry codes or standards.

A.1.20 Masonry Wall Program

The Masonry Wall Program is based on guidance provided in I.E. Bulletin 80-11, "Masonry Wall Design," and Information Notice (IN) 87-67, "Lessons Learned from Regional Inspections of Licensee Actions in Response to I.E. Bulletin 80-11." The scope of the Masonry Wall Program includes masonry walls within the scope of license renewal as delineated in 10 CFR 54.4. The program manages aging effects so that the evaluation basis established for each masonry wall within the scope of license renewal remains valid through the period of extended operation. The program has been implemented as part of the Structures Monitoring Program (Section A.1.40).

The program includes visual inspections of masonry walls identified as performing intended functions in accordance with 10 CFR 54.4. Included components are 10 CFR 50.48-required masonry walls, radiation shielding masonry walls, and masonry walls with the potential to affect safety-related components. Structural steel components, steel edge supports, and steel bracing of masonry walls are managed by the Structures Monitoring Program (Section A.1.40).

Masonry walls are inspected at least once every five years, with provisions for more frequent inspections, to ensure there is no loss of intended function between inspections.

Enhancements to this program are included in the enhancements to the Structures Monitoring Program (Section A.1.40).

A.1.21 Metal Enclosed Bus Inspection Program

The Metal Enclosed Bus Inspection Program is a condition monitoring program that provides for the inspection of the internal and external portions of metal enclosed bus (MEB) to identify age-related degradation of the bus and bus connections, the bus enclosure assemblies, and the bus insulation and insulators. The program will inspect the following MEB requirement for recovery of offsite power: MEB (non-segregated) associated with CSST A, CSST B, CSST C, USST buses (1A, 1B, 2A, 2B), the 6.9 kV start buses (1A, 1B, 2A, 2B) and the MEB (isolated phase) associated with USST 1A, USST 1B, USST 2A, and USST 2B.

MEB enclosure assembly external surfaces will be visually inspected for evidence of loss of material due to general, pitting, and crevice corrosion. Accessible elastomers (e.g., gaskets, boots, and sealants) will be inspected for changed in material properties (elastomer degradation) including surface cracking, crazing, scuffing, dimensional change (e.g., “ballooning” and “necking”), shrinkage, discoloration, hardening, and loss of strength at least once every ten years. This inspection will be performed in this program instead of in the Structures Monitoring Program.

MEB enclosure assemblies will be visually inspected internally for evidence of loss of material. Internal portions of the MEB enclosure assemblies will also be inspected for cracks, corrosion, foreign debris, excessive dust buildup, and evidence of water intrusion. Bus insulation or insulators will be visually inspected for signs of reduced insulation resistance due to thermal/ thermoxidative degradation of organics/thermoplastics, radiation-induced oxidation, moisture/ debris intrusion, or ohmic heating, as indicated by embrittlement, cracking, chipping, melting, swelling, or discoloration

which may indicate overheating or aging degradation. Internal bus supports or insulators are visually inspected for structural integrity and signs of cracks. A sample of accessible bolted connections will be inspected for increased connection resistance at least once every ten years for loose connections using quantitative measurements such as thermography or connection resistance (micro-ohm) measurements. Twenty percent of the population with a maximum sample of 25 constitutes a representative sample size for accessible bolted connections. Otherwise, a technical justification of the methodology and sample size used for selecting components should be included as part of the site documentation. The alternative to quantitative measurements could be used for accessible MEB bolted connections covered with heat shrink tape or insulating boots. A sample of accessible bolted connections covered with heat shrink tape or insulating boots per manufacturer's recommendations can be inspected using the alternate qualitative methods. If the alternate inspection method using visual is the only method performed, the visual inspection must be performed prior to the period of extended operation and at least once every five years for insulation material surface anomalies such as embrittlement, cracking, chipping, melting, discoloration, swelling, or surface contamination. Thermography will be performed on bus connections with the MEB covers in place, only if the bus enclosure is equipped with an IR window to facilitate the inspection.

These inspections were completed before the period of extended operation and every ten years thereafter provided the alternative visual inspection is not used as the only method to inspect a sample of accessible MEB bolted connections. If the alternative visual inspection is used to check a sample of accessible MEB bolted connections, the first inspection was completed prior to the period of extended operation with subsequent inspections every five years thereafter. Newly-installed components will have initial inspections 10 years after installation.

A.1.22 <u>Neutron-Absorbing Material Monitoring Program</u>

The Neutron-Absorbing Material Monitoring Program provides reasonable assurance that degradation of the neutron-absorbing material (Boral) used in spent fuel racks that could compromise the criticality analysis will be detected. The program relies on periodic inspection, testing, and other monitoring activities to assure that the required five percent sub-criticality margin is maintained during the period of extended operation.

The Neutron-Absorbing Material Monitoring Program has been enhanced as follows:

- Revise Neutron-Absorbing Material Monitoring Program procedures to perform blackness testing of the Boral coupons within the ten years prior to the period of extended operation and at least every ten years thereafter based on initial testing to determine possible changes in boron-10 areal density.

- Revise Neutron-Absorbing Material Monitoring Program procedures to relate physical measurements of Boral coupons to the need to perform additional testing.

- Revise Neutron-Absorbing Material Monitoring Program procedures to perform trending of coupon testing results to determine the rate of degradation and to take action as needed to maintain the intended function of the Boral.

A.1.23 Nickel Alloy Inspection Program

The Nickel Alloy Inspection Program manages cracking due to primary water stress corrosion cracking (PWSCC) for nickel-alloy components and loss of material due to boric acid-induced corrosion in susceptible safety-related components in the vicinity of nickel-alloy reactor coolant pressure boundary components as described in 10 CFR 50.55a. It provides (a) inspection requirements for the PWR vessel, pressurizer components, and piping that contain PWSCC-susceptible dissimilar metals (Alloys 600/82/182) and (b) inspection requirements for reactor coolant pressure boundary components.

The program monitors for reactor coolant pressure boundary cracking and leakage using various methods, including NDE techniques, radiation monitoring, and visual insections for boric acid deposits, leakage, or the presence of moisuture to identify cracking in the reactor coolant pressure boundary or loss of material. Inspection methods, schedules and frequencies for susceptible components are implemented in accordance with 10 CFR50.55a. Reactor coolant leakage is calculated and trended on a routine basis in accordance with technical specifications. The acceptance criteria for identified flaws and the methodology for evaluating the flaws is prescribed in 10 CFR 50.55a. Unacceptable indications of flaws are corrected through implementation of appropriate repair or replacement as dictated in 10 CFR 50.55a.

A.1.24 Non-EQ Cable Connections Program

The Non-EQ Cable Connections Program is a one-time inspection program that provides reasonable assurance that the intended functions of the metallic parts of electrical cable connections are maintained consistent with the current licensing basis through the period of extended operation. Cable connections included are those connections susceptible to age-related degradation resulting in increased resistance of connection due to thermal cycling, ohmic heating, electrical transients, vibration, chemical contamination, corrosion, or oxidation that are not subject to the environmental qualification requirements of 10 CFR 50.49.

This program provides for one-time inspections that were completed prior to the period of extended operation on a sample of connections. The factors considered for sample selection will be application (medium and low voltage, defined as < 35 kV), circuit loading (high loading), connection type, and location (high temperature, high humidity, vibration, etc.). The representative sample size will be based on twenty percent of the connection population with a maximum sample of 25. Inspection methods may include thermography, contact resistance testing, or other appropriate quantitative test methods without removing the connection insulation, such as heat shrink tape, sleeving, insulating boots, etc., based on plant configuration and industry guidance.

A.1.25 Non-EQ Inaccessible Power Cables (400 V to 35 kV) Program

The Non-EQ Inaccessible Power Cables (400 V to 35 kV) Program manages the aging effect of reduced insulation resistance on the inaccessible power (400 V to 35 kV) cable systems that have a license renewal intended function.

APPENDIX A

The cables to be included in this program are routed underground and are connected to the 6.9 kV yard area common board, the 6.9 kV shutdown boards, the 6.9 kV start buses (1B and 2B only), and the 480 V shutdown boards.

Non-EQ Underground Power Cable (400 V to 35 kV) Circuits That Require an AMP

Equipment ID	Voltage Level	Description
6.9 kV Start Buses		
0-BCTA-202-CL/1414	6900 V	6.9kV CSST “C” X-Winding MEB termination box to 6.9 kV Start Bus 2B

The program includes periodic actions to prevent inaccessible cables from being exposed to significant moisture. Significant moisture is defined as periodic exposures to moisture that last more than a few days (e.g., cable wetting or submergence in water). In this program, inaccessible power (400 V to 35 kV) cables exposed to significant moisture are tested at least once every six years to provide an indication of the condition of the cable insulation properties. Test frequencies

are adjusted based on test results and operating experience. The specific type of test performed is a proven test for detecting deterioration of the cable insulation. One or more proven, commercially available tests techniques will be used for detecting deterioration of the insulation system due to wetting or submergence for inaccessible power cables (400 V to 35 kV) included in this program, such as dielectric loss (dissipation factor/power factor), AC voltage withstand, partial discharge, step voltage, time domain reflectometry, insulation resistance and polarization index, line resonance analysis, or other testing that is state-of-the-art at the time the tests are performed. The program includes periodic inspections for water accumulation in manholes based on evaluations of inspection results. The inspections will include direct observation that cables are not wetted or submerged, that cables, splices and cable support structures are intact, and dewatering systems (i.e., sump pumps) and associated alarms, if applicable, operate properly. In addition, the operability of the dewatering sysems (sump pumps) will also be verified through monthly inspection of the water levels in the in-scope manholes and handholes, and through follow-up evaluation and corrective action if any abnormal water intrusion issues are identified. Abnormal water intrusion is defined as either an increasing trend of water levels in a particular manhole/handhole, or a manhole/handhole where the power cables are or have been submerged. Both Maintenance and Engineering have corrective actions to perform if abnormal water levels are found in a manhole or handhole. In addition to the periodic manhole inspections, manhole inspections for water after event-driven occurrences, such as flooding, will be performed. Inspection frequency will be increased as necessary based on evaluation of inspection results.

A.1.26 <u>Non-EQ Instrumentation Circuits Test Review Program</u>

The Non-EQ Instrumentation Circuits Test Review Program manages the aging effects of the applicable cables in the neutron monitoring and process radiation monitoring systems or sub-systems.

- Neutron Monitoring: Excore Power Range
- Process Radiation Monitoring:
    - ► Containment building purge exhaust monitors
    - ► Fuel pool air space monitors
    - ► Main control room air intake monitors: emergency
    - ► Main control room air intake monitors: normal

The program provides reasonable assurance the intended functions of sensitive, high-voltage, low-signal cables exposed to adverse localized equipment environments caused by heat, radiation and moisture (i.e., neutron flux monitoring instrumentation and process radiation monitoring) can be maintained consistent with the current licensing basis through the period of extended operation. Most sensitive instrumentation circuit cables and connections are included in the instrumentation loop calibration at the normal calibration frequency, which provides sufficient indication of the need for corrective actions based on acceptance criteria related to instrumentation loop performance. The review of calibration results or findings of surveillance testing programs will be performed once

every ten years, with the first review occurring before the period of extended operation. For sensitive instrumentation circuit cables that are disconnected during instrument calibrations, testing using a proven method for detecting deterioration for the insulation system (such as insulation resistance tests or time domain reflectometry) will occur at least once every ten years, with the first test occurring before the period of extended operation. Applicable industry standards and guidance documents are used to delineate the program.

A.1.27 <u>Non-EQ Insulated Cables and Connections Program</u>

The Non-EQ Insulated Cables and Connections Program provides reasonable assurance the intended functions of insulated cables and connections exposed to adverse localized environments caused by heat, radiation and moisture can be maintained consistent with the current licensing basis through the period of extended operation. An adverse localized environment is a condition in a limited plant area that is significantly more severe than the plant design environment for the cable or connection insulation materials.

Accessible insulated cables and connections within the scope of license renewal installed in an adverse localized environment will be visually inspected for cable and connection jacket surface anomalies such as embrittlement, discoloration, cracking, melting, swelling, or surface contamination. The program sample consists of all accessible cables and connections in localized adverse environments. This program sample of accessible cables will represent, with reasonable assurance, all cables and connections in the adverse localized environment.

An adverse localized equipment environment is a plant-specific condition that will be determined based on a plant spaces approach. The plant spaces approach provides for a review of all buildings and rooms in the scope of license renewal to determine potential adverse localized environments. The determination of a potential adverse localized equipment environment will be based on the most limiting temperature, radiation, or moisture conditions for the cables and connection insulation material located at SQN. The evaluation of an adverse localized equipment environment will be based on the most limiting temperature, radiation or moisture conditions for the cables and connection insulation material located within that plant space that has a potential adverse localized equipment environment.

This program will visually inspect accessible cables in an adverse localized environment at least once every ten years, with the first inspection prior to the period of extended operation.

A.1.28 <u>Oil Analysis Program</u>

The Oil Analysis Program ensures that loss of material, cracking, and fouling are not occurring by maintaining the quality of lubricating oil. The program ensures that contaminants (primarily water and particulates) are within acceptable limits. Testing activities include sampling and analysis of lubricating oil for detrimental contaminants. Testing results indicating presence of water in oil samples initiate corrective action that may include evaluating for in-leakage.

The One-Time Inspection Program utilizes inspections or nondestructive evaluations of representative samples to verify that the Oil Analysis Program has been effective at managing the aging effects of loss of material, cracking and fouling.

A.1.29 <u>One-Time Inspection Program</u>

The One-Time Inspection Program consists of a one-time inspection of selected components to accomplish the following:

- Verify the effectiveness of AMPs designed to prevent or minimize the effects of aging to the extent that they will not cause the loss of intended function during the period of extended operation. The aging effects evaluated are loss of material, cracking, and fouling.

- Confirm the insignificance of an aging effect for situations in which additional confirmation is appropriate using inspections that verify unacceptable degradation is not occurring.

- Trigger additional actions if necessary to ensure the intended functions of affected components are maintained during the period of extended operation.

For components managed by Diesel Fuel Monitoring Program (Section A.1.8), Oil Analysis Program (Section A.1.28), and Water Chemistry Program (Section A.1.43), determination of the sample size will be based on 20 percent of the components in each material-environment-aging effect group up to a maximum of 25 components. Otherwise, a technical justification of the methodology and sample size used for selecting components for one-time inspection should be included as part of the programs's documentation. The sample size of components to be inspected will also be based on an assessment of operating experience. Identification of inspection locations will be based on the potential for the aging effect to occur. Examination techniques will be established NDE methods with a demonstrated history of effectiveness in detecting the aging effect of concern, including visual, ultrasonic, and surface techniques. Acceptance criteria will be based on applicable ASME or other appropriate standards, design basis information, or vendor-specified requirements and recommendations. The need for follow-up examinations will be evaluated based on inspection results.
The One-Time Inspection Program will not be used for structures or components with known age-related degradation mechanisms or when the environment in the period of extended operation is not expected to be equivalent to that in the prior 40 years.

APPENDIX A

The following table identifies parameters monitored and inspection methods for specific aging effects.

Aging Effect	**Aging Mechanism**	**Parameter(s) Monitored**	**Inspection Method**
Loss of material	Crevice corrosion	Surface condition Wall thickness	Visual (VT-1 or equivalent) and/or volumetric (ultrasonic testing [UT])
Loss of material	Galvanic corrosion	Surface condition Wall thickness	Visual (VT-3 or equivalent) and/or volumetric (UT)
Loss of material	General corrosion	Surface condition Wall thickness	Visual (VT-3 or equivalent) and/or volumetric (UT)
Loss of material	MIC	Surface condition Wall thickness	Visual (VT-3 or equivalent) and/or volumetric (UT)
Loss of material	Pitting corrosion	Surface condition Wall thickness	Visual (VT-1 or equivalent) and/or volumetric (UT)
Loss of material	Erosion	Surface condition Wall thickness	Visual (VT-1 or equivalent) and/or volumetric (UT)
Loss of material	Wear	Wall thickness	Eddy current
Reduction of heat transfer	Fouling	Surface condition	Visual (VT-3 or equivalent)
Cracking	SCC or cyclic loading	Surface condition	Enhanced visual (EVT-1 or equivalent) or surface examination (magnetic particle, liquid penetrant) or volumetric (radiographic testing or UT)

The program will include activities to verify effectiveness of aging management programs and activities to confirm the insignificance of aging effects as described below.

Diesel Fuel Monitoring Program (Section A.1.8)	One-time inspection activity will verify the effectiveness of the Diesel Fuel Monitoring Program by confirming that unacceptable loss of material is not occurring.
Oil Analysis Program (Section A.1.28)	One-time inspection activity will verify the effectiveness of the Oil Analysis Program by confirming that unacceptable cracking, loss of material, and fouling is not occurring.
Water Chemistry Control Program (Section A.1.43)	One-time inspection activity will verify the effectiveness of the Water Chemistry Control Primary and Secondary Program by confirming that unacceptable cracking, loss of material, and fouling is not occurring.
Reactor vessel flange leak-off lines	One-time inspection activity and subsequent evaluation will confirm that cracking and loss of material are not occurring or are occurring so slowly that they will not affect the component intended function during the period of extended operation.
Internal surfaces of the containment spray piping water seal area at water line region	One-time inspection activity and subsequent evaluation will confirm that cracking is not occurring or is occurring so slowly that it will not affect the component intended function during the period of extended operation.
External surfaces of RHR heat exchanger tubes	One-time inspection activity and subsequent evaluation will confirm that loss of material is not occurring or is occurring so slowly that it will not affect the component intended function during the period of extended operation.

A.1.30 One-Time Inspection – Small-Bore Piping Program

The One-Time Inspection – Small-Bore Piping Program augments ASME Code, Section XI requirements and is applicable to small-bore ASME Code Class 1 piping and components with a nominal pipe size diameter less than 4 inches (NPS < 4) and greater than or equal to NPS 1 in systems that have not experienced cracking of ASME Code Class 1 small-bore piping. The program can also be used for systems that have experienced cracking but have implemented design changes to effectively mitigate cracking.

The program provides a one-time volumetric or opportunistic destructive inspection of a three percent sample or maximum of ten ASME Class 1 piping butt weld locations and a three percent sample or a maximum of ten ASME Class 1 socket weld locations that are susceptible to cracking. Volumetric examinations are performed using a demonstrated technique that is capable of detecting the aging effects in the volume of interest. In the event the opportunity arises to perform a destructive examination of an ASME Class 1 small-bore socket weld that meets the susceptibility criteria, then the program takes credit for two volumetric examinations. The program includes pipes, fittings, branch connections, and full and partial penetration welds.

This program includes a sampling approach. Sample selection is based on susceptibility to stress corrosion, cyclic loading (including thermal, mechanical, and vibration fatigue), thermal stratification,

thermal turbulence, dose considerations, operating experience, and limiting locations of total population of ASME Class 1 small-bore piping locations.

The program includes measures to verify that degradation is not occurring, thereby either confirming that there is no need to manage age-related degradation or validating the effectiveness of any existing program for the period of extended operation. If evidence of cracking is revealed by this one-time inspection, follow-up periodic inspection will be managed by a plant-specific program.

A.1.31 <u>Periodic Surveillance and Preventive Maintenance Program</u>

The Periodic Surveillance and Preventive Maintenance (PSPM) Program manages for specific components' aging effects not managed by other aging management programs, including loss of material, fouling, cracking, loss of coating integrity, and change in material properties.

Each inspection occurs at least once every five years, with the exception of the Emergency Diesel Generator Starting Air Aluminum Valves (since the valves are replaced prior to 5 years of service) and coating inspections for which frequency is based on coating condition. For each activity that refers to a representative sample, with the exception of coating inspection activities related to piping, a representative sample is 20 percent of the population (defined as components having the same material, environment, and aging effect combination) with a maximum of 25 components. For coated piping, a representative sample is 50% of in-scope coated piping systems or an area equivalent to the entire interior surface of 73 1-foot piping segments for each combination of type of coating, substrate material, and environment.

<u>Internal Service Level III or Other Coatings</u>

For in-scope components that have internal Service Level III or Other coatings, initial inspections will begin no later than the last scheduled refueling outage prior to the PEO. Subsequent inspections will be performed based on the initial inspection results.

Credit for program activities has been taken in the aging management review of systems, structures and components as described below.

- Prior to the PEO, perform a visual inspection of a 50% sample of the coated piping in each of the following coated piping systems or an area equivalent to the entire inside surface of 73 1-foot piping segments for each combination of type of coating, substrate material , and environment. Inspection location selection will be based on an evaluation of the effect of a coating failure on component intended function, potential problems identified during prior inspections, and service life history. Visually inspect the surface condition of the coated components to manage loss of coating integrity due to cracking, debonding, delamination, peeling, flaking, and blistering. In addition, if coatings are credited for corrosion prevention, the base material (in the vicinity of delamination, peeling, or blisters where base metal has been exposed) will be inspected to determine if corrosion has occurred.

Piping

i. High pressure fire protection (cement lined piping)

- Prior to the PEO, perform a visual inspection of the following coated tanks and heat exchangers. Visually inspect the surface condition of the coated components to manage loss of coating integrity due to cracking, debonding, delamination, peeling, flaking, and blistering. For the Condensate Storage Tanks, blisters should be limited to a few intact small blisters that are completely surrounded by sound coating/lining bonded to the substrate. Coatings/linings that do not meet acceptance criteria are repaired, replaced, or removed. If a blister is not repaired, physical testing is conducted to ensure that the blister is completely surrounded by sound coating/lining bonded to the surface. Physical testing consists of adhesion testing using ASTM International Standards endorsed in RG 1.54.

Tanks

i. Safety injection lube oil reservoir (where 0.006 inch plastic coating applied)
ii. EDG 7 day fuel oil storage (where Belzona applied)
iii. Condensate storage tanks

Heat Exchangers

i. Electric board room chiller packages (where Belzona applied)
ii. Incore instrument room water chiller package B (where Belzona applied)

- Include the following loss of coating integrity acceptance criteria (1) peeling and delamination are not permitted, (2) cracking is not permitted if accompanied by delamination or loss of adhesion, and (3) blisters are limited to intact blisters that are completely surrounded by sound coating bonded to the surface. If delamination, peeling, or blisters are detected, follow-up physical testing will be performed where physically possible (i.e., sufficient room to conduct testing) on at least three locations. The testing will consist of destructive or nondestructive adhesion testing using ASTM International standards endorsed in Regulatory Guide 1.54.

- Ensure coating inspections are performed by individuals certified to ANSI N45.2.6, "Qualifications of Inspection, Examination, and Testing Personnel for Nuclear Power Plants," and that subsequent evaluation of inspection findings is conducted by a nuclear coatings subject matter expert qualified in accordance with ASTM D 7108-05, "Standard Guide for Establishing Qualifications for a Nuclear Coatings Specialist."

    - Ensure an individual knowledgeable and experienced in nuclear coatings work will prepare a coating report that includes a list of locations identified with coating deterioration including, where possible, photographs indexed to inspection location, and a prioritization of the repair areas into areas that must be repaired before returning the system to service and areas where coating repair can be postponed to the next inspection.

APPENDIX A

- With the exception of the EDG 7-day fuel oil tanks, perform subsequent inspections of coatings based on the following.

    i. If no flaking, debonding, peeling, delamination, blisters, or rusting are observed, and any cracking and flaking has been found acceptable, subsequent inspections will be performed at least once every six years. If the coating is inspected on one train and no indications are found, the same coating on the redundant train would not be inspected during that inspection interval.
    ii. If the inspection results do not meet (i), yet a coating specialist has determined that no remediation is required, then subsequent inspections will be conducted every other refueling outage.
    iii. If coating degradation is observed that required newly installed coatings, subsequent inspections will occur during each of the next two refueling outage intervals to establish a performance trend on the coating.

EDG 7-day fuel oil tanks coating inspection:

Subsequent coating inspections for the EDG 7-day fuel oil tanks will be at the same 10 year interval as TS Surveillance Requirement 4.8.1.1.2.f. If any applied Belzona coating on the interior of the fuel oil tanks is peeling, delaminating, or blistering, then the condition will be repaired and entered into the CAP. Given the favorable SQN experience with the current Belzona repairs, it is justifiable to repair the existing coating applied to localized pits with Belzona and not inspect the coating for another 10 years, provided a detached Belzona engineering transportability evaluation has determined that the amount of Belzona applied will not migrate from the EDG 7-day tank to the day-tank. The evaluation will consider Belzona's 2.5 to 3 times higher specific gravity than diesel fuel, potential size of loosened Belzona particles, surface area and depth of the applied Belzona, diesel fuel fluid velocity in the immediate area of the applied Belzona, proximity of the repaired area to the suction line, and other factors.

The application of Belzona to repair additional localized pitting in the 7-day EDG fuel oil tanks in the future will be installed per vendor specifications. An engineering evaluation will be performed to ensure that that additional Belzona cannot be transferable out of the tank during the interval between tank inspections and to determine if the interval of inspections should meet the more frequent inspection guidelines of LR-ISG-2013-01, or the NRC approved TS Surveillance Requirement of 10 years. The engineering transportability evaluation will considerfactors such as specific gravity, size, depth, surface area, and fluid velocity in the evaluation.

APPENDIX A

Miscellaneous Aging Management Inspections

- Pressure test the divider barrier seal test coupon, and manually flex and visually monitor the surface condition of elastomeric components related to the seal between the upper and lower compartments (divider barrier) in reactor building to verify the absence of cracks, loss of material, and change in material properties.

- Replace the standby diesel generator starting air aluminum valve bodies prior to 5 years of service.

  Perform EVT-1 visual inspection of the surface condition to monitor for cracks in the standby DG exhaust expansion joint.

- Visually inspect the inside and outside surface condition of the component cooling carbon steel spool piece exposed to air – indoor to manage loss of material. In addition, for component cooling carbon steel piping exposed to stagnant treated water > 130ºF, perform sample inspection using ultrasonic testing (UT) to ensure no cracks.

- Use visual or other NDE techniques to inspect internal surfaces of fire pump B diesel engine heat exchanger copper alloy tubes exposed to raw water to manage fouling.

- Visually inspect the inside surface condition of carbon steel and stainless steel RCP oil collection piping exposed to waste lube oil to manage loss of material.

- For ESF room coolers, perform air flow testing to manage fouling for copper alloy tubes and fins. Perform an inspection of the heat exchanger (tubes) surface condition to manage loss of material. Perform an EVT-1 visual inspection of the surface condition of a representative sample of aluminum valve bodies to verify the absence of cracking due to stress corrosion/IGA. Visually inspect surface condition of fan housing and exhaust fan cover surface condition to manage loss of material.

- Perform an air-side visual inspection of the surface condition of the auxiliary controlled air system after-cooler copper alloy tubes/fins for debris.

- Perform a flow rate monitoring of the charging pump mini-flow orifices for evidence of erosion in the chemical and volume control system.

- Use visual or other NDE techniques to inspect the surface condition of the waste disposal stainless steel piping in the water line region in the containment floor and equipment sumps to manage the potential accelerated loss of material.

- Visually inspect the inside and outside surface condition of the carbon steel essential raw cooling water spool pieces exposed to air – indoor to manage loss of material.

APPENDIX A

Recurring Corrosion Inspections

- Perform wall thickness measurements using UT or other suitable techniques at selected locations to identify loss of material due to microbiologically Influenced corrosion (MIC) in carbon steel piping components exposed to raw water in the following systems.
  - System 24 – Raw cooling water
  - System 25 – Raw service water
  - System 26 – High Pressure Fire Protection
  - System 27 – Condenser circulating water
  - System 67 – Essential raw cooling water

  Choose selected locations based on pipe configuration, flow conditions and operating history to represent a cross-section of potential MIC sites. Periodically review the selected locations to validate their relevance and usefulness, and modify accordingly.

  Compare wall thickness measurements to nominal wall thickness or previous measurements to determine rates of corrosion degradation. Compare wall thickness measurements to minimum allowable wall thickness (T_{min}) to determine acceptability of the component for continued use. Perform subsequent wall thickness measurements at intervals determined for each selected location based on the rate of corrosion and expected time to reach T_{min}. Perform a minimum of five MIC degradation inspections per year until the rate of MIC corrosion occurrences no longer meets the criteria for recurring internal corrosion.

  If more than one MIC-caused leak or a wall thickness less than T_{min} is identified in the yearly inspection period, an additional five MIC inspections over the following 12 month period will be performed for each MIC leak or finding of wall thickness less than T_{min}. The total number of inspections need not exceed a total of 25 MIC inspections per year.

  Prior to the period of extended operation, select a method (or methods) from available technologies for inspecting internal surfaces of buried piping that provides suitable indication of piping wall thickness for a representative set of buried piping locations to supplement the set of selected inspection locations.

Non-Safety Related Systems Affecting Safety Related Systems Inspections

- Visually inspect the internal surface condition of a representative sample of components in the following material, environment, and aging effect combinations:
  -Aluminum in Waste Water for Loss of Material
    -System 059/959
  -Carbon Steel in Air-Indoor for Loss of Material
    -Systems 030, 031, 044, 300, 311, 312 and 313
  -Carbon Steel in Raw Water for Loss of Material
    -System 024

-Carbon Steel in Waste Water for Loss of Material
 -System 001
 -System 012
 -System 015
 -System 024

 -Systems 030, 031, 044, 300, 311, 312 and 313
 -System 037
 -System 043
 -System 059/959
 -System 062
 -System 067
 -System 070
 -System 077
 -System 087
 -System 090
-Copper Alloy in Waste Water for Loss of Material

 -Systems 030, 031, 044, 300, 311, 312 and 313
-Stainless Steel in Raw Water for Loss of Material
 -System 024
-Stainless Steel in Waste Water for Loss of Material
 -System 001
 -System 012
 -System 015
 -System 024

 -System 043
 -System 059/959
 -System 062
 -System 067
 -System 070
 -System 077
 -System 081
 -System 087

- Visually inspect the interior and exterior surface of the fire/flood mode carbon steel pumps and piping and piping components exposed to raw water to manage loss of material.

- Visually inspect the internal surface condition of stainless steel station drainage and sewage (040/305) piping to manage loss of material.

- Perform wall-thickness evaluations of carbon steel filter housings, piping, pump casings, tank, and valve bodies in the waste disposal system (System 077) associated with the cask decontamination collector tank (CDCT) to identify loss of material.

The PSPM Program has been enhanced as follows.

Revise PSPM Program procedures as necessary to assure that the effects of aging will be managed such that applicable components will continue to perform their intended functions consistent with the current licensing basis through the period of extended operation.

A.1.32 Protective Coating Monitoring and Maintenance Program

The Protective Coating Monitoring and Maintenance Program monitors and maintains Service Level I coatings applied to carbon steel and concrete surfaces inside containment (e.g., steel containment vessel shell, structural steel, supports, penetrations, and concrete walls and floors). The program serves to prevent or minimize loss of material due to corrosion of carbon steel components and aids in decontamination. The program addresses accessible coated surfaces inside containment. The SQN program was developed based on the guidance contained in NRC RG 1.54, Revision 0; however, the program will be enhanced to meet the technical basis of Regulatory Position C4 in NRC RG 1.54, Revision 2, and ASTM D 5163-08. With these enhancements, the program provides an effective method to assess coating condition through visual inspections by identifying degraded or damaged coatings and providing a means for repair of identified problem areas.

Service Level I protective coatings are not credited to manage the effects of aging. Proper monitoring and maintenance of protective coatings inside containment ensures operability of post-accident safety systems that rely on water recycled through the containment. The proper monitoring and maintenance of Service Level I coatings ensures there is no coating degradation that would impact safety functions, for example, by clogging emergency core cooling systems suction strainers, reducing flow through the system and possibly causing unacceptable head loss for the pumps.

The Protective Coating Monitoring and Maintenance Program has been enhanced as follows.

- Revise Protective Coating Monitoring and Maintenance Program procedures to clarify that detection of aging effects will include inspection of coatings near sumps or screens associated with the emergency core cooling system.

- Revise Protective Coating Monitoring and Maintenance Program procedures to clarify that instruments and equipment needed for inspection may include, but not be limited to, flashlights, spotlights, marker pen, mirror, measuring tape, magnifier, binoculars, camera with or without wide-angle lens, and self-sealing polyethylene sample bags.

- Revise Protective Coating Monitoring and Maintenance Program procedures to clarify that the last two performance monitoring reports pertaining to the coating systems will be reviewed prior to the inspection or monitoring process.

A.1.33 Reactor Head Closure Studs Program

The Reactor Head Closure Studs Program manages cracking and loss of material for reactor head closure studs using inservice inspection (ASME Section XI 2001 Edition 2003 Addendum Table IWB-2500-1) and preventive measures to mitigate cracking. The program also relies on

recommendations to address reactor head closure studs degradation listed in NUREG-1339 and NRC Regulatory Guide 1.65.

The Reactor Head Closure Studs Program has been enhanced as follows.

- Revise Reactor Head Closure Studs Program procedures to ensure that replacement studs are fabricated from bolting material with actual measured yield strength less than 150 ksi.
- Revise Reactor Head Closure Studs Program procedures to exclude the use of molybdenum disulfide (MoS_2) on the reactor vessel closure studs and to refer to Reg. Guide 1.65, Rev. 1.

A.1.34 <u>Reactor Vessel Internals Program</u>

The Reactor Vessel Internals Program includes reactor vessel internal components for SQN Unit 1 and Unit 2, which are Westinghouse NSSS design, with the exception of fuel assemblies, reactivity control assemblies, nuclear instrumentation, and welded attachments to the reactor vessel. The program performs the following: (1) manages cracking, loss of material, reduction of fracture toughness, change in dimension and loss of preload for reactor vessel internal components intended to provide core support; (2) consistent with a living program implements applicable NEI 03-08 guidance (e.g. Electric Power Research Institute (EPRI) “Materials Reliability Program (MRP): Pressurized Water Reactor Internals Inspection and Evaluation Guidelines (MRP-227) and MRP: Inspection Standard for PWR Internals (MRP-228); (3) incorporates “acceptance criteria” recommendations from Section 3.1.2.2 of NUREG-1800; (4) discusses how to disposition nonconforming reactor vessel internals components; (5) incorporates the definition of sampling-based condition monitoring found in NRC Branch Technical Position RSLB-1; and (6) uses a four-step ranking process (i.e., primary, expansion, existing and no additional measure components).

The result of the four-step sample selection process is a set of primary internals component locations for the SQN reactor vessel internals design that are expected to show leading indications of the degradation effects, with another set of expansion internals component locations that are specified to expand the sample should the indications be more severe than anticipated. The degradation of the third set of internals locations are deemed to be adequately managed by existing programs, such as American Society of Mechanical Engineers (ASME) Code Section XI Examination Category B-N-3, examinations of core support structures. A fourth set of internal locations are deemed to require no additional measures. This process used appropriate component functionality criteria, age-related degradation susceptibility criteria, and failure consequences criteria to identify the components that will be inspected under the program. Consequently, the sample selection process is adequate to assure that the intended functions of the reactor internal components are maintained during the period of extended operation.

The program uses inspection techniques consistent with MRP-227-A and MRP-228.

The Reactor Vessel Internals Program has been enhanced as follows.

- Revise Reactor Vessel Internals Program procedures to perform direct measurement of Unit 1 304 SS hold down spring height within three cycles of the beginning of the period of extended operation. If the first set of measurements is not sufficient to determine life, spring height measurements must be taken during the next two outages, in order to extrapolate the expected spring height to 60 years.

- Revise Reactor Vessel Internals Program procedures to include preload acceptance criteria for the Type 304 stainless steel hold-down spring in Unit 1.

A.1.35 Reactor Vessel Surveillance Program

The Reactor Vessel Surveillance Program manages reduction of fracture toughness and long-term operating conditions for reactor vessel beltline materials using material data and dosimetry. The program includes all reactor vessel beltline materials as defined by 10 CFR 50 Appendix G, Section II.F, and complies with 10 CFR 50, Appendix H for vessel material surveillance. In addition, the program will consider reduction in fracture toughness and long-term operating conditions for the area outside the beltline.

The objective of the Reactor Vessel Surveillance Program is to provide sufficient material data and dosimetry to (a) monitor irradiation embrittlement at the end of the period of extended operation and (b) determine the need for operating restrictions on the inlet temperature, neutron spectrum, and neutron flux. If surveillance capsules are not withdrawn during the period of extended operation, operating restrictions are specified to ensure that the plant is operated under the conditions to which the surveillance capsules were exposed. Capsules removed from the reactor vessel are tested and reported in accordance with ASTM E 185-82 to the extent practicable for the configuration of the specimens in the capsule.

The Reactor Vessel Surveillance Program has been enhanced as follows.

- Revise Reactor Vessel Surveillance Program procedures to consider the area outside the beltline such as nozzles, penetrations and discontinuities to determine if more restrictive

pressure-temperature limits are required than would be determined by just considering the reactor vessel beltline materials.

- B.1 Revise Unit 2 Reactor Vessel Surveillance Program procedures to incorporate an NRC-approved schedule for capsule withdrawals to meet ASTM-E185-82 requirements, including the possibility of operation beyond 60 years (refer to the TVA letter to NRC, “Sequoyah Nuclear Plant – Request To Revise The Reactor Pressure Vessel Surveillance Capsule Withdrawal Schedule for Unit 2” dated 12/23/16, ML16362A207; NRC final safety evaluation report approved on 12/04/17, ML17317A608).

- Revise Unit 1 Reactor Vessel Surveillance Program procedures to incorporate an NRC-approved schedule for capsule withdrawals to meet ASTM E 185-82 requirements, including the possibility of operation beyond 60 years (refer to the TVA Letter to NRC, Sequoyah Nuclear Plant, Revision to Reactor Pressure Vessel Surveillance Capsule Withdrawal Schedule for License Renewal dated May 14, 2015).

A.1.36 RG 1.127, Inspection of Water-Control Structures Associated with Nuclear Power Plants Program

SQN is not committed to the requirements of NRC Regulatory Guide (RG) 1.127, "Inspection of Water-Control Structures Associated with Nuclear Power Plants." However, the program at SQN was developed based on guidance provided in the NRC RG 1.127, Revision 1, "Inspection of Water-Control Structures Associated with Nuclear Power Plants," and provides an inservice inspection and surveillance program for the SQN slopes, channels and raw water-control structures associated with emergency cooling water systems or flood protection. The scope of the SQN program includes water-control structures within the scope of license renewal as delineated in 10 CFR 54.4. The program performs periodic visual examinations to monitor the condition of water-control structures and structural components. The program addresses age-related deterioration, degradation due to extreme environmental conditions, and the effects of natural phenomena that may affect water-control structures so that the consequences of age-related deterioration and degradation can be prevented or mitigated in a timely manner. The program has been implemented as part of the Structures Monitoring Program (Section A.1.40).

The program provides guidance on engineering data compilation, inspection activities, technical evaluation, inspection frequency, and the content of inspection reports. Inspections of water-control structures are conducted by or under the direction of qualified engineers experience in the investigation, design, construction, and operation of the structures. Inspections are conducted systematically using checklists and other documents as required to minimize the possibility of overlooking significant features. Technical evaluations are performed if observed degradations have the potential for impacting the intended function of the water-control structures.

Enhancements to this program are included in the enhancements to the Structures Monitoring Program (Section A.1.40).

A.1.37 Selective Leaching Program

The Selective Leaching Program demonstrates the absence of selective leaching in a selected sample of components (i.e., 20 percent of the population with maximum of 25 components) fabricated from gray cast iron the only components constructed of this material in the scope of license renewal are eight valves in the High Pressure Fire Protection (HPFP System) and copper alloys (except for inhibited brass) that contain greater than 15 percent zinc or greater than 8 percent aluminum exposed to raw water, waste water, treated water, or ground water. A sample population is defined as components with the same material and environment combination. The sample population will focus on bounding or leading components most susceptible to aging due to time in service, severity of operating condition, and lowest design margin. The program includes a one-time visual inspection of selected components coupled with hardness measurement or other mechanical examination techniques such as destructive testing, scraping or chipping to determine whether loss of material is occurring due to selective leaching that may affect the ability of a component to perform its intended function during the period of extended operation.

Follow-up for unacceptable inspection findings includes an evaluation using the corrective action program and possible expansion of the inspection sample size and location.

This inspection was performed within the five years prior to the period of extended operation with exception of the gray cast iron HPFP valves. These valves were installed in 1998, and based on the guidance in NUREG-1801, Rev. 2, the inspection of these valves for selective leaching shall take place between 2033 and 2038.

A.1.38 Service Water Integrity Program

The Service Water Integrity Program manages loss of material and fouling for components fabricated from carbon steel, carbon steel clad with stainless steel, cast iron, copper alloy, nickel alloy, or stainless steel exposed to ERCW as described in the SQN response to NRC GL 89-13. The program includes (a) surveillance and control techniques to manage effects of biofouling, corrosion, erosion, coating failures, and silting; (b) tests to verify heat transfer capability of heat exchangers important to safety; (c) system walkdowns to ensure compliance with the licensing basis; and (d) routine inspections and maintenance.

The Service Water Integrity Program has been enhanced as follows.

- Revise Service Water Integrity Program procedures to perform periodic visual inspections to manage loss of coating integrity due to cracking, debonding, delamination, peeling, flaking, and blistering in heat exchangers credited in the NRC Generic Letter (GL) 89-13 response. Include the following coating integrity acceptance criteria: (1) peeling and delamination are not permitted, (2) cracking is not permitted if accompanied by delamination or loss of adhesion, and (3) blisters are limited to intact blisters that are completely surrounded by sound coating bonded to the surface.

- Revise Service Water Integrity Program procedures to ensure coating inspections are performed by individuals certified to ANSI N45.2.6, "Qualifications of Inspection, Examination, and Testing Personnel for Nuclear Power Plants," and that subsequent evaluation of inspection findings is conducted by a nuclear coatings subject matter expert qualified in accordance with ASTM D 7108-05, "Standard Guide for Establishing Qualifications for a Nuclear Coatings Specialist."

- Revise Service Water Integrity Program procedures to ensure an individual knowledgeable and experienced in nuclear coatings work will prepare a coating report that includes a list of locations identified with coating deterioration including, where possible, photographs indexed to inspection location, and a prioritization of the repair areas into areas that must be repaired before returning the system to service and areas where coating repair can be postponed to the next inspection.”

- Revise Service Water Integrity Program procedures to periodically place normally ERCW stagnant/dead legs in service for the purpose of flushing. Alternatively, periodically flush the normally stagnant/dead leg by temporarily/permanently installing a flushing valve (without placing the line in service). In lieu of flushing, periodic radiograph, demonstrated ultrasonic or visual inspections of ERCW stagnant/dead leg piping are acceptable to confirm the absence of fouling/clogging. Any identified fouling or clogging will be documented in the corrective action program and the impact on ERCW system design functions evaluated. This enhancement is applicable to ERCW flow-paths that fulfill a safety-related function.

A.1.39 Steam Generator Integrity Program

The Steam Generator Integrity Program manages aging effects for the steam generator tubes, plugs, sleeves, and secondary side components contained within the steam generator in accordance with the plant technical specifications and commitments to NEI 97-06. Preventive and mitigative measures include foreign material exclusion programs and other primary and secondary side maintenance activities.

The Steam Generator Integrity Program has been enhanced as follows.

- Revise Steam Generator Integrity Program procedures to ensure that corrosion resistant materials are used for replacement steam generator tube plugs.

A.1.40 Structures Monitoring Program

The Structures Monitoring Program provides for aging management of structures and structural components, including structural bolting, within the scope of license renewal. The program was developed based on guidance in Regulatory Guide 1.160, Revision 2, "Monitoring the Effectiveness of Maintenance at Nuclear Power Plants," and NUMARC 93-01, Revision 2, "Industry Guidelines for Monitoring the Effectiveness of Maintenance at Nuclear Power Plants," to satisfy the requirement of 10 CFR 50.65, "Requirements for Monitoring the Effectiveness of Maintenance at Nuclear Power Plants." The scope of the Structures Monitoring Program includes structures within the scope of license renewal as delineated in 10 CFR 54.4. The program performs periodic visual examinations to monitor the condition of structures and structural components, including components such as concrete and steel components, structural bolting, component supports, concrete masonry blocks, and other structures such as earthen structures. Inspections are performed at least once every five years, with provisions for more frequent inspections, to ensure there is no loss of intended function between inspections. The scope of the program also includes the condition monitoring of masonry walls and water-control structures as described in the Masonry Wall Program (Section A.1.20) and in

the NRC Regulatory Guide 1.127, "Inspection of Water-Control Structures Associated with Nuclear Power Plants," aging management program (Section A.1.36).

The Structures Monitoring Program is augmented by plant procedures to ensure that the selection of bolting material, installation torque or tension, and the use of lubricants and sealants are appropriate for the intended purpose. These procedures include the guidance of EPRI TR-104213, NUREG-1339, and EPRI NP-5769 to ensure proper specification of bolting material, lubricant, and installation torque.

The Structures Monitoring Program has been enhanced as follows.

- Revise Structures Monitoring Program procedures to include the following in-scope structures.
  - Carbon dioxide building
  - Condensate storage tanks' (CSTs) foundations and pipe trench
  - East steam valve room Units 1 & 2
  - Essential raw cooling water (ERCW) pumping station
  - High pressure fire protection (HPFP) pump house and water storage tanks' foundations
  - Radiation monitoring station (or particulate iodine and noble gas station) Units 1 & 2
  - Service Building
  - Skimmer wall (Cell No. 12)
  - Transformer and switchyard support structures and foundations
- Revise Structures Monitoring Program procedures to specify the following list of in-scope structures are included in the RG 1.127, Inspection of Water-Control Structures Associated with Nuclear Power Plants Program (Section A.1.36):
  - Condenser cooling water (CCW) pumping station (also known as intake pumping station) and retaining walls
  - CCW pumping station intake channel
  - ERCW discharge box
  - ERCW protective dike
  - ERCW pumping station and access cells
  - Skimmer wall, skimmer wall Dike A and underwater dam

APPENDIX A

- Revise Structures Monitoring Program procedures to include the following in-scope structural components and commodities.
    - Anchor bolts
    - Anchorage/embedments (e.g., plates, channels, unistrut, angles, other structural shapes)
    - Beams, columns and base plates (steel)
    - Beams, columns, floor slabs and interior walls (concrete)
    - Beams, columns, floor slabs and interior walls (reactor cavity and primary shield walls; pressurizer and reactor coolant pump compartments; refueling canal, steam generator compartments; crane wall and missile shield slabs and barriers)
    - Building concrete at locations of expansion and grouted anchors; grout pads for support base plates
    - Cable tray
    - Cable tunnel
    - Canal gate bulkhead
    - Compressible joints and seals
    - Concrete cover for the rock walls of approach channel
    - Concrete shield blocks
    - Conduit
    - Control rod drive missile shield
    - Control room ceiling support system
    - Curbs
    - Discharge box and foundation
    - Doors (including air locks and bulkhead doors)
    - Duct banks
    - Earthen embankment
    - Equipment pads/foundation
    - Explosion bolts (E. G. Smith aluminum bolts)

APPENDIX A

- Exterior above and below grade; foundation (concrete)
- Exterior concrete slabs (missile barrier) and concrete caps
- Exterior walls: above and below grade (concrete)
- Foundations: building, electrical components, switchyard, transformers, circuit breakers, tanks, etc.
- Ice baskets
- Ice baskets lattice support frames
- Ice condenser support floor (concrete)
- Insulation (fiberglass, calcium silicate)
- Intermediate deck and top deck of ice condenser
- Kick plates and curbs (steel—inside steel containment vessel)
- Lower inlet doors (inside steel containment vessel)
- Lower support structure structural steel: beams, columns, plates (inside steel containment vessel)
- Manholes and hand holes
- Manways, hatches, manhole covers, and hatch covers (concrete)
- Manways, hatches, manhole covers, and hatch covers (steel)
- Masonry walls
- Metal siding
- Miscellaneous steel (decking, grating, handrails, ladders, platforms, enclosure plates, stairs, vents and louvers, framing steel, etc.)
- Missile barriers/shields (concrete)
- Missile barriers/shields (steel)
- Monorails
- Penetration seals
- Penetration seals (steel end caps)
- Penetration sleeves (mechanical and electrical not penetrating primary containment boundary)

- Personnel access doors, equipment access floor hatch and escape hatches
- Piles
- Pipe tunnel
- Precast bulkheads
- Pressure relief or blowout panels
- Racks, panels, cabinets and enclosures for electrical equipment and instrumentation
- Riprap
- Rock embankment
- Roof or floor decking
- Roof membranes
- Roof slabs
- RWST rainwater diversion skirt
- RWST storage basin
- Seals and gaskets (doors, manways and hatches)
- Seismic/expansion joint
- Shield building concrete foundation, wall, tension ring beam and dome: interior, exterior above and below grade
- Steel liner plate
- Steel sheet piles
- Structural bolting
- Sumps (concrete)
- Sump liners (steel)
- Sump screens
- Support members; welds; bolted connections; support anchorages to building structure (e.g., non-ASME piping and components supports, conduit supports, cable tray supports, HVAC duct supports, instrument tubing supports, tube track supports,pipe whip restraints, jet impingement shields, masonry walls, racks, panels, cabinets and enclosures for electrical equipment and instrumentation)

APPENDIX A

- Support pedestals (concrete)
- Transmission, angle and pull-off towers
- Trash racks
- Trash racks associated structural support framing
- Traveling screen casing and associated structural support framing
- Trenches (concrete)
- Tube track
- Turning vanes
- Vibration isolators
- Portions of the pressurizer relief tanks (feet, shell, and saddles at tank piping penetrations, etc.) that provide structural support for the pressurizer safety valve/PORV discharge piping.

• Revise Structures Monitoring Program procedures to specify masonry walls located in the following in-scope structures are in the scope of the Masonry Wall Program:
  - Auxiliary building
  - Reactor building Units 1 & 2
  - Control bay
  - ERCW pumping station
  - HPFP pump house
  - Turbine building

• Revise Structures Monitoring Program procedures to include periodic sampling and chemical analysis of ground water chemistry for pH, chlorides, and sulfates on a frequency of at least every five years.

• Revise Structures Monitoring Program procedures to include the following parameters to be monitored or inspected:
  - Requirements for concrete structures based on ACI 349-3R and ASCE 11 and include monitoring the surface condition for loss of material, loss of bond, increase in porosity and permeability, loss of strength, and reduction in concrete anchor capacity due to local concrete degradation.
  - Loose or missing nuts for structural bolting.
  - Monitoring gaps between the structural steel supports and masonry walls that could potentially affect wall qualification.

  - Monitor the surface condition of insulation (fiberglass, calcium silicate) to identify exposure to moisture that can cause loss of insulation effectiveness.

- Revise Structures Monitoring Program procedures to include the following components to be monitored for the associated parameters:
  - Anchors/fasteners (nuts and bolts) will be monitored for loose or missing nuts and/or bolts, and cracking of concrete around the anchor bolts.
  - Elastomeric vibration isolators and structural sealants will be monitored for cracking, loss of material, loss of sealing, and change in material properties (e.g., hardening).

- Revise Structures Monitoring Program procedures to include the following for detection of aging effects:
  - Inspection of structural bolting for loose or missing nuts.
  - Inspection of anchor bolts for loose or missing nuts and/or bolts, and cracking of concrete around the anchor bolts.
  - Inspection of elastomeric material for cracking, loss of material, loss of sealing, and change in material properties (e.g., hardening), and supplement inspection by feel or touch to detect hardening if the intended function of the elastomeric material is suspect. Include instructions to augment the visual examination of elastomeric material with physical manipulation of at least ten percent of available surface area.
  - Inspection of insulation (fiberglass, calcium silicate) to manage loss of material and change in material properties due to exposure to moisture that can cause loss of insulation effectiveness.
  - Opportunistic inspections when normally inaccessible areas (e.g., high radiation areas, below-grade concrete walls or foundations, buried structures) become accessible due to required plant activities. Additionally, inspections will be performed of inaccessible areas in environments where observed conditions in accessible areas exposed to the same environment indicate that significant degradation is occurring.
  - Inspection of submerged structures at least once every five years.
  - Inspections of water control structures which should be conducted under the direction of qualified personnel experienced in the investigation, design, construction, and operation of these types of facilities.
  - Inspections of water control structures on an interval not to exceed five years.
  - Performance of special inspections of water control structures immediately (within 30 days) following the occurrence of significant natural phenomena, such as large floods, earthquakes, hurricanes, tornadoes, and intense local rainfalls.
  - Qualifications of personnel conducting the inspections of testing and evaluation of structures and structural components meet the guidance in Chapter 7 of ACI 349.3R

- Revise Structures Monitoring Program procedures to prescribe quantitative acceptance criteria based on the quantitative acceptance criteria of ACI 349.3R and information provided in industry codes, standards, and guidelines including ACI 318, ANSI/ASCE 11 and relevant AISC specifications. Industry and plant-specific operating experience will also be considered in the development of the acceptance criteria.

- Revise Structures Monitoring Program procedures to include the following acceptance criteria for insulation (calcium silicate and fiberglass):
    - No moisture or surface irregularities that indicate exposure to moisture.

- Revise Structures Monitoring Program procedures to include the following preventive actions.
    - Specify protected storage requirements for high-strength fastener components (specifically ASTM A325 and A490 bolting.) Storage of these fastener components shall include: (1) maintaining fastener components in closed containers to protect from dirt and corrosion; (2) storage of the closed containers in a protected shelter; (3) removal of fastener components from protected storage only as necessary; and (4) prompt return of any unused fastener components to protected storage.

A.1.41 Thermal Aging Embrittlement of Cast Austenitic Stainless Steel Program

The Thermal Aging Embrittlement of Cast Austenitic Stainless Steel Program manages the aging effects of cracking and reduction in fracture toughness in cast austenitic stainless steel (CASS) components. The program consists of a determination of the susceptibility of CASS piping, piping components, and piping elements and the regenerative heat exchanger shell and channel head to thermal aging embrittlement based on Hull's equivalent factor, as described in NUREG/CR-4513, Revision 1. For potentially susceptible components, aging management is accomplished through qualified visual inspections, such as enhanced visual examination, qualified ultrasonic testing methodology, or component-specific flaw tolerance evaluation in accordance with ASME Section XI code, 2001 Edition 2003 addendum. Applicable industry standards and guidance documents are used to delineate the program. For CASS materials with estimated delta ferrite > 20% that have been determined susceptible to thermal aging, a flaw tolerance analyses may be performed using ASME Code approaches for flaw tolerance of CASS that have been accepted and approved by the time that flaw tolerance must be demonstrated. For those CASS components with delta ferrite content > 25%, additional analysis will be performed using plant-specific materials data and best available fracture toughness curves.

A.1.42 Water Chemistry Control – Closed Treated Water Systems Program

The Water Chemistry Control – Closed Treated Water Systems Program manages loss of material, cracking, and fouling in components exposed to a treated water environment through monitoring and control of water chemistry (including the use of corrosion inhibitors), as well as visual inspections to determine the presence of corrosion and/or cracking. The latest revision of the EPRI closed-cycle cooling guidelines and operating experience are used to delineate the program.

APPENDIX A

The Water Chemistry Control – Closed Treated Water Systems Program has been enhanced as follows.

- Revise Water Chemistry Control – Closed Treated Water Systems Program procedures to provide a corrosion inhibitor for the following chilled water subsystems in accordance with industry guidelines and vendor recommendations:
  - Auxiliary building cooling
  - Incore Chiller 1A, 1B, 2A, & 2B
  - 6.9 kV Shutdown Board Room A & B
- Revise Water Chemistry Control – Closed Treated Water Systems Program procedures to conduct inspections whenever a boundary is opened for the following systems:
  - Standby diesel generator jacket water subsystem
  - Component cooling system
  - Glycol cooling loop system
  - High pressure fire protection diesel jacket water system
  - Chilled water portion of miscellaneous HVAC systems (i.e., auxiliary building, Incore Chiller 1A, 1B, 2A, & 2B, and 6.9 kV Shutdown Board Room A & B)

  These inspections will be conducted in accordance with applicable ASME Code requirements, industry standards, or other plant-specific inspection and personnel qualification procedures that are capable of detecting corrosion or cracking.
- Revise Water Chemistry Control – Closed Treated Water Systems Program procedures to perform sampling and analysis of the glycol cooling system per industry standards and in no case greater than quarterly unless justified with an additional analysis.
- Revise Water Chemistry Control – Closed Treated Water Systems Program procedures to inspect a representative sample of piping and components at a frequency of once every ten years for the following systems:
  - Standby diesel generator jacket water subsystem
  - Component cooling system
  - Glycol cooling loop system
  - High pressure fire protection diesel jacket water system
  - Chilled water portion of miscellaneous HVAC systems (i.e., auxiliary building, Incore Chiller 1A, 1B, 2A, & 2B, and 6.9 kV Shutdown Board Room A & B)

Components inspected will be those with the highest likelihood of corrosion or cracking. A representative sample is 20 percent of the population (defined as components having the same material, environment, and aging effect combination) with a maximum of 25 components. These inspections will be in accordance with applicable ASME Code requirements, industry standards, or other plant-specific inspection and personnel qualification procedures that ensure the capability of detecting corrosion or cracking.

A.1.43 Water Chemistry Control – Primary and Secondary Program

The Water Chemistry Control – Primary and Secondary Program manages loss of material, cracking, and fouling in components exposed to a treated water environment through periodic monitoring and control of water chemistry. The Water Chemistry Control – Primary and Secondary Program monitors and controls water chemistry parameters such as pH, chloride, fluoride, and sulfate. EPRI Report 1014986 Rev. 6 or subsequent revision is used to provide guidance for primary water chemistry, and EPRI Report 1016555 Rev. 7 or subsequent revision is used to provide guidance for secondary water chemistry.

The One-Time Inspection Program (Section A.1.29) uses inspections or nondestructive evaluations of representative samples to verify that the Water Chemistry Control – Primary and Secondary Program has been effective at managing aging effects. The representative sample includes low flow and stagnant areas.

A.1.44 161-kV Oil-Filled Cable Program

The plant-specific 161-kV Oil-Filled Cable Program provides reasonable assurance the intended functions of the insulated cables, connections, and pressurized oil system components exposed to their respective environments can be maintained consistent with the current licensing basis through the period of extended operation.

Periodic visual walkdowns of the complete system are conducted to discover any oil leaks to prevent introducing air, water, or other contamination. Periodic oil pressure and inventory checks are conducted to maintain the integrity of the closed pressurized system.

Periodic oil sampling requires the depressurization of the pressurized system introducing the potential for ingress of outside contaminants. Oil sampling is conducted on an opportunistic basis (such as repairs or major maintenance activities), when system depressurizations are required. As opportunistic oil sampling is conducted, oil contaminant levels shall be trended and a condition report shall be initiated if contaminant levels exceed alert levels or limits.

Periodic cable testing is conducted to ensure the oil-impregnated paper insulation between the conductors and the aluminum sheath is not aging from the potential aging effects of oil contaminants.

Good industry practices, such as one-time ultrasonic test (UT) of oil reservoirs, periodic thermoscans of cable connections, periodic partial discharge checks at the potheads, and periodic pothead porcelain cleanings are also conducted to maintain the integrity of the oil-filled cable system.

A.2 EVALUATION OF TIME-LIMITED AGING ANALYSES

In accordance with 10 CFR 54.21(c), an application for a renewed license requires an evaluation of time-limited aging analyses for the period of extended operation. The following time-limited aging analyses were evaluated as part of the license renewal application to meet this requirement.

A.2.1 Reactor Vessel Neutron Embrittlement

The regulations governing reactor vessel integrity are in 10 CFR 50. Section 50.60 requires that light-water reactors meet the fracture toughness, pressure-temperature limits, and material surveillance program requirements for the reactor coolant pressure boundary set forth in Appendices G and H of 10 CFR 50. Based on the plant operating history, 52 EFPY is used to bound the expected EFPY for both units.

A.2.1.1 Reactor Vessel Fluence

Fluence is calculated based on a time-limited assumption defined by the operating term. Therefore, analyses that evaluate reactor vessel neutron embrittlement based on calculated fluence are TLAAs. The neutron fluence values for the SQN Unit 1 and Unit 2 reactor pressure vessel beltline material have been projected to 52 EFPY of operation.

The methods used to calculate the SQN Unit 1 and Unit 2 vessel fluence satisfy the criteria set forth in Regulatory Guide 1.190, "Calculational and Dosimetry Methods for Determining Pressure Vessel Neutron Fluence." These methods have been approved by the NRC and are described in detail in WCAP-14040-A, Revision 4, and WCAP-16083-NP-A, Revision 0.

UFSAR Section 5.4.3.7 provides additional information on the specimen capsules and the associated dosimeters used to monitor reactor vessel embrittlement and neutron fluence. WCAP-15224, June 1999, and WCAP-15320, December 1999 include the results of capsules T, U, X, and Y for Units 1 and 2 respectively. See Section A.1.35 for additional information on the Reactor Vessel Surveillance Program.

Fluence is treated as a TLAA that has been projected to the end of the period of extended operation in accordance with 10 CFR 54.21(c)(1)(ii) and used as an input to the analyses in the following sections.

A.2.1.2 Upper Shelf Energy

For the license renewal application, upper shelf energy (USE) was evaluated for all materials included in the original and extended beltline. Fracture toughness criteria in 10 CFR 50 Appendix G requires that beltline materials maintain USE no less than 50 ft-lb during operation of the reactor. The 52 EFPY USE values for the beltline materials were determined using methods consistent with RG 1.99, Revision 2, Radiation Embrittlement of Reactor Vessel Materials. The value of peak ¼T fluence is used.

Two methods can be used to predict the decrease in USE with irradiation, depending on the availability of credible surveillance capsule data as defined in Regulatory Guide 1.99. For vessel beltline materials that are not in the surveillance program or for locations with non-credible data, the Charpy USE is assumed to decrease as a function of fluence and copper content, as indicated in Regulatory Guide 1.99, Revision 2 (Position 1.2). When two or more credible surveillance data sets are available from the reactor, they may be used to determine the Charpy USE of the surveillance material. The surveillance data are then used in conjunction with the regulatory guide to predict the change in USE of the reactor vessel material due to irradiation (Position 2.2).

The 52 EFPY Position 1.2 USE values of the vessel materials can be predicted using the corresponding ¼T fluence projection, the copper content of the materials, and Figure 2 in Regulatory Guide 1.99, Revision 2. The predicted Position 2.2 USE values are determined for the reactor vessel materials that are contained in the surveillance program by using the plant surveillance data along with the corresponding ¼T fluence projection.

All of the original beltline and extended beltline materials in the SQN Unit 1 and Unit 2 reactor vessels are projected to remain above the USE limit of 50 ft-lb (per 10 CFR 50 Appendix G) through 52 EFPY. Therefore, the SQN Unit 1 and Unit 2 reactor vessel Charpy USE TLAAs have been projected to the end of the period of extended operation in accordance with 10 CFR 54.21(c)(1)(ii).

A.2.1.3 Pressurized Thermal Shock

10 CFR 50.61(b)(1) provides rules for protection against pressurized thermal shock events for pressurized water reactors. Licensees are required to perform an assessment of the projected values of reference temperature whenever a significant change occurs in projected values of the adjusted reference temperature for pressurized thermal shock (RT_{PTS}), or upon request for a change in the expiration date for the operation of the facility. Section 10 CFR 50.61(b)(2) establishes screening criteria for RT_{PTS} at 270°F for plates, forgings, and axial welds and 300°F for circumferential welds.

Section 10 CFR 50.61(c) provides two methods for determining RT_{PTS}. Position 1 applies for material that does not have surveillance data available, and Position 2 applies for material with surveillance data. Positions 1 and 2 are described in Regulatory Guide 1.99, Revision 2. Adjusted reference temperatures are calculated for both Positions 1 and 2 by following the guidance in Regulatory Guide 1.99, Sections 1.1 and 2.1, respectively, using copper and nickel content of beltline materials and end-of-life fluence projections.

The beltline and extended beltline materials in the Unit 1 and Unit 2 reactor vessels are below the RT_{PTS} screening criteria values of 270°F for forgings and 300°F for circumferentially oriented welds through 52 EFPY. Therefore, the SQN Unit 1 and Unit 2 reactor vessel RT_{PTS} TLAAs have been projected to the end of the period of extended operation in accordance with 10 CFR 54.21(c)(1)(ii).

A.2.1.4 Pressure-Temperature Limits

Appendix G of 10 CFR 50 requires operation of the reactor pressure vessel within established pressure-temperature (P-T) limits. These limits are established by calculations that utilize the materials and fluence data obtained through the Reactor Vessel Surveillance Program (Section A.1.35). The P-T limits are calculated for several years into the future and remain valid for an established period of time. The provisions of 10 CFR 50 Appendix G require the P-T limit curves be maintained and updated as necessary.

SQN Unit 1 Technical Specification 3.4.9.1 and the SQN Unit 2 Technical Specification 3.4.9.1 require the RCS pressure, RCS temperature, and RCS heatup and cooldown rates to be maintained within the limits specified in the P-T limits report (PTLR). The Technical Specifications Administrative Controls Section 6.9.1.15 provides additional details on the PTLR and the Westinghouse topical reports that provide the analytical methods used to determine the RCS P-T limits. It requires the analytical methods used to determine the RCS P-T limits to be those previously reviewed and approved by the NRC and requires the PTLR to be provided to the NRC within 30 days of issuance of any revision or supplement thereto.

The analyses used to determine the P-T limit curves, including the associated WCAP supporting documentation, are considered TLAAs. The SQN Unit 1 and Unit 2 P-T limit curves contained in each plant's PTLR provide the limits through 32 EFPY. Prior to exceeding 32 EFPY, SQN will generate new PTLRs to cover plant operation beyond 32 EFPY. As required by Technical Specification 6.9.1.15, the P-T limit curves will be developed using NRC-approved analytical methods.

The SQN Unit 1 and Unit 2 P-T limit curves in each plant's PTLR has been updated, as 10 CFR 50 Appendix G requires, through the period of extended operation in conjunction with the Reactor Vessel Surveillance Program (Section A.1.35). The analysis of the P-T curves will consider locations outside of the beltline such as nozzles, penetrations and other discontinuities to determine if more restrictive P-T limits are required than would be determined by considering only the reactor vessel beltline materials. Therefore, the P-T limit curves TLAAs will be adequately managed for the period of extended operation in accordance with 10 CFR 54.21(c)(1)(iii).

A.2.1.5 Low Temperature Overpressure Protection (LTOP) PORV Setpoints

The SQN Unit 1 Technical Specification 3.4.12 and SQN Unit 2 Technical Specification 3.4.12 specify that the power operated relief valve (PORV) setpoints must be at lift settings within the limits of the PTLR. Additional descriptions of the PORV setpoint and the PTLR are provided in the Technical Specification 3/4.4.12 Bases. Each time the P-T limit curves are revised, the LTOP PORV setpoints must be reevaluated. Therefore, low temperature overpressure protection limits are considered part of the calculation of P-T curves in each plant's PTLR. The P-T limit curves are updated prior to exceeding applicable EFPY limits. See UFSAR Section A.2.1.4 for further information on the P-T limit curves. Therefore, the LTOP PORV setpoint TLAA will be adequately managed for the period of extended operation in accordance with 10 CFR 54.21(c)(1)(iii).

A.2.2 <u>Metal Fatigue</u>

Fatigue analyses are considered TLAAs for Class 1 and non-Class 1 mechanical components. Fatigue is an age-related degradation mechanism caused by cyclic stressing of a component by either mechanical or thermal stresses.

The aging management reviews that were performed for license renewal identify mechanical components that are within the scope of license renewal and are subject to aging management review. When TLAA – metal fatigue is identified in the aging management program column of the tables in Section 3 of the license renewal application, the associated fatigue analyses are evaluated in this section. Evaluation of the TLAAs per 10 CFR 54.21(c)(1) determines whether

(i) the analyses remain valid for the period of extended operation,

(ii) the analyses have been projected to the end of the period of extend operation, or

(iii) the effects of aging on the intended function(s) will be adequately managed for the period of extended operation.

Documentation of the evaluation of SQN Class 1 component fatigue analyses is provided in Section A.2.2.1. Fatigue analysis of non-Class 1 mechanical components is discussed in Section A.2.2.2. Screening for environmentally adjusted fatigue effects is documented in Section A.2.2.3.

A.2.2.1 Class 1 Metal Fatigue

The major Class 1 components at SQN include the reactor vessels, pressurizers, reactor coolant pumps, steam generators, control rod drives, and all associated piping and valves. Fatigue evaluations performed in the design of SQN Class 1 components in accordance with ASME Section III requirements are contained in the equipment stress reports and associated analyses. The fatigue evaluations calculate a cumulative usage factor (CUF) for each component or subassembly based on a specified number of design cycles for that component. Because the design cycles may be the number of transient cycles that were assumed for a 40-year license term, these calculations of CUFs are considered TLAAs.

SQN Technical Specification 6.8.4.l identifies a component cyclic and transient limit program to provide controls to track the UFSAR Section 5.2.1 cyclic and transient occurrences. UFSAR Section 5.2.1 and UFSAR Table 5.2.1-1 summarize the reactor coolant system cyclic or transient limits. In addition, the Technical Requirements Manual surveillance requirement 4.4.9.2.2 requires the recording of any occurrence of pressurizer spray operation with a differential temperature greater than 320°F for evaluation of the cyclic limits.

SQN will manage the aging effects due to fatigue of these components using the Fatigue Monitoring Program in accordance with 10 CFR 54.21(1)(c)(iii). The SQN Fatigue Monitoring Program monitors transient cycles that contribute to fatigue usage and is further described in UFSAR Section A.1.11.

<u>Reactor Vessels</u>

As described in UFSAR, Section 5.4, design and fabrication of the reactor vessels was in accordance with ASME Section III, Class A. SQN will monitor transient cycles using the Fatigue Monitoring Program and assure that corrective action specified in the program is taken if any of the actual cycles approach their analyzed numbers. As such, the Fatigue Monitoring Program will manage the effects of aging due to fatigue on the reactor vessel in accordance with 10 CFR 54.21(c)(1)(iii).

<u>Reactor Vessel Internals</u>

As indicated by the title of UFSAR, Section 3.9.3, the design of SQN Units 1 and 2 reactor vessel internals was not covered by the ASME code. SQN Unit 1 and Unit 2, therefore, do not have an ASME stress report for the originally supplied reactor vessel internals.

Stress reports were generated for several specific reactor vessel internals locations to support component replacement or reanalysis. Usage factors were calculated for the CRD guide tube pins replacement components. The lower core plate was reanalyzed as part of the measurement uncertainty recapture power uprate that included the determination of a usage factor.

The Fatigue Monitoring Program will manage the effects of aging due to fatigue on the reactor vessel internals in accordance with 10 CFR 54.21(c)(1)(iii).

Pressurizers

As described in UFSAR, Section 5.5.10, the pressurizers are vertical, cylindrical vessels with essentially hemispherical top and bottom heads constructed of carbon steel, with austenitic stainless steel cladding on all surfaces exposed to reactor coolant. The surge line nozzle and electric heaters are installed in the bottom head.

The original analysis assumed the surge nozzle configuration would cause mixing of the water in the pressurizers during insurges. Later studies identified that the lower temperature water would enter the pressurizer and stratify. In a joint project with Duke Power, TVA developed an algorithm to use a mass balance approach to predict the flow rate at the bottom head of the pressurizer and calculate the associated fatigue impact.

The Fatigue Monitoring Program will manage the effects of aging due to fatigue on the pressurizer in accordance with 10 CFR 54.21(c)(1)(iii).

Replacement Steam Generators (RSGs)

The replacement steam generators for both SQN Unit 1 and Unit 2 were designed to ASME Boiler and Pressure Vessel Code, Section III, Division 1, 1989 Edition with no Addenda. The SQN Unit 1 steam generators were replaced in the spring of 2003, and the SQN Unit 2 steam generators were replaced in the fall of 2012. The replacement steam generators were designed for a 40-year life except for the Unit 2 Loop 1 FW nozzle. The 40-year design covers a time period beyond the end of the period of extended operation (2040 for Unit 1 and 2041 for Unit 2). The Unit 2 RSG Loop 1 feedwater nozzle does not have a thermal liner installed in the elbow connected to the nozzle. Without the elbow thermal liner installed the nozzle does not meet the fatigue requirements for the 40-year design cycles. To compensate for this, actual operating cycles are monitored to ensure that the cumulative usage factor remains ≤ 1.0, allowing the nozzle to be used for the 40-year RSG design life.

The Fatigue Monitoring Program (with enhancements) will manage the effects of aging due to fatigue on the steam generators in accordance with 10 CFR 54.21(c)(1)(iii).

Control Rod Drive Mechanisms

The control rod drive mechanisms are described in UFSAR, Section 4.2.3.2.2 and shown in UFSAR, Figure 4.2.3-7. The Fatigue Monitoring Program will manage the effects of aging due to fatigue on the control rod drives in accordance with 10 CFR 54.21(c)(1)(iii).

Reactor Coolant Pumps

As described in UFSAR, Section 5.2, the reactor coolant pumps are vertical, single stage, centrifugal, shaft seal pumps. The reactor coolant pump configuration is shown in UFSAR, Figure 5.5.1-1. The Fatigue Monitoring Program will manage the effects of aging due to fatigue on the reactor coolant pumps in accordance with 10 CFR 54.21(c)(1)(iii).

<u>Reactor Coolant System Piping</u>

As shown in UFSAR, Table 3.2.2-2 and discussed in UFSAR, Section 5.5.3, the original design analyses for the reactor coolant system piping was in accordance with USAS B31.1. This piping was not analyzed for specific design transients. The USAS B31.1 fatigue design is based on an implicit treatment of cyclic loadings, through a stress range reduction factor applied to the stress allowables that depends on the number of equivalent full thermal loading cycles anticipated during service of the component. In general, a stress range reduction factor of 1.0 in the stress analyses applies for up to 7000 thermal cycles. Therefore, the RCS pressure boundary piping analyzed under B31.1 is qualified for at least 7000 cycles (ASME Boiler and Pressure Vessel Code, Division 1, Subsection NC, Class 2 Components). The number of RCS heatups and cooldowns is maintained much less than 7000 cycles. Therefore, the pipe stress calculations are valid for the period of extended operation in accordance with 10 CFR 54.21(c)(1)(i).

Specific piping locations in the RCS pressure boundary were later reanalyzed to ASME Section III:

- Pressurizer surge line.
- Thermowells installed in RCS (to replace resistance temperature detector bypass piping).

The pressurizer surge line at the hot leg to surge line was evaluated for any increased effects from pressurizer insurges and outsurges as part of the NRC Bulletin 88-11 response.

When the resistance temperature detector bypass piping was removed and direct sensing nozzles installed on the hot and cold legs, thermowells were installed. UFSAR Sections, 5.5.3.2 and 5.6 provide additional details of the configuration. These thermowells were qualified to ASME Section III. Calculation determined the thermowells were exempt from a detailed fatigue analysis (no CUF was calculated) since the conditions of the 1983 ASME NB-3222.4(d) were satisfied. This exemption was based on not exceeding the number of transient cycles and is therefore treated as a TLAA that will be managed by the Fatigue Monitoring Program. See UFSAR Section A.1.11 for further information on the program.

The Fatigue Monitoring Program will manage the effects of aging due to fatigue on the reactor coolant system piping designed to ASME Section III in accordance with 10 CFR 54.21(c)(1)(iii).

A.2.2.2 Non-Class 1 Metal Fatigue

As shown in UFSAR Table 3.2.2-2, the non-Class 1 piping systems were designed to B31.1.0-1967, supplemented by use of the provisions of Class 2, NC-3600, ASME Section III, 1971 Edition up to and including Winter 1972 Addenda. Some of the SQN Unit 1 and Unit 2 non-Class 1 piping that is not part of the RCS pressure boundary was analyzed to meet ASME Section III due to modifications or reanalysis. Certain non-Class 1 heat exchangers were analyzed to ASME Section III and are reviewed in the following sections.

APPENDIX A

Non-Class 1 Pressure Boundary Piping Using Stress Range Reduction Factors

The impact of thermal cycles on non-Class 1 piping and in-line components is reflected in the calculation of the allowable stress range. The design of ASME III Code Class 2 and 3 or B31.1 piping systems incorporates a stress range reduction factor for determining acceptability of piping design with respect to thermal stresses. In general, a stress range reduction factor of 1.0 in the stress analyses applies for up to 7000 thermal cycles. The allowable stress range is reduced by the stress range reduction factor if the number of thermal cycles exceeds 7000 (ASME Boiler and Pressure Vessel Code, Division 1, Subsection NC, Class 2 Components). For the systems that are subjected to elevated temperatures above the fatigue threshold, thermal cycles have been projected for 60 years of plant operation for the piping and in-line components. These projections indicate that 7000 thermal cycles will not be exceeded for 60 years of operation. Therefore, the pipe stress calculations are valid for the period of extended operation in accordance with 10 CFR 54.21(c)(1)(i).

Non-Class 1 Piping with Fatigue Analysis

The following piping locations that are not part of the RCS pressure boundary were reanalyzed to calculate cumulative usage factors per ASME Section III:

- Feedwater elbows with thermal sleeves
- Feedwater elbow without thermal sleeve

Feedwater elbows with thermal sleeves, located just upstream of the steam generators, are installed in all four Unit 1 feedwater lines and in the Unit 2 feedwater lines for loops 2, 3 and 4 due to concerns with cracking on the feedwater piping. A Schedule 80 short radius elbow without a thermal sleeve was installed on the Unit 2 Loop 1 RSG during the U2R18 outage in November 2012. A fatigue analysis was performed on the Unit 2 Loop 1 RSG short radius elbow and the elbow has acceptable fatigue usage for the 40-year design cycles of the RSG. As identified in UFSAR Table 3.2.1-2 sheet 5, the feedwater thermal sleeves are designed to ASME Section III Class B.

The Fatigue Monitoring Program (Section A.1.11) will manage the effects of aging due to fatigue on the non-RCS pressure boundary piping with cumulative usage factors in accordance with 10 CFR 54.21(c)(1)(iii).

Non-Class 1 Heat Exchangers with Fatigue Analysis

The following non-Class 1 heat exchangers were analyzed to ASME Section III

- Residual heat removal (RHR) heat exchangers.
- Chemical and volume control system (CVCS) regenerative heat exchangers.

The RHR heat exchangers were evaluated for fatigue in a calculation by the vendor and determined to be exempt from a detailed fatigue analysis in accordance with ASME Section N-415-1. This exemption is based on cycles the heat exchangers would experience during 200 plant heatups and cooldowns. Since the plant cooldowns are tracked, the Fatigue Monitoring Program (Section A.1.11) will manage the effects of aging due to fatigue on the RHR heat exchangers in accordance with 10 CFR 54.21(c)(1)(iii).

The CVCS regenerative heat exchangers were evaluated for fatigue in a calculation by the vendor and usage factors calculated for the piping, tubing, shell, and tubesheet. The analysis considered the following transients to bound the original 40 years of plant operation including 200 plant heatups and cooldowns:

(1) 2,000 step changes in letdown stream fluid temperature from 100°F to 560°F.

(2) 24,000 step changes in letdown stream fluid temperature from 400°F to 560°F.

(3) 200 changes in letdown stream fluid temperature from 100°F to 560°F occurring over four hours.

(4) 200 changes in letdown stream fluid temperature from 560°F to 140°F occurring over 20 hours.

(5) 200 pressurizations to respective design pressure and temperature.

The resulting total cumulative usage factors for all of these transients were very low as shown in the following table:

Location	**Usage Factor (CUF)**
Piping	0.03
Tubing	0.01
Shell	0.13
Tubesheet	0.03

These low usage factors indicates the cycles could be increased if necessary. The step changes in temperature actually occur at a very low rate, and therefore, the step change cycles need not be tracked. Since the plant cooldowns are tracked, the Fatigue Monitoring Program (Section A.1.11) will manage the effects of aging due to fatigue on the CVCS regenerative heat exchangers in accordance with 10 CFR 54.21(c)(1)(iii).

A.2.2.3 Effects of Reactor Water Environment on Fatigue Life

Industry test data indicate that certain environmental effects (such as temperature and dissolved oxygen content) in the primary systems of light water reactors could result in greater susceptibility to fatigue than would be predicted by fatigue analyses based on the ASME Section III design fatigue curves. The ASME design fatigue curves were based on laboratory tests in air and at low temperatures. Although the failure curves derived from laboratory tests were adjusted to account for effects such as data scatter, size effect, and surface finish, these adjustments may not be sufficient to account for actual plant operating environments.

APPENDIX A

As reported in SECY-95-245, the NRC believes that no immediate staff or licensee action is necessary to deal with the environmentally assisted fatigue issue. In addition, the staff concluded that it could not justify requiring a backfit of the environmental fatigue data to operating plants. However, the NRC concluded that because metal fatigue effects increase with service life, environmentally assisted fatigue should be evaluated for any proposed extended period of operation for license renewal.

NUREG/CR-6260 addresses the application of environmental factors to fatigue analyses (CUFs) and identifies locations of interest for consideration of environmental effects. Section 5.5 of NUREG/CR-6260 identified the following component locations to be the most sensitive to environmental effects for SQN vintage Westinghouse plants. These locations and the subsequent calculations are directly relevant to SQN.

(1) Reactor vessel shell and lower head.

(2) Reactor vessel inlet and outlet nozzles.

(3) Pressurizer surge line (including hot leg and pressurizer nozzles).

(4) Reactor coolant piping charging system nozzle.

(5) Reactor coolant piping safety injection nozzle.

(6) Residual heat removal (RHR) system Class 1 piping.

NUREG-1801, Section X.M1 says the applicant "addresses the effects of the coolant environment on component fatigue life by assessing the impact of the reactor coolant environment on a sample of critical components for the plant." There is no analysis of environmentally assisted fatigue (EAF) under the current licensing basis. Rather, the effect on fatigue life of the reactor water environment is a new consideration for license renewal. Applying the environmental correction factor is not required during the initial 40 years of operation, consistent with the closure of Generic Safety Issue (GSI) 190.

As identified in the enhancement to the Fatigue Monitoring Program (Section A.1.11), prior to the period of extended operation, SQN will update the fatigue usage calculations using refined fatigue analyses to determine valid CUFs less than 1.0 when accounting for the effects of reactor water environment. This includes applying the appropriate F_{en} factors to valid CUFs determined using an NRC-approved version of the ASME code or NRC-approved alternative (e.g., NRC-approved code case). SQN will review design basis ASME Class 1 component fatigue evaluations to ensure the locations evaluated for the effects of the reactor coolant environment on fatigue include the most limiting components within the reactor coolant pressure boundary. Environmental effects on fatigue for these critical components will be evaluated using one of the following sets of formulae.

Carbon and Low Alloy Steels

- Those provided in NUREG/CR-6583, using the applicable ASME Section III fatigue design curve.
- Those provided in Appendix A of NUREG/CR-6909, using either the applicable ASME Section III fatigue design curve or the fatigue design curve for carbon and low alloy steel provided in NUREG/CR-6909 (Figures A.1 and A.2, respectively, and Table A.1).
- A staff-approved alternative.

Austenitic Stainless Steels

- Those provided in NUREG/CR-5704, using the applicable ASME Section III fatigue design curve.
- Those provided in NUREG/CR-6909, using the fatigue design curve for austenitic stainless steel provided in NUREG/CR-6909 (Figure A.3 and Table A.2).
- A staff-approved alternative.

Nickel Alloys

- Those provided in NUREG/CR-6909, using the fatigue design curve for austenitic stainless steel provided in NUREG/CR-6909 (Figure A.3 and Table A.2).
- A staff-approved alternative.

Original design basis fatigue calculations typically include conservatism meant to simplify the analyses, such as lumping all transients together and considering them all to be as severe as the worst transient for a particular location. As a part of incorporating the effects on fatigue of the reactor water environment, the design basis fatigue analyses may be revised for locations that would exceed a CUF of 1.0. CUFs will be determined using an NRC-approved version of the ASME code or NRC-approved alternative (e.g., NRC-approved code case). If an acceptable CUF cannot be calculated, SQN will repair or replace the affected locations before exceeding an environmentally adjusted CUF of 1.0.

Therefore, SQN will manage the effects of fatigue, including environmentally assisted fatigue, under the Fatigue Monitoring Program (Section A.1.11) for the period of extended operation in accordance with 10 CFR 54.21(c)(1)(iii).

A.2.3 Environmental Qualification of Electrical Components

All operating plants must meet the requirements of 10 CFR 50.49, which defines the scope of electrical components to be included in an EQ program and also sets forth requirements for EQ programs. Qualification is established for the environmental and service conditions expected for normal plant operation and also those conditions postulated for plant accidents. A record of qualification for in-scope components must be prepared and maintained in auditable form. Equipment qualification evaluations for EQ components that specify a qualification of at least 40 years, but less than 60 years, are considered TLAAs for license renewal.

The SQN Environmental Qualification of Electric Components Program (SQN EQ Program, Section A.1.9) manages component thermal, radiation, and cyclical aging, as applicable, through aging evaluations based on 10 CFR 50.49(f) qualification methods. As required by 10 CFR 50.49, EQ components not qualified for the current license term are to be refurbished, replaced, or have their qualification extended prior to reaching the aging limits established in the evaluation. The SQN EQ Program ensures that the EQ components are maintained in accordance with their qualification bases.

The SQN EQ Program is an existing program established to meet SQN commitments for 10 CFR 50.49. The program is consistent with NUREG-1801, Section X.E1, "Environmental Qualification (EQ) of Electric Components." The SQN EQ Program will manage the effects of aging on the intended function(s) of EQ components that are the subject of EQ TLAAs for the period of extended operation in accordance with 10 CFR 54.21(c)(1)(iii).

A.2.4 <u>Fatigue of Primary Containment, Attached Piping, and Components</u>

As described in UFSAR Section 3.8.2, the containment vessel for SQN is a low-leakage, free-standing steel structure consisting of a cylindrical wall, a hemispherical dome, and a bottom liner plate encased in concrete. UFSAR Figure 3.8.2-1 shows the outline and configuration of the containment vessel. The design of the containment vessel meets the requirements of the ASME Code, Section III, Winter Addenda 1968, applicable sections required for a Class B nuclear vessel, including Code cases 1177-5, 1290-1, 1330-1, 1413, and 1431. As described in UFSAR Section 3.8.2.5.1, shutdowns and startups do not occur with a frequency that required a design for fatigue failure, and therefore there is no TLAA for the SQN containment vessels.

Analyses were identified for bellows assemblies for the penetrations that stated they were qualified for 7000 cycles of the design displacements. The design displacements will occur much less than 7000 cycles. Therefore, the associated penetration bellows are qualified for the period of extended operation. The analysis remains valid for the period of extended operation in accordance with 10 CFR 54.21(c)(1)(i).

A.2.5 <u>Other Plant-Specific TLAAs</u>

A.2.5.1 Underclad Cracking Analysis

Reactor vessel underclad cracking involves cracks in base metal forgings immediately beneath austenitic stainless steel cladding which are created as a result of the weld-deposited cladding process. Westinghouse performed an analysis of flaw growth associated with underclad cracking in 1971 concluding that reactor vessel integrity could be assured for the entire 40-year original plant license term. Underclad cracking only requires analysis if examinations have detected flaws (the analysis is not used to postulate flaws). Indications that could be representative of underclad cracking flaws have been detected on both SQN Unit 1 and Unit 2; therefore, the underclad cracking analysis is considered a TLAA for SQN Unit 1 and Unit 2.

To extend this analysis to 60 years in support of license renewal, WCAP-15338-A, "A Review of Cracking Associated with Weld Deposited Cladding in Operating PWR Plants," provided an updated analysis of underclad cracking for Westinghouse units. This report examined the growth of underclad cracks in susceptible plants and showed that the crack growth would not threaten reactor vessel integrity through 60 years of plant operation. The NRC in their safety evaluation of this WCAP stated that any Westinghouse Owners Group plant may reference this report in a license renewal application to satisfy the requirements of 10CFR 54.21(c)(1)

regarding evaluation of TLAAs for reactor vessel components. The safety evaluation specified the following two renewal applicant action items.

(1) Verify the plant is bounded by the WCAP-15338 report, specifically the number of cycles used in the analysis.

(2) Ensure the TLAA is identified in an FSAR supplement.

Transient cycles shown in WCAP-15338-A are equal to or greater than the number of design cycles for SQN Unit 1 and Unit 2. This UFSAR supplement satisfies the second requirement.

Therefore, this analysis has been projected per 10 CFR 54.21(c)(1)(ii).

A.2.5.2 Crane Load Cycles Analysis

Cranes that were designed to Crane Manufacturer's Association of America Specification #70 (CMAA-70) have cycles specified as part of their design analysis. While there is no analysis that involves time-limited assumptions defined by the current operating term, for example, 40 years, crane cycle limits are nevertheless evaluated as a TLAA for cranes that were designed to CMAA-70.

A review of the cranes at SQN was performed to determine which cranes were designed to CMAA-70. The manipulator cranes at SQN Units 1 and 2 included CMAA-70 in their design specification. The lowest number of load cycles a crane is qualified for under CMAA-70 is 100,000 cycles. SQN determined that the number of lifts each manipulator crane would experience in 60 years with a 1.25 multiplier for margin is ~20,500. Therefore, the expected number of lifts is well below the qualification in CMAA-70, and the manipulator cranes TLAA remains valid for the period of extended operation in accordance with 10 CFR 54.21(c)(1)(i).

No other cranes at SQN were built to CMAA-70 requirements. Section 3.8.6 of the UFSAR provides descriptions of the cranes, and UFSAR Section 3.12 describes the control of heavy loads and the NUREG-0612 responses. The SQN responses to NUREG-0612 and the review of the site cranes identified that the reactor building polar crane and the auxiliary building crane were not built to the structural fatigue requirements of CMAA-70.

A.2.5.3 Leak-Before-Break Analysis

As described in UFSAR Section 3.6, the dynamic effects of double-ended postulated pipe ruptures in the reactor coolant loops have been eliminated from the SQN design basis by the application of leak-before-break (LBB) technology in accordance with the rule change to General Design Criterion 4. Authorization for their elimination is based on fracture mechanics analyses results performed by Westinghouse.

LBB analyses consider the thermal aging of the CASS piping and fatigue transients that drive flaw growth during operation of the plant. Because these two analysis considerations could be defined by the current term of operation, LBB analyses were further reviewed as potential TLAAs for SQN.

Thermal Aging of CASS

Thermal aging results in an increase in the yield strength of CASS and a decrease in fracture toughness, the decrease being proportional to the level of ferrite in the material. Thermal aging in these stainless steels will continue until the saturation, or fully aged, point is reached. Fully aged, bounding fracture toughness values were used in the evaluation for the cast fittings. As the LBB evaluations for both units use saturated (fully aged) fracture toughness properties, the evaluation of the thermal aging of CASS portion of the analysis does not have a material property time-dependency and is not considered a TLAA.

Fatigue Crack Growth

The LBB analysis determined that fatigue crack growth effects will be very small when analyzing for the full set of design transients. The basis of the evaluation of fatigue crack growth effects in the LBB analysis will remain unchanged so long as the number of transient occurrences remains below the number assumed for the analysis of fatigue crack growth effects. For SQN Unit 1 and Unit 2, no transient is projected to exceed the number of analyzed cycles prior to the end of the period of extended operation. Therefore, the LBB TLAA remains valid for the period of extended operation in accordance with 10 CFR 54.21(c)(1)(i).

A.3 10 CFR 54.37(b) Newly Identified Systems, Structures and Components

10 CFR 54.37(b) states that after a renewed license is issued, the Final Safety Analysis Report (FSAR) update required by 10 CFR 50.71(e) must include any systems, structures, and components (SSCs) newly identified that would have been subject to an aging management review or evaluation of time-limited aging analyses in accordance with 10 CFR 54.21 and the FSAR update must describe how the effects of aging will be managed such that the intended functions(s) in 10 CFR 54.4(b) will be effectively maintained during the period of extended operation. The intent of 10 CFR 54.37(b) is to capture those SSCs that, if they had been identified at the time of the license renewal application, would have been subject to an aging management review or evaluation of time-limited aging analyses. This section of Appendix A contains the newly identified SSC pursuant to the requirements of 10 CFR 54.37(b).

A.3.1 AERCW Pump Structure

The AERCW pump structure, located south of the diesel generator building, is designed as Category I structure. The entire AERCW System has been abandoned. The AERCW pump structure is reinforced concrete comprising of reinforced concrete walls and floor supported on a concrete base foundation on structural fill.

The AERCW Pump structure does not contain safety-related systems or components, but adjoins the ERCW Valve Box 4 and 5 structures. The ERCW Valve Box 4 and 5 structures provide tornado missile protection for safety-related ERCW system piping and components.

The AERCW pump structure has no intended functions for 10 CFR 54.4(a)(1) or (a)(3).

The AERCW pump structure has the following intended function for 10 CFR 54.4 (a)(2).

- Provides physical support, shelter, and protection for non-safety related systems, structures, and components whose failure could prevent satisfactory accomplishment of functions(s) identified for 10 CFR 54.4 (a)(1). 10 CFR 54.4 (a)(2)

The following aging management program manages the aging effects for the AERCW pump structure and structural components:

- Structures Monitoring Program (SQN FSAR Section A.1.40)

A.3.2 ERCW Valve Boxes 1, 3, 4, 5 and 6 and Thermometer Boxes 1 and 2

ERCW Valve Boxes 1, 3, 4, 5 and 6 and Thermometer Boxes 1 and 2 are reinforced concrete comprising of reinforced concrete walls and removable roofs supported on concrete base foundations on structural fill. ERCW Valve Boxes 4 and 5 west walls have structural carbon steel tornado missile barrier plates covering penetrations in the concrete wall.

ERCW Valve Boxes 1, 3, 4, 5 and 6 and Thermometer Boxes 1 and 2 house sections of safety-related ERCW piping and components. The ERCW piping and components are supported seismically by the surrounding soil covering and are not physically attached to any portion of the ERCW Valve and Thermometer Box structure. E R C W Valve and Thermometer Box structures provide tornado missile protection for safety related ERCW piping and components.

ERCW Valve Boxes 1, 3, 4, 5 and 6 and Thermometer Boxes 1 and 2 have the following intended functions for 10 CFR 54.4(a)(1).

- Provides physical support, shelter, and protection for safety-related systems, structures, and components. 10 CFR 54.4(a)(1)

ERCW Valve Boxes 1, 3, 4, 5 and 6 and Thermometer Boxes 1 and 2 have the following intended function for 10 CFR 54.4 (a)(3).

- Provides physical support, shelter, and protection for systems, structures, and components relied upon in safety analyses or plant evaluations to perform a function that demonstrates compliance with the Commissions’ regulations for Fire Protection (10 CFR 50.48). 10 CFR 54.4 (a)(3).

The ERCW Valve Boxes 1, 3, 4, 5 and 6 and Thermometer Boxes 1 and 2 have no intended function for 10 CFR 54.4 (a)(2).

The following aging management program manages the aging effects for ERCW Valve Boxes 1, 3, 4, 5 and 6 and Thermometer Boxes 1 and 2 structural components:

- Structures Monitoring Program (SQN FSAR Section A.1.40).

A.3.3 High Pressure Fire Protection Inaccessible Cables

Non-EQ HPFP cables from the 480 V Shutdown Boards to the Flood Mode Pump A-A (0-PMP-026-0001A-B) and B-B (0-PMP-026-0011A-B) are Safety-Related and have a LR Intended Function. In the LRA Appendix B, the cables to these two Flood Mode Pumps were identified as being in a wetted environment since they are routed through manholes.

Power cables (greater than or equal to 400 V) exposed to wet, submerged, or other adverse environmental conditions for which they were not designed are susceptible to a water treeing aging effect of reduced insulation resistance, causing a decrease in the dielectric strength of the conductor insulation. This can potentially lead to failure of the cable's insulation system.

The following aging management program manages the aging effects for the above cables by periodic testing of cable insulation resistance and inspecting for water in manholes:

- Non-EQ Inaccessible Power Cables (>=400 V to 35 kV) (SQN FSAR A.1.25).

A.3.4 Main Feedwater Control Mechanical Components – Drawing 1,2-724A850

The purpose of the feedwater control system 046 is to regulate the flow of main feedwater to the steam generators. The feedwater control system includes mechanical hydraulic control components support the operation of the main feedwater pumps. These mechanical components have no safety function. The passive mechanical components in this system are in the Turbine Building.

The feedwater control system (as shown on this drawing) have no intended functions for 10 CFR 54.4 (a)(1) or 10 CFR 54.4 (a)(3).

The feedwater control system has the following intended function for 10 CFR 54.4 (a)(2).

- Maintain integrity of non-safety-related components such that no physical interaction with safety-related components could prevent satisfactory accomplishment of a safety function (pressure boundary).

The additional component types, materials, environments and aging effects for the Main Feedwater control system and associated aging management programs are:

Component Type	Intended Function	Material	Environment	Aging Effect	Aging Management Program
Tubing	Pressure Boundary	Carbon Steel	Air - indoor (external)	Loss of Material	External Surfaces Monitoring
Tubing	Pressure Boundary	Carbon Steel	Lube Oil (Internal)	Loss of Material	Oil Analysis Program
Piping	Pressure Boundary	Stainless Steel	Air - indoor (external)	Loss of Material	None

Component Type	Intended Function	Material	Environment	Aging Effect	Aging Management Program
Piping	Pressure Boundary	Stainless Steel	Lube Oil (Internal)	Cracking	Oil Analysis Program
Piping	Pressure Boundary	Stainless Steel	Lube Oil (Internal)	Loss of Material	Oil Analysis Program
Filter Housing	Pressure Boundary	Aluminum	Air - indoor (external)	Loss of Material	None
Filter Housing	Pressure Boundary	Aluminum	Lube Oil (Internal)	Cracking	Oil Analysis Program
Filter Housing	Pressure Boundary	Aluminum	Lube Oil (Internal)	Loss of Material	Oil Analysis Program

13.9.2 License Renewal - Commitment List

The License Renewal Commitment List represents the regulatory commitments that TVA made related to aging management programs (AMPs) to manage the aging effects of structures and components. These regulatory commitments are managed and tracked by TVA for completion as part of SQN's License Renewal Program.

No.	**COMMITMENT**	**LRA SECTION / AUDIT ITEM**
1	A. Implement the **Aboveground Metallic Tanks** Program as described in UFSAR Section 13.9.1 Appendix A.1.1. [3.0.3-1, Requests 3, ML13312A005.11/4/13] B. Aboveground Metallic Tanks Program includes outdoor tanks on soil or concrete and indoor large volume water tanks (excluding the fire water storage tanks) situated on concrete that are designed for internal pressures approximating atmospheric pressure. This program includes the Refueling Water Storage Tanks and the Condensate Storage Tanks. Periodic external visual and surface examinations are sufficient to monitor degradation. Internal visual and surface examinations are conducted in conjunction with measuring the thickness of the tank bottoms to ensure that significant degradation is not occurring and that the component's intended function is maintained during the PEO. Internal inspections are conducted whenever the tank is drained, with a minimum frequency of at least once every 10 years, beginning in the 5-year interval prior to the PEO. [3.0.3-1 item 5a, ML13294A462, E-2 – 4 of 8, 10/17/13]	B.1.1
2	A. Revise **Bolting Integrity Program** procedures to ensure the actual yield strength of replacement or newly procured bolts will be less than 150 ksi B. Revise Bolting Integrity Program procedures to include the additional guidance and recommendations of EPRI NP-5769 for replacement of ASME pressure-retaining bolts and the guidance provided in EPRI TR-104213 for the replacement of other pressure-retaining bolts. C. Revise Bolting Integrity Program procedures to specify a corrosion inspection and a check-off for the transfer tube isolation valve flange bolts. D. Revise Bolting Integrity Program procedures to visually inspect a representative sample of normally submerged ERCW system bolts at least once every 5 years. (ML13252A036, Enc 1, B.1.2-2a, p20)	B.1.2
3	A. Implement the **Buried and Underground Piping and Tanks Inspection Program** as described in UFSAR Section 13.9.1 Appendix A, Section A.1.4. B. Cathodic protection will be provided based on the guidance of NUREG-1801 Rev.2, section XI.M41, as modified by LR-ISG-2015-01.	B.1.4

No.	COMMITMENT	LRA SECTION / AUDIT ITEM
4	A. Revise **Compressed Air Monitoring Program** procedures to include the standby diesel generator (DG) starting air subsystem. B. Revise Compressed Air Monitoring Program procedures to include maintaining moisture and other contaminants below specified limits in the standby DG starting air subsystem. C. Revise Compressed Air Monitoring Program procedures to apply a consideration of the guidance of ASME OMa-S/G-1998, Part 17; EPRI NP-7079; and EPRI TR-108147 to the limits specified for the air system contaminants D. Revise Compressed Air Monitoring Program procedures to maintain moisture, particulate size, and particulate quantity below acceptable limits in the standby DG starting air subsystem to mitigate loss of material. E. Revise Compressed Air Monitoring Program procedures to include periodic and opportunistic visual or nondestructive examination(NDE) inspections of surface conditions consistent with frequencies described in ASME O/Ma-SG-1998, Part 17 of accessible internal surfaces such as compressors, dryers, after-coolers, and filter boxes of the following compressed air systems: • Diesel starting air subsystem • Auxiliary controlled air subsystem • Nonsafety-related controlled air subsystem F. Revise Compressed Air Monitoring Program procedures to monitor and trend moisture content in the standby DG starting air subsystem. G. Revise Compressed Air Monitoring Program procedures to include consideration of the guidance for acceptance criteria in ASME OMa-S/G-1998, Part 17, EPRI NP-7079; and EPRI TR-108147.	B.1.5

No.	COMMITMENT	LRA SECTION / AUDIT ITEM
5	A. Revise **Diesel Fuel Monitoring Program** procedures to monitor and trend sediment and particulates in the standby DG day tanks. B. Revise Diesel Fuel Monitoring Program procedures to monitor and trend levels of microbiological organisms in the seven-day storage tanks. C. Revise Diesel Fuel Monitoring Program procedures to include a ten-year periodic inspection of the standby DG diesel fuel oil day tanks and high pressure fire protection (HPFP) diesel fuel oil storage tank. These inspections will be performed at least once during the ten-year period prior to the period of extended operation and at succeeding ten-year intervals. If a visual inspection is not possible, a volumetric inspection will be performed. The HPFP diesel fuel oil storage tank inspections will be supplemented by cleaning, if necessary based on inspection results, to remove any accumulated sediment. The standby DG diesel fuel oil day tank inspections will be supplemented by cleaning, to remove sediment, if warranted based on the results of a) periodic cleaning of the yard fuel oil storage tanks and seven-day tanks, b) periodic cleaning of the fuel pump suction strainers and filters, and c) day tank sediment and particulate monitoring. D. Revise Diesel Fuel Monitoring Program procedures to include a volumetric examination of affected areas of the diesel fuel oil tanks, if evidence of degradation is observed during visual inspection. The scope of this enhancement includes the standby DG seven-day fuel oil storage tanks, standby DG fuel oil day tanks, and HPFP diesel fuel oil storage tank and is applicable to the inspections performed during the ten-year period prior to the PEO and succeeding ten-year intervals.	B.1.8

No.	COMMITMENT	LRA SECTION / AUDIT ITEM
6 (6)	A. Revise **External Surfaces Monitoring Program** procedures to clarify that periodic inspections of systems in scope and subject to aging management review for license renewal in accordance with 10 CFR 54.4(a)(1) and (a)(3) will be performed. Inspections shall include areas surrounding the subject systems to identify hazards to those systems. Inspections of nearby systems that could impact the subject systems will include SSCs that are in scope and subject to aging management review for license renewal in accordance with 10 CFR 54.4(a)(2). B. Revise External Surfaces Monitoring Program procedures to include instructions to look for the following related to metallic components: • Corrosion and material wastage (loss of material). • Leakage from or onto external surfaces loss of material). • Worn, flaking, or oxide-coated surfaces (loss of material). • Corrosion stains on thermal insulation (loss of material). • Protective coating degradation (cracking, flaking, and blistering). • Leakage for detection of cracks on the external surfaces of stainless steel components exposed to an air environment containing halides. C. Revise External Surfaces Monitoring Program procedures to include instructions for monitoring aging effects for flexible polymeric components, including manual or physical manipulations of the material, with a sample size for manipulation of at least ten percent of the available surface area. The inspection parameters for polymers shall include the following: • Surface cracking, crazing, scuffing, dimensional changes (e.g., ballooning and necking). • Discoloration. • Exposure of internal reinforcement for reinforced elastomers (loss of material). • Hardening as evidenced by loss of suppleness during manipulation where the component and material can be manipulated. D. Revise External Surfaces Monitoring Program procedures to specify the following for insulated components. • Periodic representative inspections are conducted during each 10-year period during the PEO. • For a representative sample of outdoor components, except tanks, and indoor components, except tanks, identified with more than nominal degradation on the exterior of the component, insulation is removed for visual inspection of the component surface. Inspections include a minimum of 20 percent of the in-scope piping length for each material type (e.g., steel, stainless steel, copper alloy, aluminum). For components with a configuration which does not conform to a 1-foot axial length determination (e.g., valve, accumulator), 20 percent of the surface area is inspected. Inspected components are 20% of the population of each material type with a maximum of 25. Alternatively, insulation is removed and component inspections performed for any combination of a minimum of 25 1-foot axial length sections and individual components for each material type (e.g., steel, stainless steel, copper alloy, aluminum.)	B.1.10

No.	COMMITMENT	LRA SECTION / AUDIT ITEM

(6)	• For a representative sample of indoor components, except tanks, operated below the dew point, which have not been identified with more than nominal degradation on the exterior of the component, the insulation exterior surface or jacketing is inspected. These visual inspections verify that the jacketing and insulation is in good condition. The number of representative jacketing inspections will be at least 50 during each 10-year period.
	If the inspection determines there are gaps in the insulation or damage to the jacketing that would allow moisture to get behind the insulation, then removal of the insulation is required to inspect the component surface for degradation.
	• For a representative sample of indoor insulated tanks operated below the dew point and all insulated outdoor tanks, insulation is removed from either 25 1-square foot sections or 20 percent of the surface area for inspections of the exterior surface of each tank. The sample inspection points are distributed so that inspections occur on the tank dome, sides, near the bottom, at points where structural supports or instrument nozzles penetrate the insulation, and where water collects (for example on top of stiffening rings).
	• Inspection locations are based on the likelihood of corrosion under insulation (CUI). For example, CUI is more likely for components experiencing alternate wetting and drying in environments where trace contaminants could be present and for components that operate for long periods of time below the dew point.
	• If tightly adhering insulation is installed, this insulation should be impermeable to moisture and there should be no evidence of damage to the moisture barrier. Given that the likelihood of CUI is low for tightly adhering insulation, a minimal number of inspections of the external moisture barrier of this type of insulation, although not zero, will be credited toward the sample population.
	• Subsequent inspections will consist of an examination of the exterior surface of the insulation for indications of damage to the jacketing or protective outer layer of the insulation, if the following conditions are verified in the initial inspection.
	  • No loss of material due to general, pitting or crevice corrosion, beyond that which could have been present during initial construction
	  • No evidence of cracking
	Nominal degradation is defined as no loss of material due to general, pitting, or crevice corrosion, beyond that which could have been present during initial construction, and no evidence of cracking. If the external visual inspections of the insulation reveal damage to the exterior surface of the insulation or there is evidence of water intrusion through the insulation (e.g. water seepage through insulation seams/joints), periodic inspections under the insulation will continue as described above.
	[3.0.3-1 Request 6a, ML13357A722, E-1 – 24 of 43, 12/16/13]
	
	E. Revise External Surfaces Monitoring Program procedures to include acceptance criteria. Examples include the following:	

No.	**COMMITMENT**	**LRA SECTION / AUDIT ITEM**
(6)	• Stainless steel should have a clean shiny surface with no discoloration. • Other metals should not have any abnormal surface indications. • Flexible polymers should have a uniform surface texture and color with no cracks and no unanticipated dimensional change, no abnormal surface with the material in an as-new condition with respect to hardness, flexibility, physical dimensions, and color. • Rigid polymers should have no erosion, cracking, checking or chalks. F. For a representative sample of outdoor insulated components and indoor insulated components operated below the dew point, which have been identified with more than nominal degradation on the exterior of the component, insulation is removed for inspection of the component surface. For a representative sample of indoor insulated components operated below the dew point, which have not been identified with more than nominal degradation on the exterior of the component, the insulation exterior surface is inspected. These inspections will be conducted during each 10-year period during the PEO, [3.0.3-1 Request 6a, ML13357A722, E-1 – 23 of 43, 12/16/13] G. Specific, measurable, actionable/attainable and relevant acceptance criteria are established in the maintenance and surveillance procedures or are established during engineering evaluation of the degraded condition. [ML13357A722, E-1 – 43 of 43, 12/16/13]	

No.	COMMITMENT	LRA SECTION / AUDIT ITEM
7	A. Revise **Fatigue Monitoring Program** procedures to monitor and track critical thermal and pressure transients for components that have been identified to have a fatigue Time Limited Aging Analysis. B. Fatigue usage calculations that consider the effects of the reactor water environment will be developed for a set of sample reactor coolant system (RCS) components. This sample set will include the locations identified in NUREG/CR-6260 and additional plant-specific component locations in the reactor coolant pressure boundary if they are found to be more limiting than those considered in NUREG/CR-6260. In addition, fatigue usage calculations for reactor vessel internals (lower core plate and control rod drive (CRD) guide tube pins) will be evaluated for the effects of the reactor water environment. F_{en} factors will be determined as described in Section 4.3.3. C. Fatigue usage factors for the RCS pressure boundary components will be adjusted as necessary to incorporate the effects of the Cold Overpressure Mitigation System (COMS) event (i.e., low temperature overpressurization event) and the effects of structural weld overlays. D. Revise Fatigue Monitoring Program procedures to provide updates of the fatigue usage calculations and cycle-based fatigue waiver evaluations on an as-needed basis if an allowable cycle limit is approached, or in a case where a transient definition has been changed, unanticipated new thermal events are discovered, or the geometry of components have been modified. E. Revise Fatigue Monitoring Program procedures to track the tensioning cycles for the reactor coolant pump hydraulic studs.	B.1.11
8	A. Revise **Fire Protection Program** procedures to include an inspection of fire barrier walls, ceilings, and floors for any signs of degradation such as cracking, spalling, or loss of material caused by freeze thaw, chemical attack, or reaction with aggregates. B. Revise Fire Protection Program procedures to provide acceptance criteria of no significant indications of concrete cracking, spalling, and loss of material of fire barrier walls, ceilings, and floors and in other fire barrier materials.	B.1.12

No.	COMMITMENT	LRA SECTION / AUDIT ITEM
9	Implement the **Fire Water System Program** (FWSP) as described in UFSAR Section 13.9.1, Appendix A, Section A.1.13. **A.** [Blank] **B**. [Blank] **C**. Revise FWSP procedures to ensure sprinkler heads are tested in accordance with NFPA-25 (2011 Edition), Section 5.3.1 [3.0.3-1 Request 4a] **D**. [Blank] **E.** Revise FWSP procedures to include acceptance criteria for periodic visual inspection of fire water system internals for corrosion, minimum wall thickness, and the absence of biofouling in the sprinkler system that could cause corrosion in the sprinklers. **F**. [Blank] **G.** Revise FWSP procedures to include periodically remove a representative sample of components, such as sprinkler heads or couplings, within **five years prior to the PEO, and every five years** during the PEO, to perform a visual internal inspection of the dry fire water system piping for evidence of corrosion, and loss of wall thickness, and foreign material that may result in flow blockage using the methodology described in NFPA-25 Section 14.2.1. The acceptance criteria shall be “no debris” (i.e., no corrosion products that could impede flow or cause downstream components to become clogged). Any signs of abnormal corrosion or blockage will be removed, its source determined and corrected, and entered into the CAP. Due dates: SQN1: within five years prior to 03/17/20, and every five years during the PEO SQN2: within five years prior to 03/15/21, and every five years during the PEO [ML14113A208 pg E-1-6 due dates] [3.0.3-1, Req 4a.d, i to vi, ML13357A722, E-1 – 11], [ML14057A808, 3.0.3-1.4b, E-1 p25]	B.1.13

No.	COMMITMENT	LRA SECTION / AUDIT ITEM
(9)	**H**. Revise FWSP procedures to perform an obstruction evaluation in accordance with NFPA-25 (2011 Edition), Section 14.3.1. **I.** Revise FWSP procedures to conduct follow-up volumetric examinations if internal visual inspections detect surface irregularities that could be indicative of wall loss below nominal pipe wall thickness. **J.** Revise FWSP procedures to annually inspect the fire water storage tank exterior painted surface for signs of degradation. If degradation is identified, conduct follow-up volumetric examinations to ensure wall thickness is equal to or exceeds nominal wall thickness. The fire water storage tanks will be inspected in accordance with NFPA-25 (2011 Edition) requirements. **K.** Revise FWSP procedures to include a fire water storage tank interior inspection every five years that includes inspections for signs of pitting, spalling, rot, waste material and debris, and aquatic growth. Include in the revision direction to perform fire water storage tank interior coating testing, if any degradation is identified, in accordance with ASTM D 3359 or equivalent, a dry film thickness test at random locations to determine overall coating thickness; and a wet sponge test to detect pinholes, cracks or other compromises of the coating. If there is evidence of pitting or corrosion ensure the FWSP procedures direct performance of an examination to determine wall and bottom thickness. **L**. [Blank] **M**. Revise FWSP procedures to perform an annual spray head discharge pattern tests from all open spray nozzles to ensure that patterns are not impeded by plugged nozzles, to ensure that nozzles are correctly positioned, and to ensure that obstructions do not prevent discharge patterns from wetting surfaces to be protected. Where the nature of the protected critical equipment or property is such that water cannot be discharged, the nozzles shall be inspected for proper orientation and the system tested with air, smoke or some other medium to ensure that the nozzles are not obstructed. Ensure that the dry piping is unobstructed downstream of deluge valves protecting indoor areas containing critical equipment by flow testing with air, smoke or other medium from deluge valve through the sprinkler heads. Based on the trip testing of the deluge valves without flow through the downstream piping and sprinkler heads, additional testing in the RCA or areas containing critical equipment is not warranted due to the addition of risk-significant activities and the production of additional radwaste. [3.0.3-1.4a, ML13357A722, E-1 – 14 of 43, 12/16/13]	

No.	COMMITMENT	LRA SECTION / AUDIT ITEM
(9)	**N.** Revise FWSP procedures to perform an internal inspection of the accessible piping associated with the strainer inspections for corrosion and foreign material that may cause blockage. Document any abnormal corrosion or foreign material in the CAP. [3.0.3-1, Request 4a, ML13357A722, E-1 – 15 of 43, 12/16/13] **O.** Revise FWSP procedures to perform 25 main drain tests every 18-months with at least one main drain test performed in each of the following buildings: (1) control building, (2) auxiliary building, (3) turbine building, and (4) diesel generator building. The results of the main drain tests from the three 18-month inspection intervals will be evaluated to determine if the NFPA 25 (2014 Edition) main drain test guidance can be applied to the number of main drain tests performed (.i.e., Section 13.2.5, "A main drain test shall be conducted annually for each water supply lead-in to a building water-based fire protection system to determine whether there has been a change in the condition of the water supply" and Section 13.2.5.1 "Where the lead-in to a building supplies a header or manifold serving multiple systems, a single main drain test shall be performed.") Any flow blockage or abnormal discharge identified during flow testing or any change in delta pressure during the main drain testing greater than 10% at a specific location is entered into the CAP. Flow or main drain testing increases risk due to the potential for water contacting critical equipment in the area, and main drain testing in the RCAs increases the amount of liquid radwaste. Therefore, SQN will not perform main drain tests on every standpipe with an automatic water supply or on every system riser. [3.0.3-1, Request 4a, ML13357A722, E-1 – 15 of 43, 12/16/13] **P.** Revise FWSP procedures to perform One of the following inspection methods for those sections of dry piping described in NRC Information Notice (IN) 2013-06, where drainage is not occurring, to ensure there is no flow blockage in each five-year interval beginning with the five-year period before the PEO: (a) Perform a flow test or flush sufficient to detect potential flow blockage. (b) Remove sprinkler heads or couplings in the areas that do not drain and perform a 100% visual internal inspection to verify there are no signs of abnormal corrosion (wall thickness loss) or blockage. If option (a) is chosen, controls will be established to ensure potential blockage is not moved to another part of the system where it may be undetected. In each five-year interval during the PEO, 20% of the length of piping segments that cannot be drained or piping segments that allow water to collect will be subjected to UT wall thickness examination. The piping examined during each inspection	

No.	**COMMITMENT**	**LRA SECTION / AUDIT ITEM**
(9)	interval will be piping that was not previously examined. [9.P is added ML14057A808, E-1 p23, 3.0.3-1.4b] [9.P(c) is deleted in ML14197A267 pg E-1 - 5] If the results of a 100% internal visual inspection are acceptable, and the segment is not subsequently wetted, no further augmented tests or inspections will be performed. (3.0.3-1-3 Request 4c, ML14197A267 pg E-1 - 5)	
10	A. Revise **Flow Accelerated Corrosion** (FAC) **Program** procedures to implement NSAC-202L guidance for examination of components upstream of piping surfaces where significant wear is detected. B. Revise FAC Program procedures to implement the guidance in LR-ISG-2012-01, which will include a susceptibility review based on internal operating experience, external operating experience, EPRI TR-1011231, Recommendations for Controlling Cavitation, Flashing, Liquid Droplet Impingement, and Solid Particle Erosion in Nuclear Power Plant Piping, and NUREG/CR-6031, Cavitation Guide for Control Valves. [B.1.14-1 and B.1.38-1]. In addition, revise the FAC program procedures to include portions of the Essential Raw Cooling Water (ERCW) piping where Belzona coating is applied. These inspections are to be performed prior to the PEO, and pending results of the inspections, future inspections should be planned as part of the FAC program.	B.1.14
11	Revise **Flux Thimble Tube Inspection Program** procedures to include a requirement to address if the predictive trending projects that a tube will exceed 80% wall wear prior to the next planned inspection, then initiate a Service Request (SR) to define actions (i.e., plugging, repositioning, replacement, evaluations, etc.) required to ensure that the projected wall wear does not exceed 80%. If any tube is found to be >80% through wall wear, then initiate a Service Request (SR) to evaluate the predictive methodology used and modify as required to define corrective actions (i.e., plugging, repositioning, replacement, etc).	B.1.15

No.	COMMITMENT	LRA SECTION / AUDIT ITEM
12	A. Revise **Inservice Inspection–IWF Program** procedures to clarify that detection of aging effects will include monitoring anchor bolts for loss of material, loose or missing nuts, and cracking of concrete around the anchor bolts. B. Revise ISI - IWF Program procedures to include the following corrective action guidance. When an indication is identified on a component support exceeding the acceptance criteria of IWF-3400, but an evaluation concludes the support is acceptable for service, the program shall require examination of additional similar/adjacent supports per IWF-2430 unless the evaluation of the identified condition against similar/adjacent supports concludes that it would not adversely affect the design function of similar adjacent supports. This evaluation will be performed regardless of whether the program owner chooses to perform corrective measures to restore the component to its original design condition, per IWF-3112.3(b) or IWF-3122.3(b). [ML13190A276. E1-37of79, 7/1/13]	B.1.17
13	Inspection of **Overhead Heavy Load and Light Load** (Related to Refueling) **Handling Systems**: A. Revise program procedures to specify the inspection scope will include monitoring of rails in the rail system for wear; monitoring structural components of the bridge, trolley and hoists for the aging effect of deformation, cracking, and loss of material due to corrosion; and monitoring structural connections/bolting for loose or missing bolts, nuts, pins or rivets and any other conditions indicative of loss of bolting integrity. B. Revise program procedures to include the inspection and inspection frequency requirements of ASME B30.2. C. Revise program procedures to clarify that the acceptance criteria will include requirements for evaluation in accordance with ASME B30.2 of significant loss of material for structural components and structural bolts and significant wear of rail in the rail system. D. Revise program procedures to clarify that the acceptance criteria and maintenance and repair activities use the guidance provided in ASME B30.2	B.1.18

No.	COMMITMENT	LRA SECTION / AUDIT ITEM
14	A. Implement the **Internal Surfaces in Miscellaneous Piping and Ducting Components Program** as described in UFSAR 13.9.1, Appendix A, section A.1.19. B. Specific, measurable, actionable/attainable and relevant acceptance criteria are established in the maintenance and surveillance procedures or are established during engineering evaluation of the degraded condition. [ML13357A722, E-1 – 43 of 43, 12/16/13]	B.1.19
15	Implement the **Metal Enclosed Bus Inspection Program** as described in UFSAR Section 13.9.1 Appendix A.1.21.	B.1.21
16	A. Revise **Neutron Absorbing Material Monitoring Program** procedures to perform blackness testing of the Boral coupons within the ten years prior to the PEO and at least every ten years thereafter based on initial testing to determine possible changes in boron-10 areal density. B. Revise Neutron Absorbing Material Monitoring Program procedures to relate physical measurements of Boral coupons to the need to perform additional testing. C. Revise Neutron Absorbing Material Monitoring Program procedures to perform trending of coupon testing results to determine the rate of degradation and to take action as needed to maintain the intended function of the Boral.	B.1.22
17	Implement the **Non-EQ Cable Connections Program** as described in UFSAR 13.9.1, Appendix A, Section A.1.24.	B.1.24
18	Implement the **Non-EQ Inaccessible Power Cable** (400 V to 35 kV) **Program** as described in UFSAR 13.9.1, Appendix A, Section A.1.25. A. **B.1.25.1a** [ML13296A017, E-1-12 of 25, 10/21/13] 1. [Blank] 2. [Blank] 3. Prior to the PEO, the license renewal commitment for the Non-EQ Inaccessible Power Cables (400 V to 35 kV) Program will establish diagnostic testing activities on all inaccessible power cables in the 400 V to 35kV range that are in the scope of license renewal and subject to aging management review. 4. [Blank] 5. Once 18.A.1, 2, and 4 are fully completed, these commitments can be deleted from this list or the UFSAR .	B.1.25

No.	COMMITMENT	LRA SECTION / AUDIT ITEM
19	Implement the **Non-EQ Instrumentation Circuits Test Review Program** as described in UFSAR 13.9.1, Appendix A, Section A.1.26.	B.1.26
20	Implement the **Non-EQ Insulated Cables and Connections Program** as described in UFSAR 13.9.1, Appendix A, Section A.1.27.	B.1.27
21	Implement the **Oil Analysis Program** as described UFSAR 13.9.1, Appendix A, Section A.1.28.	B.1.28
22	Implement the **One-Time Inspection Program** as described in UFSAR Section 13.9.1 A.1.29.	B.1.29
23	Implement the **One-Time Inspection – Small Bore Piping Program** as described in UFSAR 13.9.1, Appendix A, Section A.1.30.	B.1.30
24	A. Revise **Periodic Surveillance and Preventive Maintenance Program** procedures as necessary to include activities provided in UFSAR 13.9.1, Appendix A, Section A.1.31. B. For in-scope components that have internal Service Level III or Other coatings, initial inspections will begin no later than the last scheduled refueling outage prior to the PEO. Subsequent inspections will be performed based on the initial inspection results. [3.0.3-1, Request 3, ML13312A005, pages E-1- 2,5,7 of 51] Note: The commitment was revised by ML14057A808, E1 p8 and replaced by commitments C, D, E, F, and G. Note 2: The Pressurizer Relief Tanks (PRTs) for pressure boundary and the Cask Decontamination Collector Tank (CDCT) are not considered in-scope,. Although ERCW is in-scope, evaluation of the failure modes of the Belzona coating have determined inspection is not required. C. Revise Periodic Surveillance and Preventive Maintenance Program procedures to perform a minimum of five MIC degradation inspections per year until the rate of MIC occurrences no longer meets the criteria for recurring internal corrosion. [CNL-14-105, E1p11] If more than one MIC-caused leak or a wall thickness less than T_{min} is identified in the yearly inspection period, an additional five MIC inspections over the following 12 month period will be performed for each MIC leak or finding of wall thickness less than T_{min}. The total	B.1.31

No.	COMMITMENT	LRA SECTION / AUDIT ITEM
(24)	number of inspections need not exceed a total of 25 MIC inspections per year. [ML14057A808, E-1 p8, 3.0.3-1-3a] Prior to the period of extended operation, select a method (or methods) from available technologies for inspecting internal surfaces of buried piping (System 26/HPFP Firewater and 67/ERCW) that provides suitable indication of piping wall thickness for a representative set of buried piping locations to supplement the set of selected inspection locations [3.0.3-1, Req 1a, ML13357A722, E-1 – 4 of 43, 12/16/13] [3.0.3-1 Req 1, ML13294A462, E-1- 6 of 13, 10/17/13] [Moved 9.F to 24.C in ML14057A808, E-1 p13,29] **D**. 1. Prior to the PEO, perform a visual inspection of a 50% sample of the coated piping in each of the following coated piping systems or an area equivalent to the entire inside surface of 73 1-foot piping segments for each combination of type of coating, substrate material, and environment. Inspection location selection will be based on an evaluation of the effect of a coating failure on component intended functions, potential problems identified during prior inspections, and service life history. Visually inspect the surface condition of the coated components to manage loss of coating integrity due to cracking, debonding, delamination, peeling, flaking, and blistering. In addition, if coatings are credited for corrosion prevention, the base material (in the vicinity of delamination, peeling, or blisters where base metal has been exposed) will be inspected to determine if corrosion has occurred. **Piping**: i. High pressure fire protection (cement-lined piping) 2. With the exception of the EDG 7-day fuel oil tanks, perform subsequent inspections of coatings based on the following. i. If no flaking, debonding, peeling, delamination, blisters, or rusting are observed, and any cracking and flaking has been found acceptable, subsequent inspections will be performed at least once every six years. If the coating is inspected on one train and no indications are found, the same coating on the redundant train would not be inspected during that inspection interval. ii. If the inspection results do not meet (i), yet a coating specialist has determined that no remediation is required, then subsequent inspections will be conducted every other refueling outage. iii. If coating degradation is observed that requires newly installed coatings, subsequent inspections will occur during each of the next two refueling outage intervals to establish a performance trend on the coating. EDG 7-day fuel oil tanks coating inspection: Subsequent coating inspections for the EDG 7-day fuel oil tanks will be at the same 10 year interval as TS Surveillance (Requirement 4.8.1.1.2.f [SAME REQUIREMENT IS NOW IN	

No.	COMMITMENT	LRA SECTION / AUDIT ITEM
(24)	TECHNICAL REQUIREMENTS MANUAL (TRM) AS TRV 8.8.4.1 UNDER ITS]. If any applied Belzona coating on the interior of the fuel oil tanks is peeling, delaminating, or blistering, then the condition will be repaired and entered into the CAP. Given the favorable SQN experience with the current Belzona repairs, it is justifiable to repair the existing coating applied to localized pits with Belzona and not inspect the coating for another 10 years, provided a detached Belzona engineering transportability evaluation has determined that the amount of Belzona applied will not migrate from the EDG 7-day tank to the day-tank. The evaluation will consider Belzona's 2.5 to 3 times higher specific gravity than diesel fuel, potential size of loosened Belzona particles, surface area and depth of the applied Belzona, diesel fuel fluid velocity in the immediate area of the applied Belzona, proximity of the repaired area to the suction line, and other factors. The application of Belzona to repair additional localized pitting in the 7-day EDG fuel oil tanks in the future will be installed per vendor specifications. An engineering evaluation will be performed to ensure that that additional Belzona cannot be transferable out of the tank during the interval between tank inspections and to determine if the interval of inspections should meet the more frequent inspection guidelines of LR-ISG-2013-01, or the NRC approved TS Surveillance Requirement (NOW TRM TRV 8.8.4.1 UNDER ITS) of 10 years. The engineering transportability evaluation will consider factors such as specific gravity, size, depth, surface area, and fluid velocity in the evaluation. [ML14057A808, E-1 p7] **E**. Prior to the PEO, perform a visual inspection of the following coated tanks and heat exchangers. Visually inspect the surface condition of the coated components to manage loss of coating integrity due to cracking, debonding, delamination, peeling, flaking, and blistering. **Tanks** i. Safety injection lube oil reservoir (where 0.006 inch plastic coating applied) ii. EDG 7-day fuel oil (where Belzona applied) iii. Condensate storage tank **Heat Exchangers** i. Electric board room chiller package (where Belzona applied) ii. Incore instrument room water chiller package B (where Belzona applied) [ML14057A808, E-1 p6] **F**. Any indication or relevant condition of degradation detected is evaluated. Include the following acceptance criteria for loss of coatings integrity: For any indication or relevant condition of coating degradation, the indication or relevant condition is evaluated for loss of coatings integrity. [ML14063A542, E-1 p2]	

No.	COMMITMENT	LRA SECTION / AUDIT ITEM
(24)	(1) Peeling and delamination are not permitted, (2) Cracking is not permitted if accompanied by delamination or loss of adhesion, and (3) Blisters are limited to intact blisters that are completely surrounded by sound coating bonded to the surface. Corrective Action: If delamination, peeling, or blisters are detected, follow-up physical testing will be performed where physically possible (i.e., sufficient room to conduct testing) on at least three locations. The testing will consist of destructive or nondestructive adhesion testing using ASTM International standards endorsed in Regulatory Guide 1.54. [ML14057A808, E-1 p6] **G**. 1. Coating inspections are performed by individuals certified to ANSI N45.2.6, "Qualifications of Inspection, Examination, and Testing Personnel for Nuclear Power Plants," and that subsequent evaluation of inspection findings is conducted by a nuclear coatings subject matter expert qualified in accordance with ASTM D 7108-05, "Standard Guide for Establishing Qualifications for a Nuclear Coatings Specialist." 2. An individual knowledgeable and experienced in nuclear coatings work will prepare a coating report that includes a list of locations identified with coating deterioration including, where possible, photographs indexed to inspection location, and a prioritization of the repair areas into areas that must be repaired before returning the system to service and areas where coating repair can be postponed to the next inspection. [ML14057A808, E-1 p6]	
25	A. Revise **Protective Coating Program** procedures to clarify that detection of aging effects will include inspection of coatings near sumps or screens associated with the emergency core cooling system. B. Revise Protective Coating Program procedures to clarify that instruments and equipment needed for inspection may include, but not be limited to, flashlights, spotlights, marker pen, mirror, measuring tape, magnifier, binoculars, camera with or without wide-angle lens, and self-sealing polyethylene sample bags. C. Revise Protective Coating Program procedures to clarify that the last two performance monitoring reports pertaining to the coating systems will be reviewed prior to the inspection or monitoring process.	B.1.32

No.	COMMITMENT	LRA SECTION / AUDIT ITEM
26	A. Revise **Reactor Head Closure Studs Program** procedures to ensure that replacement studs are fabricated from bolting material with actual measured yield strength less than 150 ksi. B. Revise Reactor Head Closure Studs Program procedures to exclude the use of molybdenum disulfide (MoS_2) on the reactor vessel closure studs and to refer to Reg. Guide 1.65, Rev1.	B.1.33
27	A. Revise **Reactor Vessel Internals Program** procedures to perform direct measurement of Unit 1 304 SS hold down spring height within three cycles of the beginning of the period of extended operation. If the first set of measurements is not sufficient to determine life, spring height measurements must be taken during the next two outages, in order to extrapolate the expected spring height to 60 years. (ML13324A982, 11/15/13, Enc 1, pages 24-25) B. Revise Reactor Vessel Internals Program procedures to include preload acceptance criteria for the Type 304 stainless steel hold-down springs in Unit 1. C. Continued monitoring of industry operating experience in the area of RVI Clevis Bolt will be performed and the program will be modified, if necessary. [ML14057A808, E-1 p35, B.1.34-8] D. [Blank] E. Revise Reactor Vessel Internals Program procedures to identify the observation of cracking in the lower core barrel girth weld as the primary trigger for the EVT-1 expansion inspection of the upper core plate. [B.1.34-9d (follow-up) in Cnl-14-221, Enc 1.	B.1.34

No.	COMMITMENT	LRA SECTION / AUDIT ITEM
28	A. Revise **Reactor Vessel Surveillance Program** procedures to consider the area outside the beltline such as nozzles, penetrations and discontinuities to determine if more restrictive pressure-temperature limits are required than would be determined by just considering the reactor vessel beltline materials. B.1 Revise Unit 2 Reactor Vessel Surveillance Program procedures to incorporate an NRC-approved schedule for capsule withdrawals to meet ASTM-E185-82 requirements, including the possibility of operation beyond 60 years (refer to the TVA Letter to NRC, “Sequoyah Nuclear Plant - Request To Revise The Reactor Pressure Vessel Surveillance Capsule Withdrawal Schedule for Unit 2” dated 12/23/16, ML16362A207; NRC final safety evaluation report approved on 12/04/17, ML17317A608). B.2 Revise Unit 1 Reactor Vessel Surveillance Program procedures to incorporate an NRC-approved schedule for capsule withdrawals to meet ASTM-E185-82 requirements, including the possibility of operation beyond 60 years (refer to the TVA Letter to NRC, Sequoyah Nuclear Plant, Revision to Reactor Pressure Vessel Surveillance Capsule Withdrawal Schedule for License Renewal dated May 14, 2015, ML15197A176). C. Revise Reactor Vessel Surveillance Program procedures to withdraw and test a standby capsule to cover the peak fluence expected at the end of the PEO.	B.1.35
29	Implement the **Selective Leaching Program** as described in UFSAR 13.9.1, Appendix A, Section A.1.37.	B.1.37
30	Revise **Steam Generator Integrity Program** procedures to ensure that corrosion resistant materials are used for replacement steam generator tube plugs.	B.1.39

Revise SMP procedures to include periodic sampling and chemical analysis of ground water chemistry for pH, chlorides, and sulfates on a frequency of at least every five years. **E**. Revise Masonry Wall Program procedures to specify masonry walls located in the following in-scope structures are in the scope of the Masonry Wall Program: • Auxiliary building • Reactor building Units 1 & 2 • Control bay • ERCW pumping station • HPFP pump house • Turbine building **F**. Revise SMP procedures to include the following parameters to be monitored or inspected:	

No.	COMMITMENT	LRA SECTION / AUDIT ITEM
(31)	• Requirements for concrete structures based on ACI 349-3R and ASCE 11 and include monitoring the surface condition for loss of material, loss of bond, increase in porosity and permeability, loss of strength, and reduction in concrete anchor capacity due to local concrete degradation. • Loose or missing nuts for structural bolting. • Monitoring gaps between the structural steel supports and masonry walls that could potentially affect wall qualification. • Monitor the surface condition of insulation (fiberglass, calcium silicate) to identify exposure to moisture that can cause loss of insulation effectiveness. • **G**. Revise SMP procedures to include the following components to be monitored for the associated parameters: • Anchors/fasteners (nuts and bolts) will be monitored for loose or missing nuts and/or bolts, and cracking of concrete around the anchor bolts. • Elastomeric vibration isolators and structural sealants will be monitored for cracking, loss of material, loss of sealing, and change in material properties (e.g., hardening). • [Blank] The NRC Commitment List references CNL-14-221, E2, ML14350A683 dated 12/11/14. **H**. Revise SMP procedures to include the following for detection of aging effects: • Inspection of structural bolting for loose or missing nuts. • Inspection of anchor bolts for loose or missing nuts and/or bolts, and cracking of concrete around the anchor bolts. • Inspection of elastomeric material for cracking, loss of material, loss of sealing, and change in material properties (e.g., hardening), and supplement inspection by feel or touch to detect hardening if the intended function of the elastomeric material is suspect. Include instructions to augment the visual examination of elastomeric material with physical manipulation of at least ten percent of available surface area. • Opportunistic inspections when normally inaccessible areas (e.g., high radiation areas, below grade concrete walls or foundations, buried or submerged structures) become accessible due to required plant activities. Additionally, inspections will be performed of inaccessible areas in environments where observed conditions in accessible areas exposed to the same environment indicate that significant degradation is occurring. • Inspection of submerged structures at least once every five years. Inspections of water control structures should be conducted under the direction of qualified personnel experienced in the investigation, design, construction, and operation of these types of facilities. • Inspections of water control structures shall be performed on an interval not to exceed five years.	

No.	COMMITMENT	LRA SECTION / AUDIT ITEM
(31)	• Perform special inspections of water control structures immediately (within 30 days) following the occurrence of significant natural phenomena, such as large floods, earthquakes, hurricanes, tornadoes, and intense local rainfalls. • Insulation (fiberglass, calcium silicate) will be monitored for loss of material and change in material properties due to potential exposure to moisture that can cause loss of insulation effectiveness. • Revise SMP procedures to clarify that detection of aging effects will include the following. Qualifications of personnel conducting the inspections or testing and evaluation of structures and structural components meet the guidance in Chapter 7 of ACI 349.3R. **I.** Revise SMP procedures to prescribe quantitative acceptance criteria based on the quantitative acceptance criteria of ACI 349.3R and information provided in industry codes, standards, and guidelines including ACI 318, ANSI/ASCE 11 and relevant AISC specifications. Industry and plant-specific operating experience will also be considered in the development of the acceptance criteria. **J.** [Blank] **K**. Revise SMP procedures to include the following acceptance criteria for insulation (calcium silicate and fiberglass) • No moisture or surface irregularities that indicate exposure to moisture. **L**. Revise SMP procedures to include the following preventive actions. Specify protected storage requirements for high-strength fastener components (specifically ASTM A325 and A490 bolting). Storage of these fastener components shall include: 1. Maintaining fastener components in closed containers to protect from dirt and corrosion; 2. Storage of the closed containers in a protected shelter; 3. Removal of fastener components from protected storage only as necessary; and 4. Prompt return of any unused fastener components to protected storage. **M**. RAI B.1.40-4a Response (Turbine Building wall crack): 1. SQN will map and trend the crack in the condenser pit north wall. 2. SQN will test water inleakage samples from the turbine building condenser pit walls and floor slab for minerals and iron content to assess the effect of the water inleakage on the concrete and the reinforcing steel.	

No.	COMMITMENT	LRA SECTION / AUDIT ITEM
(31)	3. SQN will test concrete core samples removed from the turbine building condenser pit north wall with a minimum of one core sample in the area of the crack. The core samples will be tested for compressive strength and modulus of elasticity and subjected to petrographic examination. 4. The results of the tests and SMP inspections will be used to determine further corrective actions, including, but not limited to, more frequent inspections, sampling and analysis of the inleakage water for minerals and iron, and evaluation of the affected area using evaluation criteria and acceptance criteria of ACI 349.3R. [Outcome of the NRC 01/14/14 telecom] 5. Commitment #31.M will be implemented before the PEO for SQN Units 1 and 2. . [ML13296A017, E-1-10 of 25, 10/21/13, for 31.M.1 to 5]	
32	Implement the **Thermal Aging Embrittlement of Cast Austenitic Stainless Steel (CASS)** as described in UFSAR 13.9.1, Appendix A, Section A.1.41. A. B.1.41-4**a**: For those CASS components with delta ferrite content > 25%, additional analysis will be performed using plant-specific materials data and best available fracture toughness curves. (B.1.41-4a, ML13225A387, E-1 – 19 of 25) B. B.1.41-4**b**: For CASS materials with estimated delta ferrite > 20% that have been determined susceptible to thermal aging, a flaw tolerance analysis may be necessary. If a flaw tolerance analysis will be required for the susceptible CASS components, the SQN-specific flaw tolerance method will be submitted to the NRC for review and approval at least **two years** prior to the PEO; unless ASME has approved the flaw tolerance analysis methodology that SQN will use. [ML13357A722, E-1 – 1 of 43, 12/16/13]	B.1.41

No.	COMMITMENT	LRA SECTION / AUDIT ITEM
33	A. Revise **Water Chemistry Control - Closed Treated Water Systems Program** procedures to provide a corrosion inhibitor for the following chilled water subsystems in accordance with industry guidelines and vendor recommendations: • Auxiliary building cooling • Incore Chiller 1A, 1B, 2A, & 2B • 6.9 kV Shutdown Board Room A & B B. Revise Water Chemistry Control - Closed Treated Water Systems Program procedures to conduct inspections whenever a boundary is opened for the following systems: • Standby diesel generator jacket water subsystem • Component cooling system • Glycol cooling loop system • High pressure fire protection diesel jacket water system Chilled water portion of miscellaneous HVAC systems (i.e., auxiliary building, Incore Chiller 1A, 1B, 2A, & 2B, and 6.9 kV Shutdown Board Room A & B) C. Revise Water Chemistry Control-Closed Treated Water Systems Program procedures to state these inspections will be conducted in accordance with applicable ASME Code requirements, industry standards, or other plant-specific inspection and personnel qualification procedures that are capable of detecting corrosion or cracking. D. Revise Water Chemistry Control - Closed Treated Water Systems Program procedures to perform sampling and analysis of the glycol cooling system per industry standards and in no case greater than quarterly unless justified with an additional analysis. E. Revise Water Chemistry Control - Closed Treated Water Systems Program procedures to inspect a representative sample of piping and components at a frequency of once every ten years for the following systems: • Standby diesel generator jacket water subsystem • Component cooling system • Glycol cooling loop system • High pressure fire protection diesel jacket water system • Chilled water portion of miscellaneous HVAC systems (i.e., auxiliary building, Incore Chiller 1A, 1B, 2A, & 2B, and 6.9 kV Shutdown Board Room A & B) F. Components inspected will be those with the highest likelihood of corrosion or cracking. A representative sample is 20% of the population (defined as components having the same material, environment, and aging effect combination) with a maximum of 25 components. These inspections will be in accordance with applicable ASME Code requirements, industry standards, or other plant-specific inspection and personnel qualification procedures that ensure the capability of detecting corrosion or cracking.	B.1.42

No.	**COMMITMENT**	**LRA SECTION / AUDIT ITEM**
34	Revise **Containment Leak Rate Program** procedures to require venting the SCV bottom liner plate weld leak test channels to the containment atmosphere prior to the CILRT and resealing the vent path after the CILRT to prevent moisture intrusion during plant operation.	B.1.7
35	A. From **RAI B.1.6-1** Response: Modify the configuration of the SQN Unit 1 test connection access boxes to prevent moisture intrusion to the leak test channels. Prior to installing this modification, TVA will perform remote visual examinations inside the leak test channels by inserting a borescope video probe through the test connection tubing. B. From B.1.6-**1b** Response: To monitor the condition of the access boxes and associated materials, develop and implement an instruction/procedure to perform visual examinations of all accessible surfaces, including the access box surfaces, cover plate, welds, and gasket sealing surfaces of the access boxes on each unit every other refueling outage with the gasketed access box lid removed. C. From B.1.6-**2b** Response: develop and implement an instruction/procedure to continue volumetric examinations where the SCV domes were cut at the frequency of once every five years until the coatings are reinstalled at these locations.	B.1.6

No.	COMMITMENT	LRA SECTION / AUDIT ITEM
36	A. Revise **Inservice Inspection Program** procedures to include a supplemental inspection to monitor cracking of Class 1 CASS piping components that do not meet the materials selection criteria of NUREG-0313, Revision 2, with regard to ferrite and carbon content when an inspection technique has been qualified by ASME or EPRI. If an inspection technique has not been qualified by ASME or EPRI prior to the commitment due date, revise program procedures to continue monitoring the development of a qualified inspection technique. Once an ASME or EPRI inspection technique is qualified, revise Inservice Inspection Program procedures to perform the supplemental inspections. Inspections will be conducted on a sampling basis. The extent of sampling will be based on the established method of inspection and industry operating experience and practices when the program is implemented, and will include components determined to be limiting from the standpoint of applied stress, operating time and environmental considerations. (RAI 3.1.2.2.6.2-1) B. Revise the Inservice Inspection Program procedures to perform an augmented visual inspection of the Unit 1 and Unit 2 CRDM thermal sleeves and a wall thickness measurement of the six thermal sleeves exhibiting the greatest amount of wear. The results of the augmented inspection should be used to project if there is sufficient wall thickness for the PEO, or until the next inspection. (RAI B.1.23-2d) C. Evaluate industry operating experience related to CRDM housing penetration wear and initiatives to measure CRDM housing penetration wear and resulting wall thickness. Upon successful demonstration of a wear depth measurement process, SQN will revise Inservice Inspection Program procedures to use the demonstrated process at accessible locations to measure depth of wear on the CRDM housing penetration wall associated with contact with the CRDM thermal sleeve centering pads. (RAI B.1.23-2c; Cnl-14-105, Enc 1, A & B.1.16, Inservice Inspection Program, rev 17) D. Revise Inservice Inspection Program procedure to perform an examination of the accessible CRDM housing penetrations to determine the amount of wear in the area of the thermal sleeve centering pads for Units 1 and 2. The accessible locations consist of the centermost CRDM housing penetrations 1 through 5 on Unit 1 and penetrations 2 through 5 on Unit 2. (RAI B.1.23-2c)	B.1.16

No.	**COMMITMENT**	**LRA SECTION / AUDIT ITEM**
(36)	E. Revise Inservice Inspection Program procedure to estimate the wall thickness of the accessible CRDM housing penetration wear in the area of the thermal sleeve centering tabs at the end of the next RVH inspection interval and compare the projected wall thickness to the thickness used in Sequoyah design basis analyses to demonstrate validity of the analyses. (RAI B.1.23-2c; Cnl-14-105, Enc 1, A & B.1.16, Inservice Inspection Program, rev 17) F. Revise Inservice Inspection Program procedure to monitor the wear of the accessible CRDM housing penetrations in weld examination volume. (RAI B.1.23-2c) G. TVA ASME Section XI Program procedure which defines the Class 1 components subject to examination will be revised to specifically require a visual examination method VT-3 of the clevis bolts, dowel pins and tack welds as well as the six core support pads. [ML14063A542, E-1 p4, B.1.34-8a] H. Revise SQN's Category B-N-3 inspection procedure to reference the September 22, 2014, NRC RAI B.1.34-9c and the SQN's response (ML14254A204 and CNL-14-181) to identify that the inspection of the accessible regions the upper core plate lower surface (core support structure components, VT-3 inspection below the upper core plate to determine the general mechanical and structural condition of components) as a required License Renewal Inspection during the PEO. (CNL-14-181)	

No.	**COMMITMENT**	**LRA SECTION / AUDIT ITEM**
37	TVA will implement the **Operating Experience** for the **AMPs** in accordance with the TVA response to the RAI B.0.4-1 on 07/29/13, ML13213A027; and 10/17/13 letter, RAIs B.0.4-1a and A.1-1a. A. Revise OE Program Procedure to include current and future revisions to NUREG-1801, “Generic Aging Lessons Learned (GALL) Report,” as a source of industry OE, and unanticipated age-related degradation or impacts to aging management activities as a screening attribute. B. Revise the Corrective Action Procedure (CAP) Procedure to provide a screening process of corrective action documents for aging management items, the assignment of aging corrective actions to appropriate AMP owners, and consideration of the aging management trend code. C. Revise AMP procedures as needed to provide for review and evaluation by AMP owners of data from inspections, tests, analyses or AMP OEs. [ML14063A542, E-1 p3] D. Revise the OE Program Procedure to provide guidance for reporting plant-specific OE on unanticipated age-related degradation or impact to aging management activities to the TVA fleet and/or INPO. E. Revise the OE, CAP, Initial and Continuing Engineering Support Personnel Training to address age-related topics, the unanticipated degradation or impacts to the aging management activities; including periodic refresher/update training and provisions to accommodate the turnover of plant personnel, and recent AMP-related OE from INPO, the NRC, Scientech, and nuclear industry-initiated guidance documents and standards.” F. A comprehensive and holistic AMP training topic list will be developed before the date the SQN renewed operating license is scheduled to be issued. G. [Blank], Reference ML14350A683 dated12/11/14. Once Commitment 37 is fully completed, Commitment 37 can be deleted from this list or the UFSAR.	B.0.4

No.	COMMITMENT	A SECTION / AUDIT ITEM
38	A. Implement the **Service Water Integrity Program** (SWIP) as described in UFSAR 13.9.1, Appendix A, Section A.1.38. [3.0.3-1, Requests 3, ML13312A005.E-1 - 11 of 51, 11/4/13, for 38.A to F] B. Parameters Monitored/Inspected: Revise SWIP procedures to monitor the condition of coated surfaces in the heat exchangers credited in the response to NRC Generic Letter (GL) 89-13 response. C. Detection of aging Effect: Revise the SWIP procedures to perform periodic visual inspections to manage loss of coating integrity due to cracking, debonding, delamination, peeling, flaking, and blistering in heat exchangers credited in the NRC Generic Letter (GL) 89-13 response. D. Acceptance Criteria: Revise the SWIP procedures to include the following coating integrity acceptance criteria: (1) peeling and delamination are not permitted, (2) cracking is not permitted if accompanied by delamination or loss of adhesion, and (3) blisters are limited to intact blisters that are completely surrounded by sound coating bonded to the surface. E. Monitoring and Trending: Revise SWIP procedures to ensure an individual knowledgeable and experienced in nuclear coatings work will prepare a coating report that includes a list of locations identified with coating deterioration including, where possible, photographs indexed to inspection location, and a prioritization of the repair areas into areas that must be repaired before returning the system to service and areas where coating repair can be postponed to the next inspection. F. Qualification: Revise SWIP procedures to ensure coating inspections are performed by individuals certified to ANSI N45.2.6, "Qualifications of Inspection, Examination, and Testing Personnel for Nuclear Power Plants," and that subsequent evaluation of inspection findings is conducted by a nuclear coatings subject matter expert qualified in accordance with ASTM D 7108-05, "Standard Guide for Establishing Qualifications for a Nuclear Coatings Specialist."	B.1.38

No.	COMMITMENT	LRA SECTION / AUDIT ITEM
(38)	G. Before the PEO, revise Service Water Integrity Program procedures to (1) Monitor the existence of fouling or clogging in ERCW stagnant/dead leg piping. This enhancement is applicable to ERCW flow-paths that fulfill a safety-related function. (2) Periodically place normally ERCW stagnant/dead legs in service for the purpose of flushing. Alternatively, periodically flush the normally stagnant/dead leg by temporarily/permanently installing a flushing valve (without placing the line in service). (3) In lieu of flushing, perform periodic radiograph, demonstrated ultrasonic or visual inspections of ERCW stagnant /dead leg piping are acceptable to confirm the absence of fouling/clogging, and (4) When ERCW clogging/fouling of stagnant/dead leg piping is identified, enter findings into the corrective action program and perform an evaluation of the impact of ERCW design functions. (Cnl-14-105, Enc 1, A&B.1.38 Service Water Integrity, rev 17)	
39	Implement the **Boric Acid Corrosion Program** as described in UFSAR 13.9.1, Appendix A, Section A.1.3.	B.1.3
40	Implement the **Environmental Qualification (EQ) Of Electric Components Program** as described in . UFSAR 13.9.1, Appendix A, Section A.1.9	B.1.9
41	Implement the **Masonry Wall Program** as described in UFSAR 13.9.1, Appendix A, Section A.1.20.	B.1.20
42	Implement the **Nickel Alloy Inspection Program** as described in UFSAR 13.9.1, Appendix A, Section A.1.23.	B.1.23
43	Implement the **Water Chemistry Control – Primary And Secondary Program** as described in UFSAR 13.9.1, Appendix A, Section A.1.43.	B.1.43
44	Implement the **RG 1.127, Inspection Of Water-Control Structures Associated With Nuclear Power Plants Program** as described in UFSAR 13.9.1, Appendix A, Section A.1.36.	B.1.36
45	Implement the **161-kV Oil-Filled Cable Program** as described in UFSAR 13.9.1, Appendix A, Section A.1.44.	N/A

LIST OF FIGURES

14.0 INITIAL TESTS AND OPERATIONS

Chapter 14 describes the test program for initial startup and is provided here for historical purposes. Organizational names and references to other sections of this FSAR are retained to historically reflect those at the time the initial test and operations were performed.

14.1 TEST PROGRAM

This chapter describes the overall startup testing program for the Sequoyah Nuclear Plant. The program, as shown in Figure 14.1-1, is divided into ten parts which extend from the point at which plant construction has progressed to the extent that individual components and systems may be operated and tested through the plant acceptance test at rated power. Figure 14.1-1 also illustrates the grouping of the various test program parts into categories referred to as construction tests, preoperational tests, and startup tests. As subsequently used in this chapter, these categories are defined as follows:

Construction Tests--The adequacy of installation and preliminary operation of systems and components is verified by a construction test program consisting of various inspections and electrical/mechanical tests performed in accordance with written procedures and instructions. This test program is normally completed before the preoperational testing phase and encompasses Parts 1, 2, 3, and 4 of the initial test program as shown on Figure 14.1-1 and as described below:

1. Installed Equipment Inspection Program--Installed equipment is inspected for nameplate data, correct location and orientation, proper materials application, completeness of installation, and possible installation damage. Installation of interconnecting piping and wiring is verified to comply with design requirements. Deviations from applicable design specifications, codes, or standards are detected and corrected. The conduct and documentation of installation inspection activities are prescribed by approved construction procedures.

2. Cleaning and Flushing Program--Installed equipment and systems are cleaned such that operational cleanliness, process chemistry, and flow requirements may be reliably achieved during subsequent startup operations. Detailed written procedures are developed and followed for the cleaning and flushing of major and/or critical systems to ensure that specified cleanliness levels are achieved and maintained. Documentation of results is in accordance with the requirements of the Construction Quality Assurance Program.

3. Integrity Test Program--Field-installed equipment, components, interconnecting piping, and wiring are subjected to various integrity tests to verify conformance with applicable code requirements and to verify adequacy of installation. A comprehensive program of written instructions is utilized to ensure that appropriate tests are defined and performed. These instructions also include precautions to ensure that damage does not result from exceeding specified limitations of the installed equipment.

4. Equipment Checkout, Initial Operation, and Adjustment--An initial operation test program has been developed to include every component or subsystem in the plant. The general objectives of this testing phase are to ensure readiness for operation, to define the operational steps in preparing and actually energizing the equipment for the first time, and to describe and document operating data, subsequent operational adjustment calibration, and general adjustments of controls and supporting apparatus.

The formality and degree of this phase of the construction test program depends on the particular component or subsystem to be tested and the amount and type of data required. For those systems and components which are later subject to a formal preoperational test, all construction tests will be conducted in accordance with detailed, written instructions which define the specific test objectives and provide for the required documentation. In such instances, satisfactory completion of the construction testing is a necessary prerequisite to the conduct of preoperational testing described below:

The construction testing program as defined above is implemented, conducted, and documented by the Sequoyah site construction organization. The construction test documentation becomes a part of the permanent plant records.

<u>Preoperational Tests</u>--Refers to those tests included in Table 14.1-1.

Such tests include all system functional testing which verifies insofar as possible that safety-related systems and equipment perform as described in the FSAR.

Tests in this category normally can be completed before core loading. However, the nature of certain tests require that portions of the test be delayed until after fuel loading.

<u>Startup Tests</u>--Refers to those tests included in Table 14.1-2 (unit 1) and Table 14.1-3 (unit 2).

Such tests include the initial core loading, low power physics testing to verify core design parameters, and subsequent power ascension tests through the plant acceptance test at rated power.

Detailed test instructions are prepared for the conduct of all testing designated as either preoperational or startup tests as defined above. A listing and brief description of the individual tests in each of these categories is presented in Tables 14.1-1, 14.1-2, and 14.1-3 respectively. The sequence of testing for each category is shown in Figures 14.1-2, 14.1-3, and 14.1-4 respectively.

The organization of the material presented in this chapter is similar to that outlined in the following documents:

"Guide for the Planning of Preoperational Testing Programs," USAEC, December 7, 197O

"Guide for the Planning of Initial Startup Programs," USAEC, December 7, 197O (revised)

"Standard Format and Content of Safety Analysis Reports for Nuclear Power Plants," Chapter 14, USAEC, October l972, (Revision 1).

Paragraphs 14.1.1.1 and 14.1.1.2 present a detailed description of the preoperational and startup portions of the test program respectively. The suggested discussions of organizational responsibilities and qualifications of personnel participating in the test program are not included in those descriptions, but are presented in Section 14.2 along with a discussion of planned augmentation of the normal plant staff during the testing program.

14.1.1 Administrative Procedures (Testing)

14.1.1.1 Preoperational Test Program

The preoperational testing program ensures that equipment and systems important to safety are performing in accordance with design criteria before the initial core loading. As the installation of individual components and systems is completed, they are tested and evaluated according to pre-determined and approved written instructions. Analyses of test results are made to verify that systems and components are performing satisfactorily and, if not, to provide a basis for recommended corrective action.

The program includes tests, adjustments, calibrations, and systems operations necessary to assure that initial fuel loading, initial criticality, and subsequent power operation can be safely undertaken.

Whenever practicable, these tests are performed under the same conditions as experienced under subsequent station operations. During system tests for which unit parameters are not available and cannot be simulated due to existing plant conditions, the systems are operationally tested as far as practicable without these parameters. The remainder of the tests are performed under plant conditions when the parameters are available. Abnormal unit conditions are simulated during testing when required and when such conditions are practicable and do not endanger personnel or equipment, or contaminate systems whose cleanliness has been established.

In general, preoperational testing is completed prior to core loading. As individual systems are completed, preoperational tests are performed to verify as near as possible, the performance of the system under actual operating conditions. Where required, simulated signals or inputs are used to verify the full operating range of the system and to calibrate and align the systems and instruments at these conditions. Later systems that are used during normal operation are verified and calibrated under actual operating conditions.

Systems that are not used during normal plant operation, but must be in a state of readiness to perform safety functions, are checked under all modes and test conditions prior to plant startup. Examples of these systems are the Reactor Trip System and Engineered Safety Features System logic, operation checks, and setpoint verifications.

Testing performed during the preoperational test program is outlined in Table 14.1-1 and shown in sequence of performance in Figure 14.1-2. In general, all preoperational testing was completed before fuel loading. In some cases, certain preoperational tests were not completed until after core loading. These include such tests as the complete rod control system, rod position indication, and complete incore movable detector system. These tests are identified in Table 14.1-1. Prior to the performance of hot testing, following core loading, prerequisite cold testing is performed. Examples of these tests are the cold rod drop time measurement tests.

The training program to prepare plant supervisors and operating personnel for the initial testing program and subsequent plant operation is described in Section 13.2.

14.1.1.1.1 Preparation of Test Instructions, Conduct of Tests, and Evaluation of Results

Within the Tennessee Valley Authority, the Division of Nuclear Power (NUC PR) has responsibility for the overall preoperational test program administration. As described in Section

13.1, the Nuclear Production Manager is responsible for coordination of all NUC PR activities affecting operation, engineering, and maintenance in TVA's nuclear power plants. In this capacity, he provides overall guidance to the plant superintendent in the conduct of the test program.

A system of planned and periodic program management audits is provided by the Office of Power quality assurance organization. Additional review of the overall testing and startup programs is provided by the Nuclear Safety Review Board.

The plant superintendent is the onsite NUC PR representative responsible for the overall conduct and coordination of the preoperational test program. He directs the onsite implementation of the program through the preoperational test section supervisor who acts as the test program coordinator. Members of this section are designated as "test director" for specific tests and, in this capacity, are responsible for preparation of the detailed test instructions, conduct of the tests, evaluation of test results, and final documentation of results for each preoperational test so assigned. The qualifications of these personnel are discussed in Section 14.2.

Scoping documents which describe the objectives and acceptance criteria for each test are utilized as the basis for the preparation of detailed test instructions. The scoping documents for tests involving systems and components within the TVA scope of supply are prepared by the Division of Engineering Design (EN DES). Tests on equipment within the Westinghouse scope are similarly described in documentation provided by Westinghouse, which is reviewed and revised by EN DES and issued as scoping documents.

Detailed test instructions in draft form are prepared by the designated test directors. Each instruction is written in sufficient detail to ensure that the test demonstrates that the system and components perform in accordance with the requirements contained in applicable design documents; that specified acceptance criteria are satisfied; that the system operates in all required modes; and that deficiencies are identified, evaluated, and corrected. Normal station operating instructions are utilized in the test instructions where possible to provide a thorough check of the operating instructions.

The test instructions, in draft form, are reviewed by the NUC PR plant staff, EN DES, the Division of Construction (CONST), in some instances by the Division of Occupational Health and Safety (OC H&S), and by Westinghouse. Upon completion of the review phase, a final draft of the test instruction is submitted to the Plant Operations Review Committee (PORC). The organization of the PORC is described in Section 6.0 of plant technical specifications. The PORC recommends approval or disapproval of the instruction to the plant superintendent. Subsequent major revisions to test instructions are numbered sequentially and undergo the same review and approval as the original instruction. Final drafts of all test instructions were completed approximately six months before the initial core loading.

The test directors follow construction progress on those systems for which they have been assigned responsibility and, when satisfied that all test prerequisites have been completed, recommend conduct of the test. Authorization to conduct a test is given jointly by the TVA construction project manager and the plant superintendent.

Tests are conducted under the direction of the designated test director assisted by test representatives from EN DES, CONST, and Westinghouse as necessary. During performance of

the test, minor changes to the test instruction not involving safety related aspects and not interfering with test objectives or invalidating test results may be made at the direction of the test director. Such changes are documented and reported to the test program coordinator. As previously described, major or significant changes to a test instruction are subject to the same review and approval process as the original instruction.

At the completion of each test, the test director coordinates a field evaluation of the test results. In the event that test results do not satisfy applicable acceptance criteria and the deficiency involves system design, EN DES evaluates the deficiency and specifies the appropriate corrective actions. In the event that test results do not satisfy applicable acceptance criteria and the deficiency involves equipment performance because of improper installation or pretest checkout and does not involve system design, CONST evaluates the deficiency and initiates the appropriate corrective measures.

14.1.1.1.2 Documentation

When it is demonstrated that test results meet the applicable acceptance criteria for a specific test, the test director initiates a data package for final approval. The data package contains the test instruction, a record of all changes to the basic instruction, all test data sheets, a chronological log of the conduct of the test, and a final test summary document.

After appropriate review and final approval by the plant superintendent, the data package is filed for future reference and becomes part of the permanent plant records.

14.1.1.2 Startup Test Program

The startup test program ensures that the plant actually performs in accordance with design requirements.

The program includes the initial core loading and the startup and power ascension tests which take the unit from initial criticality through the 100 percent power condition acceptance test.

The startup test program incorporates several operational and testing phases as follows:

1. Initial Core Loading

2. Postloading Tests

3. Low Power Testing

4. Power Escalation Tests

A general discussion of plant conditions and the activities occurring during each of these testing phases is presented in Subsection 14.1.4. A specific listing of individual tests performed during the startup program is shown in Tables 14.1-2 (unit 1) and 14.1-3 (unit 2) and shown in sequence of performance in Figures 14.1-3 (unit 1) and 14.1-4 (unit 2).

14.1.1.2.1 Preparation of Test Instructions, Conduct of Tests, and Evaluation of Results

The Division of Nuclear Power (NUC PR) is responsible for the overall administration of the startup test program. Within the division, the Nuclear Production Manager is responsible for

coordinating all activities affecting operation, maintenance, and engineering in nuclear plants. In this capacity, he provides overall administrative guidance in the conduct of the startup test program.

The Nuclear Quality Audit and Evaluation Staff provides overall test program review through formal audits of the operational quality assurance program. Technical guidance during conduct of testing is provided by Westinghouse Electric Corporation in their capacity as nuclear steam supply system contractor. Additional assistance from within TVA is provided by the Division of Engineering Design (EN DES), the Division of Construction (CONST), and the Department of Occupational Health and Safety (OC H&S) as necessary. Direct plant assistance is also provided to the operating staff from within NUC PR by the Electrical and Instrument and Controls Branch, Mechanical Branch, Reactor Engineering Branch, and other TVA nuclear plants as described in Section 14.2.

The plant superintendent directs the onsite implementation of the program through the plant engineering supervisor who acts as the startup test program coordinator. The engineering supervisor is responsible for the preparation of detailed test instructions, conduct of the tests, evaluation of test results, documentation of results, and final disposition of test records.

Detailed test instructions in draft form are prepared by NUC PR engineers based on guideline-type documentation provided by Westinghouse. Each test instruction is written in sufficient detail to ensure that the specific objectives of the test are identified and that all testing steps necessary to accomplish the objectives are stated; that acceptance criteria are specified; and that any deficiencies are identified, evaluated, and corrected.

Review of each draft instruction is performed, within NUC PR, by the plant staff and the Nuclear Production Manager. Additional review of the draft instructions is provided on a selective basis, by the Division of Engineering Design. The test program coordinator ensures that all comments from reviewers are resolved and then submits a final draft of the test instruction to the Plant Operations Review Committee (PORC). The PORC reviews the individual instructions and recommends approval only after it is satisfied that the safety of plant personnel and equipment are not jeopardized during conduct of the test. Final approval of test instructions for use is given by the plant superintendent.

Tests are conducted under the technical direction of the test program coordinator with assistance from TVA support organizations and from Westinghouse as necessary. Tests that result or may result in reactivity changes are performed only with the knowledge and consent of an operator or senior operator licensed pursuant to 10 CFR 55. During testing, field changes may be made to the test instruction as prescribed by plant administrative procedures. Field changes are limited to those changes which do not change the intent of the test. Major revisions to an instruction involving either safety-related aspects or changes in the intent of the instruction are subject to the same review and approval process as the original instruction.

The startup test program is structured in such a manner as to establish acceptance criteria at each test plateau which must be met before proceeding to the next test plateau. For this purpose, test plateaus are fuel loading, initial criticality, low power physics testing, and testing performed at 30, 50, 75, 90, and 100 percent power. If deficiencies in plant performance are

noted during testing, the PORC reviews and resolves the deficiencies as described in Subsection 14.1.2. Copies of all test data and analyses are distributed to Westinghouse and reviewed within TVA by NUC PR and, on a selective basis, by EN DES.

14.1.1.2.2 Documentation

Upon final approval and acceptance of test results, the original records of all test data, a chronological log of the conduct of the test, and a final test summary are filed for future reference and become part of the permanent plant records.

14.1.2 Administrative Procedures (Modifications)

Deficiencies in either a critical system's design or performance, the methods of conducting a test, or station operating instructions which become apparent as a result of the preoperational test program are documented and handled as described below, depending on the particular type of deficiency which is involved. Similarly, deficiencies which become apparent as a result of the startup test program are documented and submitted to the Plant Operations Review Committee (PORC) which reviews each such deficiency report and recommends appropriate corrective actions to the plant superintendent.

If the deficiency is in either the test instruction or an operating instruction utilized during testing, the applicable section of the instruction is revised and appropriately reviewed. All such revisions which affect testing are documented, reviewed by the PORC, and approved by the plant superintendent before plant use. Except that minor changes to testing instructions may be made as described in subparagraphs 14.1.1.1 and 14.1.1.2.1.

If the deficiency is in equipment performance because of improper installation or checkout and does not involve a change in design, the site construction organization corrects the deficiency. The corrective action is documented and testing resumed.

In the event that modifications to system hardware are necessary to meet the test objectives or improve system performance, the Division of Engineering Design (EN DES) specifies the appropriate corrective actions to be taken. Such modifications are subject to the same design review and construction quality assurance as the original system design described in the TVA Nuclear Quality Assurance Plan. The test program coordinator initiates any changes necessary in the test instruction and retests affected systems as necessary.

Administrative procedures prescribe the documentation required for all temporary changes in plant design made to facilitate conduct of the tests. Such controls ensure that temporary modifications are restored to the normal operating condition upon completion of the testing program.

14.1.3 Test Objectives and Procedures

A brief discussion of the preoperational and startup test programs is presented below:

14.1.3.1 Preoperational Test Program

A listing of planned preoperational tests is shown in Table 14.1-1. The listing includes the title of each test to be performed; a general listing of test prerequisites such as plant conditions,

etc.; and a brief discussion of the test objectives with an overall summary of how the test is conducted to achieve these objectives. The tests described in Table 14.1-1 are generally applicable to the test program for each reactor unit. However, for those auxiliary support systems which are common to each unit (e.g., essential raw cooling water system, emergency gas treatment system, etc.), the applicable test summary describes only the total system functional testing to be performed and does not specify individually the testing which is performed as part of each reactor unit's test program. Generally, a system such as an auxiliary cooling water system is tested as follows: Major components such as pumps and main header valves are tested and main header flows verified as part of the Unit 1 test program. Verification of branch flows to equipment associated with a specific reactor unit and automatic response of system components to actuation signals originating from a specific reactor unit are included in that unit's test program. Testing of other types of common systems are conducted in a similar manner.

Acceptance standards for specific tests are based on the functional requirements for the applicable component or system as discussed elsewhere in the Final Safety Analysis Report. A detailed listing of the acceptance criteria for each test is contained in the final test instruction to facilitate rapid field evaluation of the test results.

Where special consideration must be given to testing system or component response under specific environmental conditions, it is discussed in the summary of testing included in Table 14.1-1. Whenever practicable, tests are performed under the same conditions as experienced during subsequent plant operations. Abnormal conditions are simulated when required and practicable and when such conditions do not endanger personnel and equipment or contaminate systems whose cleanliness has been established.

The scope of testing includes the analysis of system and component interactions where possible considering plant conditions at the time of testing. This is primarily accomplished during the hot functional testing phase of the program.

14.1.3.2 Startup Test Program

A listing of planned startup tests is shown in Tables 14.1-2 (unit 1) and 14.1-3 (unit 2). The listing includes the title of each test to be performed; a general listing of plant prerequisites such as plant conditions, etc., and a brief discussion of test objectives along with an overall summary of how the test is conducted to achieve these objectives.

Acceptance standards for specific tests are based on the functional requirements for the plant as discussed elsewhere in the Final Safety Analysis Report. Applicable standards against which the nuclear core performance characteristics are evaluated are derived from the nuclear design manual and the kinetic coefficients assumed in the safety analyses.

A brief description of the various phases of the startup test program and of the testing and operational activities associated with each phase is presented in Subsection 14.1.4.

14.1.4 Fuel Loading and Initial Operation

14.1.4.1 Fuel Loading

Fuel loading begins when all prerequisite preoperational testing has been satisfactorily completed. Upon completion of fuel loading, the reactor upper internals and pressure vessel

head are installed and additional mechanical and electrical tests are performed as discussed in preoperational testing. The purpose of this phase of activities is to prepare the system for nuclear operation and to establish that all design requirements necessary for operation are achieved.

The reactor containment structure is completed and the containment integrity established, as discussed in the technical specifications, and maintained during fuel loading.

Fuel handling tools and equipment are checked out and dry runs conducted in the use and operation of equipment.

The reactor vessel and associated components are in a state of readiness to receive fuel. Water level is maintained above the bottom of the nozzles and recirculation maintained to ensure a uniform boron concentration. Boron concentration can be increased via the recirculation system or by addition directly to the open vessel.

The overall process of initial core loading is, in general, directed from the refueling floor of the containment structure. Standard procedures for the control of personnel and the maintenance of containment security are established and implemented prior to fuel loading.

The as-loaded core configuration is specified as part of the core design studies conducted well in advance of station startup and as such is not subject to change at startup. In the event mechanical damage is sustained during core loading operations to a fuel assembly of a type for which no spare is available onsite, an alternate core loading scheme whose characteristics closely approximate those of the initially prescribed pattern will be determined by Westinghouse and TVA.

The core is assembled in the reactor vessel and submerged in reactor grade water containing adequate dissolved boric acid to maintain a calculated core effective multiplication factor of 0.95 or lower. The refueling cavity is dry during initial core loading. Core moderator chemistry conditions (particularly, boron concentration) are prescribed in the core loading instruction document and are verified periodically by chemical analysis of moderator samples taken prior to and during core loading operations.

Core loading instrumentation consists of two permanently installed source range (pulse type) nuclear channels and two temporary incore source range channels plus a third temporary channel which can be used as a spare. The permanent channels when responding are monitored in the main control room by licensed station operators; the temporary channels are installed in the containment structure and are monitored by reactor engineering personnel and licensed station operators. At least one permanent channel is equipped with an audible count rate indicator. Both plant channels have the capability of displaying the neutron flux level on a strip chart recorder. The temporary channels indicate on-rate meters with a minimum of 1 channel recorded on a strip chart recorder. Response checks on each of the above source range channels to a source of neutrons are conducted within eight hours prior to initial loading or resumption of loading if loading is delayed or interrupted for eight hours or more. At all times following installation of the initial nucleus of ten fuel assemblies, a minimum count rate of 1/2 count per second with a signal to noise ratio of greater than two shall be maintained on two of the source range channels.

Fuel assemblies, together with inserted components (control rod assemblies, burnable poison inserts, source spider, or thimble plugging devices) are placed in the reactor vessel one at a time according to a previously established and approved sequence. The core loading documents include detailed tabular check sheets which prescribe and verify the successive movements of each fuel assembly and its specified inserts from its initial position in the storage racks to its final position in the core. Multiple checks are made of component serial numbers and types at successive transfer points to guard against possible inadvertent exchanges or substitutions of components. Fuel assembly status boards are maintained throughout the core loading operation.

An initial nucleus of ten fuel assemblies, the second of which contains an activated neutron source, is the minimum source-fuel nucleus which permits subsequent meaningful inverse count rate monitoring. This initial nucleus is determined by calculation. Previous experience indicates that this nucleus is markedly subcritical ($k_{eff} \leq 0.95$) under the required conditions of loading. Each subsequent fuel addition is accompanied by detailed neutron count rate monitoring to determine that the just loaded fuel assembly does not excessively increase the count rate and that the extrapolated inverse count rate ratio is not decreasing for unexplained reasons. The results of each loading step are evaluated before the next prescribed step is started.

Criteria for safe loading require that loading operations stop immediately if:

1. An unanticipated increase in the neutron count rates by a factor of 2 occurs on all responding nuclear channels during any single loading step after the initial nucleus of 10 fuel assemblies are loaded (excluding anticipated change due to detector and/or source movement).

2. The neutron count rate on any individual nuclear channel increases by a factor of five during any single loading step after the initial nucleus of 10 fuel assemblies are loaded (excluding anticipated changes due to detector and/or source movements).

Alarms in the containment and main control room are coupled to the source range channels with a setpoint at no more than two times the current count rate. This alarm automatically alerts the loading operation personnel of high count rate and requires an immediate stop of all operations until the situation is evaluated. Normally the alarm used for this purpose is the containment evacuation alarm. In the event the evacuation alarm is actuated during core loading and after it has been determined that no hazards to personnel exist, preselected personnel are permitted to reenter the containment vessel to evaluate the cause and determine future action.

Core loading instructions specify the condition of fluid systems to prevent inadvertent dilution of the reactor coolant, specify the movement of fuel to preclude the possibility of mechanical damage, prescribe the conditions under which loading can proceed, designate responsibility and authority and provide for continuous and complete fuel and core component accountability.

14.1.4.2 <u>Postloading Tests</u>

Upon completion of core loading, the reactor upper internals and the pressure vessel head are installed and additional mechanical and electrical tests as discussed in preoperational testing program, are performed prior to initial criticality. The final pressure test is conducted after filling and venting is completed to check the integrity of the vessel head installation.

Mechanical and electrical tests are performed on the control rod drive mechanisms. These tests include a complete operational checkout of the mechanisms and calibration of the individual rod position indication.

Tests are performed on the reactor trip circuits to test manual trip operation. The actual control rod assembly drop times are measured for each control rod assembly. The Reactor Control and Protection Systems are checked with simulated signals to produce a trip signal for the various conditions that require plant trip.

At all times that the control rod drive mechanisms are being tested, the boron concentration in the coolant-moderator is maintained such that criticality cannot be achieved with all control rod assemblies out.

A complete functional electrical and mechanical check is made of the incore nuclear flux mapping system at the operating temperature and pressure. After final precritical tests, nuclear operation of the reactor begins. This final phase of startup and testing includes initial criticality, low power testing, and power level escalation. The purpose of these tests is to establish the operational characteristics of the unit and core, to acquire data for the proper calibration of setpoints, and to ensure that operation is within license requirements. A brief description of the testing is presented in the following sections. Table 14.1-2 (unit 1) and Table 14.1-3 (unit 2) summarize the tests which are performed from initial core loading to rated power and Figure 14.1-3 (unit 1) and 14.1-4 (unit 2) shows the sequence in which these tests are performed.

Initial criticality is established by sequentially withdrawing the shutdown and control groups of control rod assemblies from the core, leaving the last withdrawn control group inserted far enough in the core to provide effective control when criticality is achieved, and then continuously diluting the heavily borated reactor coolant until the criticality is achieved.

Successive stages of control rod assembly group withdrawal and of boron concentration reduction are monitored by observing changes in neutron count rate as indicated by the normal plant source range nuclear instrumentation as functions of group position during rod motion and, subsequently, of reactor coolant boron concentration and primary water addition to the Reactor Coolant System during dilution. Throughout this period, samples of the primary coolant are obtained and analyzed for boron concentration.

Inverse count rate ratio monitoring is used as an indication of the proximity and rate of approach to criticality of the core during control rod assembly group withdrawal and during reactor coolant boron dilution. The rate of approach is reduced as the reactor approaches the point extrapolated for criticality to ensure that effective control is maintained at all times. Written procedures specify the plant conditions, precautions, and specific instructions for the approach to criticality.

14.1.4.3 Low Power Testing

A prescribed program of reactor physics measurements is undertaken to verify that the basic static and kinetic characteristics of the core are as expected and that the values of the kinetic coefficients assumed in the safeguards analysis are indeed conservative.

The measurements are made at low power and primarily at or near operating temperature and pressure. Measurements, to include verification of calculated values of control rod assembly group reactivity worths, of isothermal temperature coefficient under various core conditions, of

differential boron concentration reactivity worth and of critical boron concentrations as functions of control assembly group configuration are made. In addition, measurements of the relative power distributions are made. Concurrent tests are conducted on the instrumentation including the source and intermediate range nuclear channels.

Instructions are prepared to specify the sequence of tests and measurements to be conducted and the conditions under which each is to be performed to ensure both safety of operation and the relevancy and consistency of the results obtained. If significant deviations from design predictions exist, unacceptable behavior is revealed, or apparent anomalies develop, the testing is suspended and the situation reviewed to determine whether a question of safety is involved, prior to resumption of testing.

14.1.4.4 Power Level Escalation

When the operating characteristics of the reactor and unit are verified by the low power testing, a program of power level escalation in successive stages brings the unit to its full rated power level. Both reactor and unit operational characteristics are closely examined at each stage and the conformance with the safeguards analysis verified before escalation to the next programmed level is effected.

Measurements are made to determine the relative power distribution in the core as functions of power level and control assembly group position.

Secondary system heat balances ensure that the indications of power level are consistent and provide bases for calibration of the power range nuclear channels. The ability of the Reactor Coolant System to respond effectively to signals from primary and secondary instrumentation under a variety of conditions encountered in normal operations is verified. At prescribed power levels the dynamic response characteristics of the reactor coolant and steam systems are evaluated. The responses of the systems are measured for design step load changes of + 10 percent, rapid 50 percent load reductions and plant trips.

Adequacy of radiation shielding is verified by gamma and neutron radiation surveys at selected points inside the containment and throughout the station site at various power levels. Periodic sampling is performed to verify the chemical and radio-chemical analysis of the reactor coolant.

Testing performed following core loading and during plant startup is outlined in Tables 14.1-2 (unit 1) and 14.1-3 (unit 2). All precritical tests shall be completed prior to initial criticality and the results evaluated. Prerequisites for performing a test are specified in the individual test instruction. The sequence of testing is outlined in a start-up test sequence, such that required prerequisite testing is completed before performing subsequent testing. Any special test instruments required are specified to be installed, calibrated, and checked in the test instruction that specifies the test equipment. Where these test instruments are not left installed for future use, they are removed from the systems and removal is verified. The sequence of testing following core loading is shown by Figures 14.1-3 (unit 1) and 14.1-4 (unit 2).

14.1.5 Administrative Procedures (System Operation)

Systems operations during the initial testing program are performed by NUC PR plant personnel. As discussed in Section 13.5, instructions for integrated plant operations, systems operation, and equipment operation are prepared in those instances where written instructions are required

to ensure safety and reliability. Whenever possible, the detailed instructions for conduct of a particular test utilize the applicable station operating instruction to demonstrate the station instructions. Those tests which require special operating conditions are accomplished using detailed test instructions which prescribe any off-normal operational sequences required for conduct of the tests.

Revisions to station operating instructions resulting from deficiencies discovered during the testing program are accomplished as described in Subsection 14.1.2.

14.1.6 Special Test Program

This section is included for historical purposes only. It indicates the steps taken to comply with the TMI Task Action Plan statement that "applicants for operating licenses will perform a set of low-power tests to increase the capability of shift crews and ensure training in plant evaluation and off-normal events."

The special low-power test program was conducted at Sequoyah Unit 1 starting July 21, 1980. NRC staff representatives, including the Sequoyah resident inspectors, were present to observe these tests. At least one NRC representative was present during the first run of each of the 10 tests, identified as follows:

1. Natural circulation test
2. Natural circulation test with simulated loss of offsite power
3. Natural circulation test with loss of pressurizer heaters
4. Effect of steam generator secondary side isolation on natural circulation
5. Natural circulation at reduced pressure
6. Cooldown capability of the charging and letdown system
7. Simulated loss of all onsite and offsite A.C. power
8. Establishment of natural circulation from stagnant conditions

9A. Forced circulation cooldown

9B. Boron mixing and cooldown

Test 6, 8, and 9A were each conducted only once. All other tests were repeated on each shift so that each operating crew gained "hands-on" experience for each test. Not repeating tests 6, 8, and 9A was acceptable to the staff because they have little training value.

The Special Test Program will not be conducted at Sequoyah Unit 2. The unit 2 personnel will receive their special test training on the Sequoyah simulator at the Power Operations Training Center.

TABLE 14.1-1 (Sheet 1)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
W-1.1	Pressurizer Relief Tank	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing activities of all associated equip-associated equipment have been completed. Electrical power and control air are available to all components requiring Instrumentation and alarms are available for service. The Waste Disposal System is in service and available for processing liquid and gaseous effluents from the Pressurizer Relief Tank (PRT). The Primary Makeup Water Tank is available to provide water to the PRT. The Sampling and Water Quality System is available to vent the PRT. The Reactor Coolant System is to remain depressurized during the test.	The test verifies the appropriate flow rates and the indicating and control capabilities of the PRT services. The vent header valve will be tested for automatic actuation and the valve position indicator lights checked for proper operation. Liquid level and gas pressure alarm setpoints and cooling spray slow rate will be checked. Capabilities of the nitrogen pressure regulators to maintain blanket gas pressure and downstream pressure to the gas analyzer will be demonstrated. Acceptance criteria for the PRT will be that the requirements given in FSAR section 5.5.11 have been satisfied.
W-1.2A	Reactor Coolant System Functional	The prerequisites for this test is the availability of the RCS for functional testing.	The test will address initial operability of RCS components and instrumentation and will be performed prior to initial RCS heatup. The objective is to perform control and logic verification of those portions of the RCS which have not been addressed in other tests. The test will address: A. All manual and automatic logic associated with the reactor coolant pumps, the RCP oil lift pumps, RCS valves (pressurizer relief, pressurizer block, pressurizer spray, and reactor vessel flange

TABLE 14.1-1 (Sheet 2)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
			leakoff valves), and the pressurizer backup and control heater breakers. The test will verify breaker operation, valve travel, unit switch operation, lights at handswitches, alarms, etc.; B. Instrumentation loop checks, of RCS pressure, level, temperature loops, and RCS overpressure mitigating system, and steam generator narrow range level loops using simulated conditions (note that each instrument loop will be tested by inducing test signals downstream of the primary transmitter, varying the signal over the range of the instrument, and verifying that all interlocks, alarms, annunciators, and bistables associated with that loop operate at the proper current; the primary transmitters are not tested here but are addressed in W-1.3; and C. Proper operation of pressurizer heater breaker and RCP breaker protection circuitry and their associated alarms (e.g., overcurrent, undercurrent, undervoltage, under-frequency, etc., as applicable). Acceptable criteria for these tests will be determined from the specific logic and current scaling calculations associ-ated with each component or

TABLE 14.1-1 (Sheet 3)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
			instrument loop. All items must operate in accordance with the design logic from both the main control room and auxiliary (remote) control locations.
W-1.2B	Reactor Coolant System Heatup	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing activities of all associated equipment have been completed. Pressurizer relief tank tests have been completed. Reactor Coolant System (RCS) hydrotest has been completed and reactor vessel full flow filters have been installed. Operational systems required are: Waste Disposal Primary Makeup Water, Component Cooling, Essential Raw-cooling Water, Chemical and Volume Control, Sampling, Secondary Plant (to the point receiving and dumping steam), and Auxiliary Feedwater System. The RCS and pressurizer heaters are operable to maintain RCS temperature and pressure within design limitations. The diesel-generator units are operable in a stand-by mode and alternate offsite power is available. Instrumentation and control systems have been calibrated and are operational. The RCS has been filled and vented.	The Reactor Coolant System (RCS) will be heated to normal operating temperature and pressure using RC pump heat. The pressurizer will initially be filled with water (water solid), with system letdown controlled by the Residual Heat Removal (RHR) system to the Chemical and Volume Control System (CVCS). The ability to control RCS pressure during water solid operation will be verified prior to initiating RCS heatup. Control of water chemistry and flow to RC pump seals will be demonstrated. Measurement of RCS piping and component thermal expansion and pump vibration will be taken at 100 F temperature increments during heatup. The pressurizer steam bubble will be formed as soon as practical following completion of solid system pressure control testing and the steam generator levels then lowered to the normal no-load operating level. Operability of the pressurizer heaters and spray valves will be demonstrated. The normal letdown flow path will be demonstrated. Upon establishment of normal letdown flow path and RCS temperature reaching approximately 350°F, the RHR system will be removed from service. At this time, either the steam generator

TABLE 14.1-1 (Sheet 4)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
			atmospheric dump valves or the condenser dump valves will be placed in service to control secondary side pressure. The anti-reverse-rotation device will be checked on each RC pump and all reactor coolant low-flow alarms and trips verified. Acceptance criteria for this test will be that the RCS functions properly during all phases of plant operation.
W-1.3	RCS at Temperature	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing activities of all associated equipment have been completed. All systems required to support testing and operation have either been preoperationally tested or cleared under an IOR. Instrumentation has been checked, tested, and calibrated.	Test objective is to perform all of the functional checks on RCS components and instrumentation required during plant operation at design temperature and pressure. Automatic operation of the pressurizer pressure and level control systems and associated instrumentation will be checked. Setpoints and operability will be verified for pressurizer pressure and level actuation signals for both reactor trip and SIS actuation signals and for related annunciation and alarms. Interlocks associated with automatic reset of manual block of SIS actuation signal and with power operated relief valves will be functionally tested. Operation and response time of the pressurizer relief valves and temperature increase in the pressurizer relief tank will be recorded. Operation of the SG atmospheric dump valves and level control system will be demonstrated. Settings of the pressurizer and main steam safety valves will be checked and adjusted and the cross calibration of the incore

TABLE 14.1-1 (Sheet 5)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
			thermocouples and RTD's will be completed. The capability of maintaining the RCS at the hot shutdown condition from the auxiliary control room will be demonstrated. The RCS 240-hour full flow run will be completed. Acceptance criteria for this test shall be that the requirements given in the applicable portions of FSAR sections 7.2 and 7.3 have been satisfied.
W-1.4	RCS Cooldown	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing activities of all associated equipment have been completed. Instrumentation has been checked, tested, and calibrated. All primary water storage contains adequate water to accommodate RCS contraction to cooldown. The PRT, its services systems and the RHR System are fully operable. RCS at temperature testing is completed. The prerequisites for W-1.3 are also applicable to this test.	This test verifies the proper operation of all systems and instrumentation required for cooldown of the RCS from the hot standby condition to the depressurized condition of 140°F. At least one reactor coolant pump will be maintained in operation. Temperature drop limitations will be observed. When the RCS pressure is below 450 psig and the temperature below 350°F, the RHR system will be initiated for cooling in addition to steam dump. Steam stop valves are closed when condenser vacuum can no longer be maintained. RHR cooling continues with steam generator wet layout at 210°F until temperature reaches 150°F when the remaining RC pump is stopped. Cooling continues to 140°F and 50 psig, and the system is drained to the refueling level. Tests results will be considered acceptable if a controlled smooth cooldown can be accomplished.
W-1.5	*Pressurizer Spray Verification	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and	The test demonstrates the capability of the pressurizer heaters and spray. Specifically the test includes:

TABLE 14.1-1 (Sheet 6)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		required installation inspections, integrity testing, and cleaning and flushing activities have been completed. Preoperational test on the Reactor Coolant System heatup and cooldown have been successfully completed and is in hot standby conditions with no load temperature and pressure. The reactor core has been installed. The primary coolant has been borated to refueling concentration and the reactor coolant pumps are in operation. The pressurizer level is at the no load programmed level and the level controlled is in automatic. The test equipment has been calibrated and is ready for use.	1) To establish the proper pressurizer continuous spray bypass flow rate; 2) To verify the normal pressurizer spray effectiveness, and 3) To verify the pressurizer heater effectiveness. The bypass flow rate is established so that: 1) The spray line temperature is never more than 200°F cooler than pressurizer water, and 2) The line temperature is high enough to prevent actuation of the line low-temperature alarm. The bypass valves are adjusted open with temperature data taken at 10 minute intervals until the minimum bypass flow is determined. The pressurizer spray effectiveness test consists of a transient initiated by full spray to reduce pressurizer pressure to 2000 psig during which data is continuously recorded. The heater effectiveness test is a similar transient with the spray valves manually closed and the heaters fully energized to increase the pressure to 2300 psig. The tolerance on the response times is verified to be within specified limits. Acceptance criteria will be that the requirements given in FSAR section 5.5.10 have been satisfied by the pressurizer spray.

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
W-1.6	*RCS Flow Measurement	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing activities of all associated equipment have been completed. The RCS must be in the hot shutdown mode with the reactor core in place. All RC pumps must be operable. All instrumentation has been calibrated and is available. All associated equipment is available for service.	Test objective is to obtain data for calculation of the full flow reactor coolant flow rate as derived from the reactor coolant pump power. Each of the four RCS loops will be specially instrumented and data will be taken with each pump running alone and in combination with one, two, and all three of the other pumps. Acceptance Criteria is that the data obtained must meet the functional design requirements specified in FSAR Section 5.1.
W-1.7	RCS Thermal Expansion	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing activities of all equipment associated with the RCS have been completed. Instrumentation and recorders have been tested and calibrated, and are available for service.	Test objective is to measure the movement of the RCS piping and components due to thermal expansion to verify that no interferences occur, and to determine whether all components return to their original positions on cooling. Measurements are made at ambient temperature, at 100°F intervals up to 547°F, and after cooldown in coordination with other hot functional tests. All piping will be observed for possible unanticipated interferences. Acceptance criteria for this test will be that the cold and hot positions for the RCS piping are within specified tolerances and there are no observed interferences or obstructions during RCS heatup and cooldown.
W-1.8	*Reactor Coolant Flow Coastdown	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing and	Test objectives are to measure the rate at which reactor coolant flow rate changes subsequent to various reactor coolant pump trips, and to measure various delay times associated

TABLE 14.1-1 (Sheet 8)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		cleaning and flushing activities of all associated equipment have been completed. Initial core loading has been completed and reactor plant is at hot shutdown conditions with all control rod assemblies at bottom position. All RCS pumps are operating. System pressure is being maintained in normal control band. Pressure damping devices, installed in elbow tap d/p cell sensing lines for the RCS flow measurement test, have been removed. Special test instruments have been calibrated and are available for use.	with the loss of flow accident. Measurements are made by tripping reactor coolant pumps from various operating configurations and recording coolant loops d/p, coolant pump breaker position, low-flow trip relays output, rod position indication and reactor trip breaker position. Acceptance criteria for this test shall be that the time delays associated with reactor trip from low flow and under voltage conditions are less then the maximum acceptable values and the core flow falls more slowly than values given in FSAR Section 15.2.
W-1.9	*RTD Bypass Flow Verification	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing activities of all associated equipment have been completed. The plant is in the hot shutdown condition. Insulation has not been installed on the bypass loop piping or on the RCS piping in the vicinity of the RTD loop connections. Instrumentation has been tested and calibrated.	Test objective is to determine by calculation, the flow rates required in the hot and cold leg bypass lines to provide adequate liquid transport times, to determine flow rates, and to verify the low-flow alarm setpoints for the four RTD systems. The actual flow rates for each manifold and each hot and cold leg alone will be measured at normal operating pressure. The low-flow alarm setpoints will be checked by partially closing one manifold isolation valve. Alarm actuation should occur at 90 percent ±2 percent of normal flow. Any significant anomalies will be corrected after comparing data for all four loops. Acceptance criteria for this test shall be that the aforementioned objectives have been successfully met.

TABLE 14.1-1 (Sheet 9)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
W-1.11	RCS Post Hot Functional Inspection, Cleaning, and Testing	The tentative transfer of all the affected equipment CONST to P PROD has been completed. Installation and required installation inspections and integrity testing have been completed. Preoperational testing on RCS heatup, cool-down, and at temperature have been completed. Equipment for high velocity flushing of the reactor internals and draining of the vessel is available. Final cleaning of the contain-ment operating floor, polar and manipulator and crane surfaces, refueling cavity, and areas above the operating floor have been completed. Internals andhead stands have been cleaned and are ready to accept equipment.	Test objectives are to ensure that: 1) The RCS, including the reactor vessel internals and other components, are properly cleaned after hot functional testing, 2) The RCS is maintained in a state of cleanliness appropriate to nuclear service, and 3) The baseline inservice inspections are complete and acceptable prior to fuel loading. The RCS will be drained and the head, upper internals, and core barrel removed to their storage places. All internal clad sur-faces will be inspected and surfaces will be flushed with high-purity water. Any residue will be analyzed. All components will be inspected and reassembled and the vessel will be filled and ultrasonically tested. Performance of all other examinations required to provide preservice inspection baseline data will be accomplished. All prerequisites outlined in the initial core loading procedure will be verified. Acceptance criteria for this test will be that the RCS and vessel internals and components met the cleanliness criteria and that RCS integrity has been verified.
W-2.1A	Spent Fuel Pit Leak Test	The tentative transfer of all the affected equipment from CONST to P PROD has been com-pleted. Installation of all	Test objectives are to verify the leak-tightness of the spent fuel storage pit, transfer canal, cask loading area,

TABLE 14.1-1 (Sheet 10)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		components and equipment associated with this system has been completed in accordance with design specifications. All systems required to support Spent Fuel Pit Cooling system operation have either been preoperationally tested or cleared under an IOR for operation. Temporary means of draining the spent fuel pit, cask loading area, and transfer canal will be available. Means will be available for transferring demineralized quality water to the spent fuel pit, cask loading area, and transfer canal. Control quality air with connections to the transfer canal gate seal and the cask loading area gate will be available. The transfer canal gate seal and the cask loading area gate seal relief valves will have had their setpoints properly verified. The transfer tube blank flanges will be bolted in place.	transfer canal gate, and the cask loading area gate. Acceptance criteria for this test will be that leaktightness of the pit, canal and gates is verified.
W-2.1B	Spent Fuel Pit Cooling System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation of all components and equipment associated with this system has been completed in accordance with design specifications. All systems required to support the Spent Fuel Pit (SFP) Cooling system operation have either been preoperationally tested or cleared under an IOR for operation. Hydrostatic testing on all required piping and components has been completed. An adequate quantity of makeup water is available. Transfer canal gate and fuel cask loading pit gate are	The test objectives and criteria are: 1) To verify all alarm setpoints and to determine the valves, instrumentation, and controls function properly (the SFP will be filled from the RWST), 2) To verify operation of the skimmer loop, 3) To demonstrate filling and emptying of the SFP, transfer canal, and fuel-cask loading pit, 4) To verify circulation through the SFP demineerali-

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		operational and open. Instrumentation and alarms have been checked, tested, and calibrated.	zers and heat exchanger loops using the SFP cooling pumps, 5) To verify recirculation and purification of refueling water in the refueling water storage tank (RWST). 6) To demonstrate drainage of the transfer canal to the Chemical and Volume Control System holdup tanks and refilling, and 7) To verify that heat exchangers and pumps meet vibrational requirements. Acceptance criteria will be that the SFPC system satisfy the requirements given in FSAR section 9.1.3.
W-2.1C	Spent Fuel Pit Cooling System (Open Core Cooling)	The tentative transfer of all the affected equipment from CONST to P PROD has beem completed. Installation of all components and equipment associated with this system has been completed in accordance with design specifications. All systems required to support the Spent Fuel Pit Cooling system operation have either been preoperationally tested or cleared under an IOR for operation. The cross-tie from the SFP spool pieces to the Residual Heat Removal heat exchanger has been installed. Pressure, temperature, water level, and flow indicators have been calibrated.	The test objectives are: 1) To verify the leak tightness of the Reactor Refueling Cavity, 2) To verify the ability to align the Spent Fuel Pit Pumps to the Residual Heat Removal (RHR) System for open core cooling in an allowable time frame, 3) To verify the ability of the Spent Fuel Pit pumps to deliver adequate flow to the RCS cold leg injection line through RHR, 4) To verify recirculation and purification of refueling water in the Reactor Refueling Cavity, and

TABLE 14.1-1 (Sheet 12)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
			5) To verify the ability to drain the Reactor Refueling Cavity. Acceptance criteria for this test will be that the SFPC system satisfy the requirements given in FSAR section 9.1.3.
W-2.2	Residual Heat Removal System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections and cleaning activities have been completed in accordance with design specifications. All systems required to support operation and testing of the RHR system have either been preoperationally tested or cleared under an IOR. Electrical power supplies have been energized and all associated equipment is available for service. Instrumentation and alarms have been checked, tested, and calibrated. The RCS and auxiliary systems flushing and hydrostatic tests have been completed. The RCS is filled and vented and is at ambient temperature, with pressure less than 425 psig. The RHR System is filled and vented and all instrumentation and controls are operable. The CCS and ERCWS are also operable to supply cooling water.	The test objective is to verify the system capability of removing heat from the RCS. Secondary functions of refueling water transfer and pressure control during cooldown will be tested. Temperature and flow rate data will supply heat loads versus time for demonstration of RHR heat exchanger capability. Various valve interlocks will be tested at design conditions to verify proper operation of the system in the recirculation mode, RCS heatup and cooldown with letdown through the RHR system, and the refueling water transfer function. Acceptance criteria for the RHR system will be that the requirements given in FSAR section 5.5.7 have been satisfied.
W-3.1	Boron Recycle System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing activities have been completed. Control quality air and electrical power are available to all	The test objective is to verify the proper functioning of components of the Boron Recycle System. Using demineralized water, the tank level alarms and recirculation pump flow rate will be checked. The flow path for recirculation from the holdup tanks through the different components will be tested

TABLE 14.1-1 (Sheet 13)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		components requiring such. Instruments and controls have been checked and calibrated. Filter cartridges have been installed. Holdup tank A has been been filled to just below the high-level alarm setpoint. The following systems will be in service as required for conducting this test: 1) Primary Makeup Water System 2) WDS Gas Handling System 3) Auxiliary Boiler System 4) Component Cooling Water	for pump discharge pressure and flow rates. Distillate efflu- will be discharged to the moni- tor tank and then pumped through the various lines to the RWST, holdup tank, or to the demineralizers. All pump flow rates will be measured and compared to design values. All level alarms will be checked for proper annunciation. Boric acid concentration capability of the evaporator unit will be verified during hot functional testing. The Boron Recycle System is part of the Chemical Volume and Control System, and therefore acceptance criteria for this test will be that the require- ments given in the applicable portions of FSAR section 9.3.4 are satisfied.
W-3.2	Boric Acid System	The tentative transfer of all the affected equipment from CONST to P PROD has been com- pleted. Installation and required installation inspec- tions, integrity testing, and cleaning and flushing activi- ties have been completed. The PrimaryMakeup Water System and the Control Air System have either been preoperationally tested or cleared under an IOR. System hydrotesting has been completed. Instrumentation and controls have been checked and calibrated. Boric acid filters have been installed. Electrical power supplies have been energized. The boric acid system has been filled and vented.	Test objective is to verify and demonstrate the proper function of the equipment for batching, storing, and transferring 12- percent boric acid solution. The batching tank will be fill- ed with demineralized water, and heater capabilities and temperature alarms will be verified. Alternate use of the transfer pumps with each tank and alternate tanks will be demonstrated. The boric acid filter d/p will be measured. All pump discharge pressures and flow rates will be measured and all temperature indications and level alarms will be veri- fied. Capability to recircu- late from each boric acid tank through the boron injection tanks will be verified.

TABLE 14.1-1 (Sheet 14)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
			Demonstration of the alternate makeup and emergency boration flow paths will be performed during hot functional testing. Acceptance criteria for the Boric Acid System will be that the requirements given in FSAR Section 9.3.4, those portions which apply, are satisfied.
W-3.3A	CVCS Functional Test	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation of all equipment associated with this system has been completed. The CVCS components and piping have been hydrostatically tested, cleaned, and flushed. Instrumentation and annunciators have been checked, tested, and calibrated. Control quality air and electrical power are available to all components requiring such. The RCS will be pressurized to the point in RCS cold hydro prior to starting the reactor coolant pump.	This test will provide the pre-functional checkout for components and flowpath verifications of the high pressure side of the CVCS with the RCS under atmospheric pressure. It will provide verification of the control logic for the valves and the instrumentation and alarm setpoints for the letdown systems. The control logic for the valves and recip-charging pump (now deleted) for the Rx Coolant Charging Flow System shall be verified. The operational capability of the charging pumps to deliver seal water to the RC pump will be demonstrated. The control logic for the valves, and instrumentation and alarm set-points for the Seal Water Injection System will be tested and verified. Instrumentation and alarm setpoints and control logic of the Volume Control Tank will be checked. Acceptance criteria for this test will be that the high pressure side of the CVCS satisfy the requirements given in FSAR section 9.3.4.
W-3.3B	CVCS Functional Test	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. The Chemical Volume and Control System (CVCS) com-	The test demonstrates that the CVCS performs as required under all phases of operation. The capacities of letdown paths and the reactor coolant filter d/p

TABLE 14.1-1 (Sheet 15)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		ponents and piping have been cleaned and flushed, and hydrostatically tested. Electrically power and control quality air is available to all components requiring such. The Reactor Coolant System (RCS) is at no-load temperature and pressure. RCS heatup and temperature preoperational tests have beensuccessfully tested. Instrumentation, annunciators, and controls have been checked and calibrated. Reactor coolant filter has been installed. Mixed bed demineralizer, reactor coolant drain tank, boric acid transfer pumps and a PMWS pump are all available for service.	will be measured. Letdown temperature and pressure controller responses will be demonstrated. Proper operation of the excess letdown flow path is verified and the demineralizer is tested for design flow rates and pressure drops. Charging pumps will be tested for capability to deliver varying flow rates. Volume control tank level control, indications and alarm setpoints are checked. Operational calibration and testing of the different modes of dilution and boration will be accomplished. All flow rates of the various subsystems will be measured and verified. Acceptance criteria for this test will be that the CVCS satisfy the design requirements given in the FSAR section 9.3.4.
W-5.1	Liquid Waste Receipt and Storage	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation of all equipment associated with this system has been completed. All components have been cleaned, flushed, and hydrostatically tested. Instrumentation and alarms have been checked, tested, and calibrated. Control Air, Demineralized Water, Nitrogen Supply, and Primary Sampling Systems have either been preoperationally tested or cleared under an IOR. A filter cartridge assembly has been installed in the waste condenser tank filter housing. Primary water and electrical power supplies are available to all components requiring such. The Gaseous Waste Processing Systems has	The test demonstrates the capability of the WDS to receive liquid wastes and to transfer them to storage and/or disposal points. The tanks involved are the reactor coolant drain tank, chemical drain tank, laundry and hot shower drain tank, tritiated drain collector tank, and the sump tank. Each tank and its associated subsystem will be tested for operability including pumps, instrumentation and controls, and alarms. Purging of the tanks and vent header alignment will be done to facilitate proper functioning. Various flow rates will be determined from tank inventory changes over time for a comparison of actual pump performance to manufacturer's data. Automatic starting and stopping of the pumps will be

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		been successfully tested and is in service.	tested and all related interlocks to tank levels will be verified. Acceptance criteria for this test will be that the requirements for liquid waste receipt and storage, given in FSAR section 11.2 will be satisfied.
W-5.2A	Liquid Waste Processing	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing activities have been completed in accordance with design and testing specifications. Instrumentation and alarms are available for service. The Control Air, Demineralized Water, Nitrogen Supply, Primary Sampling, Auxiliary Steam, and Component Cooling Systems which are needed to support operation and testing have either been preoperationally tested or cleared under an IOR. The permanent filter cartridge assemblies have been installed in the waste condensate tank filter housing, cask decontamination collector tank filter housing, and waste evaporator feed filter housing. The preoperational test for liquid waste receipt and storage has been sufficiently completed to support testing of Liquid Waste Processing. Electrical power supplies have been energized. Tanks for the waste disposal system are empty except the tritiated drain collector tank which is filled with demineralized water.	This test will demonstrate the ability of the Liquid Waste Processing System to transfer and concentrate liquid waste. Also demonstrated will be the ability of the liquid waste system to safely discharge processed liquids to the environment or to recycle these liquids. Alarm setpoints and pump controller setpoints for the tritiated drain collector tank, floor drain collector tank, waste condensate tank, and the cask decontamination collector tank will be verified. Adequate flow performance for pumps will be demonstrated. Filters will be checked for capability of passing the required flow rates without developing excessive pressure differentials. Alarms will be tested for proper functioning. The waste evaporator and auxiliary waste evaporator will be checked to verify that design capacity requirements have been met. Acceptance criteria for this test will be that the liquid waste processing system satisfy the requirements given in FSAR section 11.2 (those portions which apply).

TABLE 14.1-1 (Sheet 17)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
W-5.3	Solid Waste Processing	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity tests, and cleaning, and flushing activities have been completed. The Primary Makeup Water System and the Nitrogen Supply System are available for service. Instrumentation and controls are available for are available for service. Control air and electrical power is available to all components requiring such. A sufficient supply of typical compressible solid material and an adequate inventory of resin are available.	Test objective is to demonstrate the capability to transfer radioactive waste material to drums for subsequent removal to a commercial burial site. The heat tracing on the appropriate concentrated lines is checked, drums are moved into place, and the necessary valving arrangement for each filling station will be established and tested utilizing nonradioactive liquid. Effluent paths from the evaporator, the chemical drain tank, and the spent resin storage tank to the filling station will be checked for flow rate veritifcation and automatic dispensing valve operation. The compressible waste operation will be demonstrated by filling drums. All handling components will be fully tested by operation. Acceptance criteria for the solid waste processing system will be that the requirements given in FSAR section 11.5 are satisfied.
W-5.4	Gaseous Waste Processing	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing activities have been completed. The Primary Makeup Water, Control Air, Component Cooling, and Shield Building Ventilation Exhaust Systems have either been preoperationally tested or cleared under an IOR. Electrical power and control air are available to all components requiring such. The CVCS holdup tank and Nitrogen Supply System are available. Instrumentation and alarms	Test objective is to demonstrate that the Gaseous Waste System can safely and reliably store and dispose of the gaseous effluents from the plant and transfer gaseous inventory as needed to other components. The waste gas compressors will be tested for satisfactory operation and capacity for maintaining proper vent heater pressure and transfer of gases to decay tanks. The capacity of the gas decay tanks to supply cover gas for the CVCS holdup tanks will be demonstrated. Contents of the gas decay tanks will be sampled, both automatically and manually, with the gas analyzer, then

TABLE 14.1-1 (Sheet 18)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		have been checked, tested, and calibrated. The desired gas flow rate through the shield shield building exhaust vent has been obtained.	discharged to the shield building. The decay tanks will then be purged by nitrogen from the nitrogen supply header. All gaseous waste system alarms, interlocks, and controls will be verified as well as the efficiency of the HEPA and charcoal filters. Acceptance criteria for the Gaseous Waste Processing System will be satisfied upon verification that the requirements given in FSAR section 11.3 havehave been met.
W-6.1A1	Safety Injection System Integrated Flow Testing	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing of all associated equipment have been completed. The containment spray pumps, centrifugal charging pumps, reciprocating charging pumps*, safety injection pumps, and residual heat removal pumps have been tested. The reactor vessel head and internals have been removed. The refueling seal for the reactor vessel flange has been installed and the water level has been established at the vessel flange. Provisions have been made to remove water from the refueling cavity. The Component Cooling Water, Essential Raw Cooling Water, and Ventilation Systems, which are needed to support testing have been aligned and placed into service.	This test will verify adequate net positive suction head (NPSH) during integrated operation of containment spray (CS), centrifugal charging (CC), reciprocating charging (RC), safety injection (SI), and residual heat removal (RHR) pumps. Adequate NPSH and performance during the recirculation mode will also be verified. Acceptance criteria for this test will be that there will be adequate NPSH during injection and recirculation modes for an integrated pump configuration of the RHR, SI, CC, and CS pumps.

TABLE 14.1-1 (Sheet 19)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
W-6.1A2	Safety Injection System - Integrated Actuation and Alarm Test	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing activi- of all associated equipment have been completed. All systems required to support operation and testing have either been preoperationally tested in various tests and all requirements for their operation and testing shall have been previously met.	This test shall verify to the extent practicable that required components respond in an integrated manner from a safety injection signal. Acceptance criteria for this test will be that the required components respond in an integrated manner.
W-6.1A3	SIS - Integrated Check Valve Flow and Integrity Test	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Preoperational testing of the accumulators, safety injection pumps, centrifugal charging pumps, and residual heat removal pumps has been sufficiently completed to support this test.	The primary SIS and RCS check valves will be tested for verification of opening at RCS temperature. Accumulation and injection primary and secondary check valves will be integrity tested. Acceptance criteria for this test will be that the aforementioned objectives have been successfully met.
W-6.1B	SIS - Accumulators and Related System Performance Test	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing activities of all associated equipment have been completed. The Control Air, Nitrogen Supply, Chemical Volume and Control, Waste Disposal and Safety Injection Systems have either been preoperationally tested or cleared under an IOR. Instrumentation and alarms have been calibrated and are available for service. A means of filling the accumulators from the RWST and drain-	Proper control and operation of the valves required for accumulator filling, draining, charging, blowdown and SIS testing will be verified. The capability to fill each accumulator will be made. Level alarm setpoints and pressure alarm setpoints for each accumulator will be verified. Acceptable accumulator injection characteristics during a low pressure blowdown of each accumulator will be demonstrated. Accumulator valve opening capability under maximum expected differential pressure will be verified.

TABLE 14.1-1 (Sheet 20)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		ing them to the CVCS holdup tand and reactor coolant drain tank is available. The reactor vessel head and all internals have been removed and the vessel is ready to receive water. The refueling seal on the vessel flange has been installed. The refueling cavity has been cleared and readied to receive water. Electrical power supplies have been energized and associated equipment is ready for service.	Acceptance criteria will be that the requirements given in FSAR section 6.3, those portions pertaining, have been satisfied.
W-6.1C	Centrifugal Charging Pump and Related Injection System Performance Test	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing activities of all associated equipment have been completed. Instrumentation and alarms have been checked, tested, and calibrated. All systems required to support operation and testing have either been preoperationally tested or cleared under an IOR. The reactor vessel head and internals have been removed and the vessel is ready to receive water. The refuelding cavity has been cleaned and is available to receive water. The refuelding seal on the reactor vessel flange has been installed and leak tested as required. Electrical power and control air are available to all components requiring such. A means for water removal from the vessel and refueling cavity has been provided. The status monitoring system multiplex cabinets are available so that	Proper control and operation of the valves required for high pressure injection will be verified. Control circuitry for the centrifugal charging pumps will be tested for porper operation. Pump hydraulic, mechanical, and electrical performances under miniflow and cold leg injection conditions will be demonstrated. Pump response time under these same conditions will be determined. Cold leg injection branch line throttle valves will be balanced. Acceptance criteria for this test will be that the requirements for the centrifugal charging pumps given in FSAR section 6.3, those portions applicable, have been satisfied.

TABLE 14.1-1 (Sheet 21)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		contacts from the valve circuits to the terminal strips may be verified. Ventilation for the pump room is available.	
W-6.1D	SIS - Safety Injection Pump and Related Injection System Performance Test	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing activities have been completed. The Control Air, Safety Injection, Component Cooling Water, Essential Raw Cooling Water, and Auxiliary Building ventilation systems have either been preoperationally tested or cleared under an IOR. The RWST and associated piping, valves, and instrumentation have been installed, checked, and tested. The SIS to RCS piping, valves, and instrumentation located inside containment have been installed, checked, and tested. The reactor vessel head and internals have been removed and the refueling seal on the vessel flange has been installed. refueling cavity has been cleaned and a means for water removal from the cavity and vessel has been provided. Electrical power supplies have been energized.	Proper control and operation of the valves required for high-pressure injection by the safety injection pumps will be verified. Control circuitry for the safety injection pumps will be tested for proper operation. Pump hydraulic, mechanical and electrical performance under mini flow and cold leg injection conditions will be demonstrated. Pump response time under these same conditions will be determined. Cold leg injection branch line and hot leg injection conditions will be demonstrated. Acceptance criteria will be that the requirements for the safety injection pumps, given in FSAR section 6.3, those portions applicable, have been satisfied.
W-6.1E	SIS - Residual Heat Removal Pump and Related Injection System Performance Test	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing activities of all associated equipment have been completed. Instrumentation and alarms	Proper control and operation of the valves required for low-pressure injection by the residual heat removal (RHR) pump will be verified. Various other valves used during safety injection will also be verified. Pump hydraulic, mechanical, and electrical performance under cold leg injection condi-

TABLE 14.1-1 (Sheet 22)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		have been checked, tested, and calibrated. The Safety Injection, Component Cooling Water, Essential Raw Cooling Water, Auxiliary Bldg, Ventilation Systems, and the Containment Spray Boundary Valves and Pump Suction have either been preoperationally tested or cleared under an IOR. SIS to RCS piping, valves, and instrumentation located inside containment have been installed, checked, and tested. A means for cooling the RHR pump room is available. The reactor vessel head and internals have been removed and the vessel is ready to accept water. The refueling cavity has been cleaned and a means for water removal from the cavity and vessel has been provided. The refueling seal on the vessel flange has been installed and leak tested. Electrical power supplies have been energized.	tions will be demonstrated. Response time for the RHR pumps will be determined for cold leg injection conditions. The RWST, RWST heaters, and associated functions will be verified. The automatic switchover from injection to recirculation mode is demonstrated to the extent practicable. The function of valve interlocks will be demonstrated. Acceptance criteria for the RHR pump will be that the requirements given in FSAR section 6.3, those portions applicable, have been satisfied.
W-6.1F	Integrated ESF Systems Test	Testing performed prior to fuel loading. The reactor vessel head, upper internals and lower internals have been removed. The reactor vessel and refueling canal are available to receive water. All safety systems cleaned, flushed, and hydro-tested. Safeguard circuitry sequenced and timed for proper actuation. All pumps and valves, actuated by safeguard signals, and diesel generators inspected and prepared for operation. All ESF equipment inspected and prepared for operation under ESF conditions with cooling water supplied as required.	The test objective is to demonstrate proper operation of various systems, subsystems, and equipment (valves, pumps, coolers, and valve interlocks) which are actuated by a Safety Injection signal and phase A and B Containment Isolation signal under normal plant power and blackout conditions. After reset of the signal all required ESF equipment will remain in its proper mode. All ESF equipment will be aligned such that any component receiving a Safety Injecttion or Containment Isolation signal will realign to the proper ESF position. Tests will be run on train A and on train B equip-

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
			ment with normal plant power available and on train A and B equipment under blackout conditions. All equipment will be observed to verify the equipment actuates and remains in the proper mode until after reset of Safety Injection and Containment Isolation signals. ment Isolation signals.
W-6.2	Upper Head Injection	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing of all associated equipment have been completed. Instrumentation and alarms have been checked tested, and calibrated. The CVCS has either been preoperationally tested or cleared upon an IOR. Electrical power and control air are available to all components requiring such. Primary grade water is available for filling the UHI water accumulator. Nitrogen is available for pressurizing the gas accumulators, hydraulic accumulators, and test kit accumulators. Temporary seals for sealing the head injection nozzles and the ject deflector plate are availabe for installation. An adequate supply of hydraulic fluid is available.	Proper operation and interlock function of all Upper Head Injection System (UHIS), Hydraulic Isolation Valves (HIV), test line containment isolation valves, hydraulic valve actuation system, water level trip instruments, and related monitor lights and annunicators will be verified. Verification of the proper water volume delivered to an empty reactor vessel during normal pressure blowdown will be obtained by conducting a low pressure and a high pressure blowdown to the vessel. A demonstration will be conducted of UHIS performance during addition of makeup water or gas, draining or venting gas, flushing injection headers, and during periodic testing of the water level trip setpoint. Acceptance criteria for this test will be that the requirements for the UHIS given in FSAR section 6.3, those portions applicable, have been satisfied.
W-7.1A	Fuel Handling Tools and Fixtures	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and	Proper operation of the fuel handling tools utilized in the auxiliary building will be demonstrated. Each tool will be checked for cleanliness, complete and smooth actuation,

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		cleaning and flushing activities of all associated equipment have been completed. New fuel inspection platform batteries have been installed and charged. Electrical power supplies have been energized.	and operability of locking pins and interlocks. Brake actuation of the spent fuel pit bridge and new fuel elevator will be checked. Acceptance criteria for this test will be that the requirements for the fuel handling tools and fixtures, given in FSAR section 9.1.4, have been satisfied.
W-7.1B	Fuel Handling Tools and Fixtures	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing activities of all associated equipment have been completed. Preoperation test W-7.1A has been successfully completed. The refueling and transfer canals are dry during checkout procedures using the dummy fuel assembly. A dummy fuel assembly for testing purposes has been provided.	Proper operation of the tools and equipment utilized for core loading and reloading will be demonstrated. All equipment will be checked for complete and smooth actuation, and operability of locking pins and interlocks. Proper brake actuation of the fuel transfer system and manipulator crane will be verified. Acceptance criteria for this test will be that the requirements for the fuel handling tools and equipment, given in FSAR section 9.1.4, have been satisfied. FSAR section 6.3, those portions applicable, have been satisfied.
W-7.2A	Fuel Transfer System Inside Auxiliary Bldg.	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning activities of all associated equipment have been completed. Electrical power supplies have been energized. Preoperational tests "Fuel Handling Tools and Fixtures" and "125-Ton Auxiliary Building Crane" have been successfully completed. A dummy fuel	This test is a functional demonstration of the fuel handling equipment and tools that will be needed for initial fuel receipt. Equipment tested will be the Spent Fuel Assembly Handling Tool, New Fuel Assembly Handling Fixture, Spent Fuel Pit Bridge, and the New Elevator. This equipment will will be tested for proper performance, limit switch setpoint verification, and brake actuation.

TABLE 14.1-1 (Sheet 25)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		assembly has been provided for use during testing. A temporary exclusion area has been erected around the assembly handling area. The spent fuel pit and transfer canal are dry during checkout procedures.	Acceptance criteria for this test will be that the requirements given in FSAR section 9.1, those portions applicable, have been satisfied.
W-7.2B	Fuel Transfer System Inside Reactor Building	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required testing of all associated equipment have been completed. Fuel Handling Tools testing and test W-7.2A have been successfully completed. Electrical power supplies have been energized. The dummy fuel assembly is available for use. The blind flange on the transfer tube has been removed and the gate is open. The lower internals have been installed in the vessel for acceptance of the dummy fuel assembly.	A functional demonstration of the Fuel Transfer System, the upending frames, the conveyor car, the manipulator crane, and the RCC change fixture will be made. The dummy fuel assembly will be moved from the spent fueld pit to a selected position in the reactor core via the Fuel Transfer System and the RCC change fixture, and then returned while observing for smooth operation without binding or interference of any equipment involved. Setpoints and limitations of the manipulator crane will be verified while the fuel assembly is being inserted and withdrawn from the core. Accessibility of the manipulator crane to selected core locations and accuracy of its location controls will be demonstrated. Acceptance criteria for this test will be that the requirements given in FSAR section 9.1, those portions applicable, have been satisfied.
W-7.2C	Fuel Transfer System Manipulator Crane Indexing	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required testing and cleaning have been completed. Preoperational test W-7.2B has been successfully completed. The	The manipulator crane core indexing indicator will be demonstrated by positioning a dummy fuel assembly into selected core locations. Accessibility of the crane to each location will be observed. Also scribe marks on the crane

TABLE 14.1-1 (Sheet 26)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		The fuel assembly has been moved to the reactor side up-ender, is vertical, and ready to be lifted by the Manipulator crane. The reactor vessel lower internals have been installed and are ready to accept fuel assemblies. Electrical power supplies have been energized. Special test equipment has been calibrated.	bridge rail will be made to reference the bridge location at the reactor side upender, the RCC change fixture, and all reactor center core locations for further maintenance and/or operations. Acceptance criteria will be that the requirements for the manipulator crane given in FSAR section 9.1.4.2.2 have been satisfied.
W-7.2D	Fuel Transfer System - Check-out of Fuel Storage Racks	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation of all associated equipment and required installation inspections, integrity testing, cleaning and fuel assembly storage and refueling equipment design interface requirements have been completed. Testing on fuel handing tests on the 125-ton crane have been successfully completed. The auxiliary building crane hoist has been set to limit hook seep to a maximum of 7 ft/min. A temporary exclusion area has been erected around the spent fuel and new fuel storage pits. The spent fuel pit is dry during checkout procedures. Electrical power supplies have been energized. A dummy fuel assembly is available for use.	This test shall monitor insertion and withdrawal drag forces between the dummy fuel assembly and the spent fuel pit and new fuel storage racks. Acceptance criteria for this test will be that the requirements for the fuel storage given in FSAR secitons 9.1.1 and 9.1.2, have been satisfied.
W-8.1A	*Reactor Protection System Operational Time Response Time	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections and integrity testing of all associated equipment have been completed. Instrumenta-	The primary sensors for pressure level, differential pressure, and flow measurement will be tested by replacing the process variable with a Hydraulic Ramp Generator and ramping the sensor input through the trip setpoint value. The pri-

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		tion and annunciators have been checked, tested, and calibrated. Electrical power supplies have been energized for at least four hours. Testing on the Reactor Protection System and Engineered Safety Features Actuation System has been successfully completed. successfully completed.	mary sensors for temperature will be tested by the Loop Current Step Response method in which self-heating in an RTD is induced by stepping up the current through it and observing the change in resistance. Thus the response times for all the sensors will be measured. Acceptance criteria for this test will be that the response time for each sensor is less than or equal to that listed in the Technical Specification.
W-8.1B	*Reactor Protection System Operational Time Response Time	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections and integrity testing of all associated equipment have been completed. Instrumentation and annunciators have been checked, tested, and calibrated. Electrical power supplies have been energized for at least four hours. Testing on the Reactor Protection System and Engineered Safety Features Actuation System has been successfully completed.	This test measures the time it takes for a trip signal entering the various reactor trip circuits to automatically open the series reactor trip breakers when the condition monitored reaches a preset value. The total response time is broken down into four segments to that they can be verified separately they are (1) sensor response time, (2) analog and logic circuitry delay time, (3) reactor trip breaker delay, and (4) gripper release time. The response times will be conservatively measured from the time at which the switch is thrown to initiate the signal input. All the bistables in the reactor protection system requiring clearing will be cleared with simulated signals, then each reactor protection system circuit will be tripped individually or in coincidence as required with the response times measured and recorded. Acceptance criteria for the RPS will be that the response time to reactor trip for various signals is less than or equal to the values given in FSAR section 7.2.1.2.6.

TABLE 14.1-1 (Sheet 28)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
W-8.2	Reactor Protection System Operational Test	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections and integrity testing of all associated equipment have been completed. Instrumentation and annunciators have been checked, tested, and calibrated. The plant computer has been preoperationally tested and has been operating for at least four hours. Electrical power supplies have been energized for at least four hours.	This test will demonstrate the operability of the Reactor Protection System including all field wiring from the bistables through the protection logic to the reactor trip relays and the alarms. Simulated signals will be used as needed to clear all bistables to the Reactor Protection System. Then each bistable will be tripped individually and in each combination which should produce a reactor trip. The appropriate actions (reactor trip, computer printout, annunciator actuation, etc.) will be checked after each step and verified. Acceptance criteria for the Reactor Protection System will be that the requirements given in FSAR section 7.2 have been satisfied.
W-8.3A	Engineered Safety Features Actuation System Operational Test	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Instrumentation and annunciators have been checked, tested, and calibrated. The plant processing computer has been preoperationally tested, and has been operating for at leat four hours.	This test verifies that each interlock, blown fuse, loss of power supply, and other associated logic operates the General Warning Relay in the Train A and Train B SSPS cabinets. Acceptance criteria for this test will be that the requirements given in FSAR section 7.3 have been satisfied.
W-8.3B	Engineered Safety Features Actuation System (ESFAS) Operational Test	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections and integrity testing of all associated equipment have been completed. Instrumentation and annunciators have been checked, tested, and calibrated. The plant processing computer has been preopera-	This test will demonstrate that the logic of the Engineering Safeguards System (ESS) is operating properly. The actuating relays will be verified for proper actuation when an automatic or manual safeguards system signal is initiated. Annunciators and status lights associated with operation of the ESS will be tested for proper functioning. The Safeguard

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		tionally tested and has been operating for at least four hours. Electrical power supplies have been energized for at least four hours.	Test Cabinet and the Logic Test Panel will be verified for proper operation. Acceptance criteria for this test will be that the requirements for the ESFAS, given in FSAR section 7.3 have been satisifed.
W-8.4	Control System Tests for Turbine Runback	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing activities have been completed. Instrumentation and annunciators have been checked, tested, and calibrated. Electrical power and control quality air are available to all components requiring such. Raw cooling water is available to the Electro-Hydraulic (EH) fluid unit and turbine oil heat exchangers. The turbin lube oil and EH hydraulic fluid systems are filled and the level is within the permissible band. The reactor is in cold shutdown condition. The turbine shall be latched and high pressure fluid is available to permit operation of the governor valves.	The logic that generates the control signals for the EH control system will be tested to ensure proper operation of the logic networks and proper annunciation in the control room. To ensure proper interface matching, test signals will be actuated from the source analog bistable and will result in a turbine runback situation. Key points will be monitored to ensure proper runback rate. Acceptance criteria for this test will be that after tripping the logic system, annunciators operate properly and the load reference reduction should runback at a rate of 200 percent per min. for the first 1.5 seconds of each 30 seconds during the runback. Voltage to the function generators should change similarly to the runback at a rate of 20-V DC per min.
W-8.5	*Reactor Plant Systems Setpoint Verification	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Instrumentation and equipment shall have been aligned and calibrated, and setpoints adjusted per applicable instructions. All instrumentation will have been energized at least the minimum length of time to achieve	The objectives of the test are to verify that initial setpoint adjustments have been made prior to plant startup and to specify and maintain records of these setpoints which require readjustment or probable readjustment during subsequent startup and test operations. Upon completion of all initial

TABLE 14.1-1 (Sheet 30)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		stability.	setpoint adjustments and just prior to initial startup, verification that each setpoint has been established will be made and the value of each setpoint changes performed during startup and testing operations will be recorded. When performing setpoint verification, auxiliary functions associated with a trip will also be verified and documented. Setpoints will be verified to be within the tolerances specified by applicable specification documents. Acceptance criteria for this test will be that all initial setpoints agree with the latest precautions, limitations, and setpoints as documented or proper justification for discrepancies have been recorded.
W-9.1	*Control Rod Drive Mechanism (Timing)	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections and integrity testing of all associated equipment have been completed. The RCS has been filled and vented and the boron concentration is equal to or greater than that required for refueling shutdown. All rods are fully inserted and proper drive mechanism coil polarity, stepping sequence, and operational timing has been verified. The core has been loaded and the reactor is at hot shutdown conditions. Instrumentation has been checked, tested, and calibrated.	This test will verify that the proper timing of each Rod Control System slave cycles has been properly set at the factory and will provide documentation of proper slave cycles timing and mechanism operation. An operational check of each full length Control Rod Drive Mechanism (CRDM) with a Rod Cluster Control Assembly (RCCA) attached will be performed under both cold and hot conditions. The lift coil, movable gripper coil, and stationary gripper coil currents will be checked. Acceptance criteria for this test will be that the timing of each slave cycle is acceptable, coil currents are within set limits, and that each full length CRDM is operational.

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
W-9.2	*Rod Control System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections tions and integrity testing of all associated equipment have been completed. Instrumentation and annunciators have been checked, tested, and calibrated. Electrical power supplies have been energized. The Nuclear Instrumentation System Source Range Channels are in operation and the baseline count rate has been estab-	The test demonstrates and documents that the full length Rod Control System satisfactorily performs the required control and indication functions. Each bank of shutdown rods and control rods will be operated individually in the withdraw and insert directions using the normal controls. Sufficient travel will demonstrate drive operability, position indication and other instrumentation without unduly increasing the count rate on any source channel above the estab-

NOTE: Additional testing of the rod control system was performed during the 1988 unit 2 restart program via STI-79 and -118.

		lished. The reactor is at hot shutdown condition with rods rully inserted and boron concentration at refueling shutdown level. Testing on CRDM timing, rod drop time, and position indicators have been successfully completed.	lished baseline rate. Automatic sequencing of control banks is also demonstrated and bank overlap verified. Rod bank starting and stopping positions will be compared with the control settings for verification. Acceptance criteria for this test will be that the status lights, stop counter, rod position, and speed indicators are operating properly and that the rod bank overlap switches function within the prescribed limits.
W-9.3	*Rod Drop Time Measurement	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections and integrity testing of all associated equipment have been completed. The RCS has been filled and vented, rods are fully inserted, and the boron concentration is at the level required for refueling shut-	Test objective is to measure the drop times of individual full length control rods. The drop times will be measured by recording the voltage signals of the stationary gripper coil, the rod position detector primary coil output, and the station output power bus as functions of time. The drop time of every full length rod will be measured under cold no-

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		down. The Nuclear Instrumentation System source range channels are in operation and the baseline rate has been established. Instrumentation has been checked and calibrated.	flow, cold full-flow, hot no-flow, and hot full-flow conditions, to assure no anomalous effects occur. Results will be evaluated for conformance to plant technical specifications. Acceptance criteria for this test will be that the rod release time and the rod drop time will be less than or equal to 150 milliseconds and 2.2 seconds respectively.
W-9.5	*Rod Position Indication System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections and integrity testing of all associated equipment have been completed. Instrumentation and alarms have been checked, tested, and calibrated. Electrical power supplies have been energized. The rods are fully inserted and boron concentration is at refueling shutdown levels. Proper drive mechanism coil polarity stepping sequence, and operational timing has been verified. Nuclear Instrumentation System source range channels are in operation and the baseline count rate has been established. Testing of the CRDM timing has been successfully completed.	The test objective is to verify that the Rod Position Indication System satisfactorily performs the required indication and alarm functions for each rod and to demonstrate all rods operate satisfactority over their entire range of travel. The dropped rod function will be tested confirming rod bottom bistable trip voltage and control room annunciations. Shutdown banks will be fully withdrawn by bank in 20 step increments while recording (for each rod) analog output voltage and control room readout on rod position plus the group step position indication. The banks will then be inserted to rod bottom. Any deficiencies or erratic operation will be recorded. If adjustments in the zero or scan chassis are required, the procedure is repeated. The procedure will also be completed for all the control banks, recording in addition the pulse-to-analog converter chassis bank position digital readout. Acceptance criteria for the Rod Position Indication System will be that the system indicators and alarms function as speci-

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
			fied by the vendor and in FSAR section 4.2.3.2.2 and that the full length rods operate over range of travel within the voltage-position limits.
W-10.1	*Automatic Reactor Control System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections and integrity testing of all associated equipment have been energized. All systems required to support operation and testing have either been preoperationally tested or cleared under an IOR. Plant is at equilibrium conditions of 15- to 30-percent power. The following control systems have been checked and placed in automatic control: Pressurizer Level Control System, Pressurizer Pressure Control System, Steam Dump Control System, SG Level Control System, and FW Pump Speed Control System. Reactor Rod Control System is in manual with control bank D in maneuvering band and all others withdrawn.	Test objective is to verify the performance of the Automatic Reactor Control System in maintaining reactor coolant temperature within acceptable steady state limits. Flux, power mismatch, T average, T Ref, and pressure signals are continuously recorded. Reactor control will be placed in automatic to verify that T average is within '1.5°F of T Ref. Reactor control is switched to manual and T average will be successively increased and decreased to 6°F higher and 6°F lower than the T Ref setpoint and the reactor switched to automatic control. The transient recovery of the system will be observed to within '1.5°F of T Ref. Recorder traces will be labeled with pertinent parameters and retained for documentation. Acceptance criteria for this test will be that the Automatic Reactor Control System maintains T avg within '1.5°F of T Ref.
W-10.2	*Automatic Steam Generator Level Control	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections and integrity testing of all equipment associated with the main feedwater pump turbines and their control hardware have been completed. Instrumenta-	Test objective is to verify the stability of the system follow- simulated transients at low power conditions and to verify the variable speed feature of the main feedwater pumps. Transients are simulated by manipulation of controllers and test input signals. Continuously monitored parameters are steam pressure, steam flow,

TABLE 14.1-1 (Sheet 34)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		tion and annunciators have been checked, tested, and calibrated. Electrical power supplies have been energized. supplies have been energized. All systems required to support operation and testing have either been preoperationally tested or cleared under an IOR. The reactor is 15-20 percent of rated power level with at least three RC pumps and one MFW pump running. The SG Level System is in the manual mode and the Steam Dump System is in the automatic mode.	feedwater flow, SG narrow range level, level controller output, and flow controller output. Each SG level controller will be tested individually and setpoints will all be checked. Feedwater pumps variable flows will be reasured and response times will be checked. Acceptance criteria for this test will be that the SG level overshoot/undershoot is less than ±2.5 percent for a setpoint or level increase/ decrease and the level returns to setpoint within two minutes following a change. Also the feedwater pump speed oscillation are less than 3 percent of steady state operating speed and speed stabilizes within two minutes following a step change, and the pump speed overshoot/undershoot is less than 1 percent following a 5 percent step speed change.
W-10.3	Steam Dump Control	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing activities of all associated equipment have been completed. Instrumentation and alarms have been checked, tested, and calibrated. The Control Air System and Condenser Circulating Water System have either been preoperationally tested or cleared under an IOR. The plant is in hot shutdown condition with one or more RC pumps operating and all power operated atmos-	Test objective is to verify proper operation of the Steam Dump System in the manual and automatic modes and to verify system protective functions. A variable test signal will be injected into each SG pressure controller to test the associated atmospheric relief valve response. The Condenser Steam Dump System will be checked to verify the appropriate valves modulate open on an increasing pressure controller signal and closed on a decreasing signal. Appropriate control panel lighting indications are checked and local visual observations are made for verification observations are made for verification of valve position.

TABLE 14.1-1 (Sheet 35)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		pheric, safety, and condenser dump valves operational. The Steam Dump Control System has been calibrated.	Temperature signals will be varied to check deviation alarms and turbine trip alarms. Timing tests will be conducted concurrently to record valve positions as functions of time to determine the responses. Acceptance criteria for this test will be that the condenser steam dump valves and the atmospheric steam relief valves operate properly under cold and hot no-load conditions.
W-10.4	*Initial Turbine Roll	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing activities of all associated equipment have beem completed. Equipment power and control air are available to all components requiring such. All systems required to support operation and testing have either been preoperationally tested or cleared under an IOR. RCS is at hot shutdown conditions with RCS pumps and charging pumps operational. Condenser vacuum has been maintained, steam lines have been warmed and the Condenser Circulating Water System is in operation. Strainers have been installed in the MS lines upstream of the throttle valves.	This test shall provide the guidelines, limitation, and restrictions for the operation of the turbine-generator unit and related plant systems. Acceptable performance of the turbine-generator unit will be made by rolling the turbine at various speeds with steam generated by RC pump or nuclear heat. During the test, reactor coolant temperature, steam generator level, and pressurizer level and pressure will be continuously recorded. Acceptance criteria for this test will be that the turbine has been rolled safely and the values recorded on the turbine supervisory recorder charts for the final run are within the specified limits.
W-10.5	*Dynamic Automatic Steam Dump Control	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspection, integrity testing, and cleaning and	The test objective is to verify proper closed loop operation of T average Steam Dump Control System in the turbine trip and load rejection mode, to demonstrate controller setpoint adequacy, and to obtain final set-

TABLE 14.1-1 (Sheet 36)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		flushing activities of all associated equipment have been completed. Instrumentation and alarms have been checked, tested, and calibrated. Electrical power and control air are available to all components requiring such. The reactor is critical at no load temperature and pressure, and in a condition to permit an increase in core power to approximately 15 percent. The Steam Dump Control preoperational test (W-10.3) has been successfully completed.	tings for steam pressure control of condenser dump valves. Reactor power is increased to approximately 10 percent by rod withdrawal and steam dump condenser. Setpoint on pressure controller will be increased prior to switching up T average control which will rapidly modulate open condenser dump valves. System response will be observed for stability in the automatic mode. Turbine operating conditions will be simulated with reactor at approximately 10 percent power in manual, T ref set at no load and automatic control actuated to simulate turbine trip and resulting steam dump. All essential parameters will be recorded and identified. Acceptance criteria for this test will be that the steam dump control system operates properly in the turbine trip and load rejection closed loop modes and that the steam header pressure controller responds properly to maintain a stable pressure.
W-11.1	Nuclear Instrumentation System (NIS)	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing activities of all associated equipment have been completed. Instrumentation and alarms have been checked, tested, and calibrated. The Solid State Protection and Annunciator System has either been preoperationally tested or cleared under an IOR and	Test objective is to verify the system performs the required indicating and control functions through the source, intermediate, and power ranges of operation. All functions will be tested utilizing permanently installed controls and adjustment mechanisms. All operational modes of the source range channels, intermediate range channels, power range channels, comparator, and range rate circuits will be tested for the proper functioning of all indicator lights, bistable

TABLE 14.1-1 (Sheet 37)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		has been operational for at least 4 hours. The NIS is energized and has been operational for at least 4 hours. Source range detectors located outside the reactor missile shield cavity have been electrically connected and insulated. Equipment for handling and transport of the neutron calibration source are available for use. Electrical power supplies have been energized.	trips, and alarms. High voltage power supply plateaus and operating voltage settings for the source range detectors will be determined. The source range channels will be checked for electrical noise. Acceptance criteria for this test will be that NIS performs the required indicating and control functions through the source, intermediate, and power ranges of operation.
W-11.3	Incore Thermocouple and RTD Cross Calibration	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections and integrity testing of all associated equipment have been completed. Instrumentation has been checked, tested, and calibrated. The plant computer is operational and the thermocouple temperature compensation and the in-core thermocouple mapping programs have been loaded. All thermocouple wiring has been completed and calibration data is available for RTD's and TC's. All reactor coolant pumps are in operation.	Test objective is to verify correct resistance versus temperature and millivolt versus temperature characteristics of resistance temperature detectors (RTD's) and thermocouples (TC's) respectively, and to determine necessary corrections for accurate temperature readout. Data will be recorded at nominal RCS temperatures of 250°F, 350°F,
W-11.4	*Incore Moveable Detectors	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning activities of all associated equipment have been completed. Control quality air and electrical power are available to all components requiring such.	This test will verify that the six incore detector units and controls function properly. The top and bottom core setpoints for each detector path will be set and all limit switch settings will be verified. Proper performance and switch action of the transfer units, performance of the detector drive units in all modes of operation, interlock functions, and multiple drive

TABLE 14.1-1 (Sheet 38)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		All manual isolation valves on the seal table are in the open position. The CO_2 gas purge system has been isolated. The reactor core has been loaded. The Incore Mechanical System has been cleaned, lubricated, checked, and top and bottom core set-points established for all detectors. The purge, leak detection, and drain systems are in operation.	capability will be demonstrated. Purge gas, lead detection, and alarm systems will be verified for proper operation. Contact closure inputs to the computer will be verified for accuracy. Acceptance criteria for the incore moveable detectors is that the requirements given in FSAR section 7.7.1.9.2 have been satisfied.
W-11.5	Preoperational Testing of Computer Hardware	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections and integrity testing activities of all associated equipment have been completed. Environmental control for the computer room has been established. The CO_2 system in the computer room is available and functioning. Electrical power supplies have been energized. The computer has been energized and in service for four hours.	The test verified that the internal wiring of the process computer is proper and that the internal CPU, I/O and analog converters function properly. Proper operation of the computer and all peripheral hardware is verified by running a series of diagnostic tests supplied by the vendor as a tape systems test library. Upon completion of these diagnostic tests, the computer is ready for software verification and checkout. Acceptance criteria for this test will be that the process computer functions properly, the core memory, CPU, I/O, and analog converters behave correctly, and interrupt, fail-safe operation and protection features perform as required.
W-11.6	Computer Input and Data Printout Verification	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections and integrity testing of all associated equipment have been completed. Electrical power supplies have been energized and the computer	Test objective is to verify the calibration and operation of the instrumentation involved in the measurement, transmittal, conversion, and computer printout of process parameters. The computer internal circuitry for each data point "address" will be tested prior to simulated input signals to test the

TABLE 14.1-1 (Sheet 39)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		has been operating for at least four hours. Pre-operational testing of the computer has been completed and continuously monitored and all associated programs have been loaded. The POST TRIP PRINT Program has been disabled.	data transmittal circuits. The corresponding process instrument channel signal injection switch will be placed in the test position, voltage input signals initiated, and the computer output checked for appropriate response for varied signal levels. The input test signal and the calculated converted valve will be recorded. A computer printout will be performed and verification will be made that the engineering valve output corresponds to the test input. Proper functioning of the computer alarm system will be verified. Acceptance criteria for this test will be that the check sensor calibrate computer function is accurate, conversion of input to engineering units is correct, all hardware is properly installed, and the computer alarm system functions properly.
W-11.7	*Calibration of Steam and Feedwater Flow Instrumentation at Power	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing of all associated equipment have been completed. All systems required to support operation and testing have either been preoperationally tested or cleared under an IOR. Instrumentation and special test meters have been checked, tested, and calibrated for worth and the calibration curves are on hand.	The objective of the test is to calibrate the feedwater flow and steam flow instruments to the feedwater flow as determined by special test instruments. The feedwater flow, as determined by the special test equipment, is compared to recorded readings from plant instruments indicating steam and feedwater flow in the main control room. Gain adjustments in the detector output voltage of plant instruments are performed as necessary to obtain best possible fit of plant instrument data to that of the special instrumentation. This test will be performed while

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
			the plant is at steady state conditions of approximately 0, 30, 50, 75, and 100 percent. Acceptance criteria for this test will be that the feedwater and steam flow instrumentation has been properly calibrated and its reproducibility is within the specified limits.
W-11.10	*Startup Adjustments of Reactor Control Systems	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections and integrity testing activities of all associated equipment have been completed. All systems required to support operation and testing have either been preoperationally tested or cleared under an IOR. The core has been loaded and the plant is at 0 percent power.	This test is to obtain system temperature and steam pressure data at steady-state conditions for zero power and at the hold points during power escalations. Evaluation of this data will provide the basis for the adjustments in the following manner during the power escalation: 1) Primary system temperature data will be used for making signal adjustments to programmed TAVG; 2) Turbine impulse pressure data will be used for adjusting the pressure instruments and signals to the Reactor Control System and the Turbine E-H Control System. Acceptance criteria for this test will be that the optimum TAVG program has been established without exceeding its design values.
W-12.1	Ice Condenser Reactor Containment	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing activities have	This test is divided into three sections which will be performed independently of each other. They are: (1) functional logic testing of each component of the glycol system and performance tests of the pumps and chillers, (2) verification of

TABLE 14.1-1 (Sheet 41)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		mentation and alarms have been checked, tested, and calibrated. All systems required to support operation and testing have either been preoperationally tested or cleared under an IOR. Chillers have been properly charged with refrigerant and glycol circulation system has been filled and flow balanced. Heat tracing has been installed on the Air Handling Unit drain lines. Electrical power and control air are available to all components requiring such. Setpoints for various valves have been made and verified.	the thernal integrity of the ice condenser and the success of the cooldown, and (3) actual ice loading activities. Proper operational logic and performance tests on the pumps, AHU, chillers, floor defrost heaters, expansion tank level controls, personnel and access doors, and various ice condenser associated alarms will be made. Successful cooldown, in terms of compartment and structural temperatures, shall be accomplished. Proper sealing of floor drains and condenser door performance will be verified. Ice quality and inventory will be checked. Acceptance criteria for this test will be that the ice condenser system satisfies the requirements given in FSAR section 6.5.
W-12.2A	Annunicator Equipment Checkout	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testins, and cleaning and flushing activities of all associated equipment has been completed. All systems required to support operation and testing have either been preoperationally tested or cleared under an IOR. Electrical power supplies have been energized.	Proper operation of windows, reflash, acknowledge/reset, audible alarm, and test switches for all annunciator points and monitor lights will be verified. Acceptance criteria for this test will be that the aforementioned devices operate as designed and within specifications.
W-12.2B	Annunciator Equipment Checkout	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections and integrity testing of all	Power supplies and inverters will be tested to determine if design criteria requirements have been met. Verification that each annunciator field contact being tested will light the proper annunciator window

TABLE 14.1-1 (Sheet 42)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		associated equipment have been completed. All systems required to support operation and testing have either been preoperationally tested or cleared under an IOR. Electrical power supplies have been energized.	and that the windows have proper engravings will be made. Acceptance criteria for this test will be that the aforementioned objectives have been satisfactorily met.
W-15.0	*Reactor Internals Vibration Monitoring	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections and integrity testing of all associated equipment have been completed.	A detailed description of the vibration monitoring to be conducted on the upper internals package of the Sequoyah Unit 1 Plant is contained in Westinghouse Electric Corporation Topical Report WCAP 8516-P, "UHI Plant Internals Vibration Measurement Program & Pre & Post Hot Functional Examination," dated March 1975.
TVA-1	Shield Building Inleakage Tests, Emergency Treatment System Functional Tests	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspection, integrity testing, and cleaning and flushing activities have been completed in accordance with design and testing specifications. All components and equipment required to support operation and testing have either been preoperationally tested or cleared under an initial operation release (IOR). The containment building, shield building, and the Emergency Gas Treatment System (EGTS) are operable in preparation for testing. Penetrations are fully installed and operable. Containment vessel is isolated for testing. Power and control circuitry for the EGTS are operable and associated instrumentation is calibrated and available for	The test demonstrates that the shield building and the Emergency Gas Treatment System are capable of restricting LOCA generated activity releases to or below the limits specified in 10CFR100. The following test will be performed to demonstrate fulfillment of system requirements: 1) Determination of shield building inleakage at 0.5 inches and 5.0 inches water negative pressure levels. 2) Startup tests of annulus vacuum control subsystem, verification of automatic switchover to backup train for component failure, and verification of rated flow rates and vacuum level. 3) Startup and isolation of air cleanup subsystem, verification of automatic switchover to backup train for component failure, and

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		service. Electrical power supplies are energized and associated equipment is available for service.	verification of subsystem flow rates, vacuum level, and filter cooling capacity. 4) Leak tightness and efficiency tests of the HEPA and charcoal filter banks. 5) Verification tests of relative humidity heater performance. 6) Verification tests of system instrumentation, controls, alarms, and interlocks. Acceptance Criteria: Shield building inleakage will be deemed acceptable if it does not exceed the limits specified in section 6.2.1.3.1 of the FSAR. The emergency gas treatment system performance will be deemed acceptable if the system functionally operates in accordance with section 6.2.3.2.2 of the FSAR.
TVA-2A	Containment Vessel Pressure and Leak Test - Integrated Leak Rate Test	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. The containment building is in operational status. All penetrations have been fully installed and are operational. Upper and lower compartment air handling units are operational, and service air and portable air compressors are available. Special test instrumentation has been installed and calibrated. Operability of all isolation valves has been demonstrated before testing. All test connections and	To assure that leakage of the primary reactor containment and associated system is within allowable leakage rate limits prior to initial reactor operation and to establish the maximum allowable leakage rate for all future reduced pressure tests performed on the unit during the service life of the primary reactor containment and associated systems. A Type A reduced pressure test at containment pressure between 6.0 and 6.75 psig will demonstrate that the integrated leakage rate satisfies the acceptance criteria given in FSAR section 6.2.1.4.1 part 1. The reduced pressure and the

TABLE 14.1-1 (Sheet 44)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		vents are available on systems for testing.	peak pressure test, in that order, shall each be at least 24 hours in duration. For each type A test, a verification test shall be performed to demonstrate the validity of the measurements. The test shall be deemed acceptable if verification test data demonstrate an agreement within plus or minus 25 percent of the type A test data. The "absolute pressure temperature method" will be used.
TVA-2B	Containment Vessel Pressure and Leak Test - Testable Penetrations	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. All construction prerequisites necessary for the testing of testable penetrations are complete. All temporary features associated with the integrity of testable penetrations have been cleared.	To ensure that the leakage from the testable electrical penetrations with resilient seals is within the allowable limits for unit startup. Electrical penetration leakage will be deemed acceptable upon demonstration that the requirements given in FSAR section 6.2.1.4.1 part 2 have been met.
TVA-2C	Containment Vessel Pressure and Leak Test - Containment Isolation Valve Rate Test	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Control quality air and electrical power are available to those isolation valves which require such sources. All temporary features associated with the integrity of testable isolation valves have been cleared. All construction prerequisites necessary for the testing of containment isolation valves are complete.	This test shall ensure that the leakage rate of the containment isolation valves are within the allowable limits for plant startup. Containment isolation valve leakage will be deemed acceptable if the requirements given in FSAR section 6.2.1.4.1 part 3 are satisfied.
TVA-3	Airlock Leakage and Operational Test	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity	This test will demonstrate the functional capability and leaktightness of the personnel airlocks. Specifically, it will be demonstrated that:

TABLE 14.1-1 (Sheet 45)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		testing, and cleaning activities have been completed in accordance with design and testing specifications. Overpressure tests by vendor on personnel locks and bare-blanked containment vessel have been completed. The permanent communications system between inside of the lock and outside must be installed. Clean, dry compressed air is available. Permanently installed instrumentation has been checked and calibrated. Special test instruments are available and have been calibrated.	1) Communications system from inside the lock to the outside is operable according to design. 2) Mechanical door interlock system functions properly per design. 3) Limit switches on doors for operating remote indicator lights are operable per design. 4) With airlock pressurized to between 12.0 and 13.5 psig, the air-leakage rate does not exceed 0.1 percent per hour by weight of air. 5) With spaces between double 0-ring door seals pressurized to between 12.0 and 13.5 psig, the total leakage rate does not exceed 0.6 cubit foot per hour at 12.0 psig. Tests for each door-seal volume will continue for a minimum of 15 minutes. This test will cover only the operability and leaktightness of the doors and door seals. Leaktightness of the seal between the lock and the shield building will be tested in preoperational test "Shield Bldg. Inleakage Rate Tests Emergency Gas Treatment System Functional Tests." Leaktightness of any electrical penetrations through the lock will be tested in preoperational test "Containment Vessel Pressure and Leak Test."
TVA-4	Upper Containment Ventilation System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. All systems required	Each cooling unit will be tested separately to verify individual capacity. The test will demonstrate the fan air flow to

TABLE 14.1-1 (Sheet 46)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		to support operation and testing of the UCV system have either been preoperationally tested or cleared under an IOR. Cleaning, flushing, and hydrostatic testing of Cooling Coils and Piping System shall have been completed. Construction testing of cooling coil fan operation, air flow, and control circuitry shall have been completed. Instrumentation and claims have been checked, tested, and calibrated. Essential raw cooling water is available to the UCV system. Control quality air and electrical power is available to all components requiring such sources.	be not less than 16,000 cfm and water flow to be not less than 23 gpm. Test will also confirm the automatic start of standby unit upon loss of any of three operating units. System performance will be deemed acceptable when the requirements given in FSAR section 9.4.8.2.3 have been satisfied.
TVA-5	Lower Containment Ventilation System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. All systems required to support operation and testing of the LCV system have either been preoperationally tested or cleared under an IOR. Cleaning, flushing, and hydrostatic testing of Cooling Coils and Piping System have been completed. Construction testing of cooling coil fan operation, air flow, and control circuits have been completed. Instrumentation and alarms have been checked, tested, and calibrated. Essential raw cooling water is available to the lower containment vent system. Control quality air and electrical power are available to all components requiring such sources.	This test shall verify adequate operation of the Lower Containment Cooling System including fans, air distribution duct system instrumentation, and controls. Each cooling unit will be tested separately to verify adequate air and water flow rates. Confirmation that the fan air flow to be approximately 65,000 cfm and water flow to be not less than 200 gpm and automatic start of the standby unit upon loss of any of the three operating units shall be made. Acceptance criteria will be satisfied when the system requirements given in FSAR section 9.4.8.2.1 have been met.

TABLE 14.1-1 (Sheet 47)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
TVA-6	Air Return Fans (Including Divider Barrier and Ice Condenser Doors)	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspection, integrity testing, and cleaning of all associated equipment have been completed in accordance with design and testing specifications. All components and equipment required to support operation and testing of the air return fans have either been preoperationally tested or cleared under an IOR. Electrical power and control air is available to all components requiring such sources. Construction testing on fans, motors, backdraft dampers, and inlet registers must be completed. The ice condenser is not loaded but the inlet, intermediate deck, and top-deck doors must be operational. The divider deck and all hatches must be sealed. The pool gate and CRDM missile shield must be in place. It must be confirmed that each blowout panel in instrument room and upper reactor cavity are free to operate. The containment vessel personnel airlocks and equipment and escape hatches must be closed. Lower compartment access plug must be properly installed.	This test will verify that adequate flow rates can be achieved by operation of any combination of air-return fans. Specifically this test consists of 1) Confirming ability of each air return fan to move air from the upper to lower compartment at a minimum flow of 40,000 cfm; 2) Verifying operability of the backdraft dampers and their indicating light; 3) "Demonstrates the capability to cause the ice condenser lower inlet doors to open by starting each air return fan or by other approved methods." 4) Measuring fan motor power requirements; 5) Verifying the proper operation of the control circuits, monitors, and alarms for each air return fan; 6) Adjusting the air flow to give the required minimum flow at each inlet dampers. System performance will be deemed acceptable when the design requirements given in FSAR section 6.6.2 have been met.
TVA-7	Control Rod Drive Mechanism Cooling System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. All systems required to support operation and testing of the CRDM cooling units have either been preoperation-	Each cooling unit will be tested separately to verify adequate air flow rates. The test will demonstrate the fan air flow to be not less than 31,250 cfm. The automatic start of the standby cooling

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		ally tested or cleared under an IOR. Essential raw cooling water system instrument air system, control air system, lower compartment cooling units, and electrical power supplies are in service as required. Reactor coolant pump hatches, lower compartment access plug, pool gate, CRDM shield, and any other access hatch separating upper compartment from lower compartments are properly closed. Instrumentation and alarms have been checked, tested, and calibrated. Cleaning, flushing, and hydrostatic testing of cooling coils and piping systems is completed. Construction testing of fans, dampers, and control circuits must be completed.	unit in each pair of coolers upon the loss of the operating unit in that pair will be tested. Tests will also confirm the capability to utilize the standby unit of either or both pairs of coolers when lower compartment temperature exceeds 120°F. System performance will be deemed acceptable when the design requirements given in FSAR section 9.4.8.2.2 have been met.
TVA-8	Post LOCA Hydrogen Recombiner Test	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation tion and required installation inspections, integrity testing, and cleaning activities of all associated equipment have been completed in accordance with design and testing specifications. Containment ventilation system must be operational. Instrumentation and alarms have been checked, tested, and calibrated. Electrical power supplies have been energized and power is available to all components requiring such sources.	Operation of each recombiner at design flow rate and temperature will be demonstrated. Testing will include: 1) Preliminiary check of temperature readout instruments. 2) Heatup test will consist of operating each recombiner unit for 5 hours at power input of 48 kW. If outlet temperature is not 1200°F $\pm$ 25°F, the power will be adjusted to bring temperature within this range. Acceptance criteria will be met if final power settings is less than 52 kW with a recombiner outlet temperature of 1200°F$\pm$ 25°F for containment temperatures above 68°F.

TABLE 14.1-1 (Sheet 49)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
			3) An airflow test will be run using special Westinghouse equipment and measuring air-flow with a velometer. Actual hydrogen recombination will not be included in this test as it has been shown by Westinghouse in proof-of-principle tests that hydrogen and oxygen will combine at a temperature range of 1150 to 1400°F without producing a flame. All testing will be done at atmospheric pressure. Hydrogen recombiner performance will be deemed acceptable if the average airflow is greater than 100 SCFM, as given in FSAR section 6.2.5.4.
TVA-9A	Auxiliary Building Gas Treatment Systems and Access Control System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation of all equipment associated with this system has been completed. Required installation inspections, integrity testing, and cleaning activities have been completed. All instrumentation and annunciators have been installed, tested, and calibrated. All systems required to support the ABGTS and ACS operations have either been preoperationally tested or cleared under an IOR for operation. Ductwork has been cleaned to remove all debris that could puncture filters, load the filters with dust, or poison the charocoal beds. Electrical power is available to components as required. Construction testing and	This test shall verify the capability of the Auxiliary Building Gas Treatment System to function properly during accident conditions to which it was designed. In particular verification of the following shall be made: (1) startup and control of the system, considering a single operation component failure, (2) the capability to reach and maintain the required negative pressure within the Auxiliary Building Secondary Containment Enclosure (ABSCE), and (3) the efficiency and proper operation of the components and instrumentation in the air cleanup unit. The Access Control System to be tested consists of all A, B, and C safety related doors that are contained within or are part of the ABSCE. This part of the tested related to the ACS will verify proper operation of locks, latches, and alarm annunciators.

TABLE 14.1-1 (Sheet 50)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		balancing of air-flow rates for the Gas Treatment System have been completed.	Acceptance criteria will be met for the ABGTS upon demonstration that the requirements given in the FSAR sections 6.2.3.3.3 and 6.2.3.4.3 have been satisfied. The access control system performance will be deemed acceptable if latches, alarms, and interlocks function as shown on the appropriate TVA schematic diagram.
TVA-9B	Reactor Building Purge System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation of all equipment associated with the RBP system has been completed and functionally tested. Electrical power and control quality air are available to those system components which require such. Ductwork associated with the containment purge system has been cleaned to remove foreign debris that might puncture the filters, dust that could load the filters, or material that might poison the charcoal. All instrumentation and alarms have been checked, tested, and calibrated. All systems required to support the RBPS operation have either been preoperationally tested or cleared under an IOR for operation.	The objective of this test is to verify adequate performance of the containment purge system including fans, air cleanup filter assemblies, isolation valves, air distribution duct systems, instrumentation, controls, and alarms. Airflow rates for the incore instrument room purge system and the reactor building purge system will be verified. Also the efficiencies for the HEPA and charcoal filters will be verified. Acceptance criteria for the RBPS will be satisfied upon demonstration that the requirements given in FSAR section 9.4.7.2 have been met.
TVA-9C	Auxiliary Building Heating, Ventilating, and Cooling System	The tenative transfer of all the affected equipment from CONST to P PROD has been completed. Installation of all equipment associated with the AB HVAC system has been functionally tested. Ductwork has been cleaned to remove all debris that could puncture filters, load the filters with dust, or poison the	The auxiliary building heating, ventilating, and cooling system to be tested consists of fans, water chillers, refrigerant compressors, condensers, water circulating pumps, cooling-heating coils, filters, heaters, air-conditioning units, aircooling units, air cleanup assemblies, dampers, ductwork, and piping systems, instruments, controls, and alarms.

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		charcoal bed. Electrical power and control air are available to components as required. Construction testing and balancing of airflow rates for the HVAC system have been completed. All instrumentation and annunciators shall be installed, tested and calibrated. Essential Raw Cooling Water or a temporary water supply shall be available to supply water to cooling units and shutdown board room air-conditioning units.	This test will verify the capability of the auxiliary building heating, ventilating, and cooling subsystems to provide design flow rates to each designated section of the building and to maintain each section of the building at design pressure. Each subsystem's components will be verified to show proper operation during normal and abnormal conditions. 1) Auxiliary Building General Ventilating System. 2) Shutdown Board Rooms Air-Conditioning System. 3) Auxiliary Board and Battery Rooms Ventilating Systems. 4) Engineered Safety Feature Equipment Emergency Cooling System. 5) Miscellaneous systems such as radio-chemical laboratory and hot instrument shop ventilation systems. Acceptance criteria for the AB HVAC systems will be satisfied upon demonstration that the requirements in FSAR section 9.4.2 have been met.
TVA-10	Control Building Heating, Ventilating, and Air-Conditioning Systems	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Construction testing and balancing of air flow rates for each system is complete. Control air is available to operate damper motors and other pneumatic devices. Lubrication of fans and	Test objective is to verify the adequate performance of all systems in maintaining a controlled acceptable environments within the building for protection of mechanical and electrical equipment and for safety and comfort of operating personnel. A controlled, safe environment will also be assured for continuous occupancy of the main control room

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		motors is assured and all instrumentation have been installed, calibrated, and are operational. Essential raw cooling water is available to each Air-Conditioning System condensing unit. Annunciators have been installed, tested, and calibrated.	during any accident or off normal condition. Complete isolation will be demonstrated. The following capabilities will be demonstrated or confirmed: 1) Building pressurizing fans, main and auxiliary, operate automatically for normal operation and isolation; 2) Control building can be maintained at 1/8-inch positive static pressure relative to the outside environment; 3) Control room indicating lights operate properly; 4) Flow switches operate to automatically start redundant fans; 5) All motor-operated dampers operate automatically and properly for normal and emergency conditions; and 6) Refrigerant compressors, air handling units, heaters, thermostat controls, and humidifiers operate properly. In-place leak rate testing of the Charcoal and HEPA Supply System filters will demonstrate adequacy of filter installation. Operate of the charcoal heater for each filter assembly and its associated controls will be verified. The CBHVAC system performance will be deemed acceptable upon demonstration that the requirements given in FSAR section 9.4.1.2 have been satisfied.

TABLE 14.1-1 (Sheet 53)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
TVA-11A	Plant Communications System - Emergency Sound Powered Telephone System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation of all equipment associated with the system is complete. All required installation inspection activities have been completed.	The Emergency Sound-Powered Telephone System provides a very reliable source of communication that requires no external power supply to operate. This test will demonstrate the operability of the primary shutdown control center,health physics-electrical control rooms, and diesel building-control room communications systems. Intelligible reception and transmission of voice communications at all stations required will be verified. Particular emphasis will be placed on showing that communications at all stations required for the initial fuel loading are functioning properly. Acceptance criteria for the emergency sound-powered telephone system will be that the requirements given in FSAR section 9.5.2 will be satisfied.
TVA-11B	Plant Cummunications Systems - Evacuation Signal	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections of all equipment associated with this system have been completed. Electrical power is available to all equipment requiring such.	This test is designed to verify the proper operation and adequacy of the Evacuation Alarm System and to demonstrate that the evacuation signal can be heard in all designated areas of the plant. Acceptance criteria for the evacuation signal will be that the requirements given in FSAR section 9.5.2 will be satisfied.
TVA-12A	TVA Offsite Power System (161-kV Switchyard)	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections of all equipment associated with this system has been completed. Construction	This test will verify that two offsite power sources would be continuously available for immediate delivery of offsite power from the transmission network of the standby onsite power system. In the event of an electrical fault in the switchyard or on the two sel-

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		wiring and functional checks on the 161-kV switchyard, relay settings, and electrical tests have been completed by the Division of Power System Operations (DPSO), AC and DC control power is available and in service as required.	ected offsite power would still be available thru the two independent onsite power circuits. Acceptance criteria for the performance of the 161-kV switchyard will be met upon demonstration that the requirements given in FSAR section 8.2.1.2 have been satisfied.
TVA-12B	TVA Offsite Power System (Start Boards)	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Construction tests have been performed on the systems and associated equipment. Normal and alternate control power is available from the 25-Volt DC system. Relay settings and electrical tests have been completed. Functional tests on the start bus differential protective relays and common board feeder breakers have been completed. The start bus alarm system is installed and operational.	This test is to demonstrate that the interlocks and transfer scheme for the 6.9-kV start boards function as design signed. Acceptance criteria for the start board performance will be met upon demonstration that the requirements given in FSAR section 8.2.1.3 have been satisfied.
TVA-12C	TVA Offsite Power System (Unit Boards)	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections and integrity testing activities of all equipment associated with this system have been completed. Instrumentation and alarms have been installed, tested, and calibrated. Relay settings and electrical tests on the 6.9-kV unit boards have been completed by DPSO. Electrical power supplies have been energized and the associated equipment is available for service.	This test will be performed on the interlocks and automatic transfer scheme of the 6.9kV unit boards to verify proper oreation of air circuit breakers, transfer switches, interlocks, relays, and alarms. Tests will be conducted by simulating phase-to-phase and phase-to-ground faults and power circuits breaker failure. Unit board performance will be deemed acceptable upon demonstration that the requirements given in FSAR section 8.2.1.3 have been satisfied.
TVA-13A	Onsite AC Distribution System	The tentative transfer of all the affected equipment from CONST to P PROD has been	This test verifies that the interlocks and mode selector switch allow or prevent, as

TABLE 14.1-1 (Sheet 55)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		completed. Installation of all components and equipment associated with this system and required installation inspections have been completed. All construction checks and functional tests of circuit breakers, relays, and control circuits have been completed. All systems required to support operation and testing of this system have either been preoperationally tested or cleared under an IOR. Electrical power supplies have been energized and the necessary associated equipment is available for service. The diesel generator sets and supporting auxiliaries are operational.	required, the operation of the feeder, and diesel generator breakers on the 6.9-kV shutdown board under manual or automatic It also demonstrates that the separation of control features between the normal and auxiliary controls will function in accordance with design criteria and that the board protective devices operate properly. Acceptance criteria will be that the breakers perform under manual and automatic conditions as described in FSAR Subsection 8.3.1.1.
TVA-13B1	TVA Onsite AC Distribution System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspection activities of all equipment associated with this system have been completed in accordance with test and design specifications. All components and equipment required for system operaiton and/or testing have been preoperationally tested or cleared under an IOR.	This test shall verify that the diesel generator loading logic relays will start the diesel generator, connect the diesel to the shutdown board bus, and disconnect and connect the required loads in sequence for the condition of loss of preferred power. This test shall also verify, by the absence of voltage to the power trains not under test, that each power train is independent of the other. Acceptance criteria shall be met if the required loads are tripped and are sequentially applied to the board in the correctly timed sequence per FSAR section 8.3.1.1. Power train independent will be deemed acceptable if voltage on power trains not under test remain deenergized throughout testing of the train under test.

TABLE 14.1-1 (Sheet 56)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
TVA-13B2	Onsite AC Distribution System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspection activities have been completed in accordance with design and test specifications. All components and equipment required to support operation and/or testing have been preoperationally tested or cleared under an IOR. Control power from the Vital Barrety System must be available for the operation of control, protective, and instrumentation circuits. The diesel generator sets and supporting auxiliaries shall be operational.	This test shall confirm that the diesel loading logic relays will start the diesel generator connect the diesel generator to the shutdown board bus, and disconnect and connect the required loads for the condition for the condition of loss of preferred power followed by or concurrent with an accident. Also, system response time to a safety injection, and a safety injection concurrent with a blackout condition, will be verified. Acceptable system performance will be demonstrated when the requirements given in FSAR section 8.3.1.1 have been satisified.
	NOTE: Additional diesel generator testing was performed via STI-63, -77, -78, -110, and -111 during 1988 unit 2 restart program.		
TVA-13C	Onsite AC Distribution System (Diesel Generator Qualification Test)	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required inspection activities have been completed in accordance with design and testing specifications. The Diesel Generator Fuel Oil, Starting Air, Heating and Ventilating, and 125V Battery Systems have been preoperationally tested. The diesel generator sets and supporting auxiliaries shall be operational.	Qualification testing of the diesel generators will be conducted in three major parts. These tests shall demonstrate: 1) The diesel generators' capability to start, accelerate to rated speed and volt age, automatically tie to the shutdown board, and be loaded to at least 50 percent of nameplate rating 23 consecutive times without a failure, 2) The diesel generators' capability of carrying the continuous rating of 5,500 kVA for a time required to reach a equilibrium temperature plus 1 hour, 3) The diesel generators' capability of carrying the short time rating or 5,000 kVA for

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
			a period of 2 hours without exceeding manufacturer's design limits, 4) The diesel generators' capability to start and carry loads that are greater than the most severe load step change within the plant design loading sequence without experiencing instability resulting in generator voltage collapse or instability of the engine speed to recover. A load of at least 1,000 horse-power shall be used. Acceptance criteria will be met upon demonstration that the diesel generator set can start and accept 50 percent load, carry the continuous load of 5,550 kVA, and the 2 hour load of 5,000 kVA for the designated period of time without exceeding the manufacturer's design limits as specified in FSAR section 8.3.1.1.
TVA-13D	Onsite AC Distribution System (Blackout with Diesel Generator in Test Mode)	The tentative transfer of all affected equipment from CONST to P PROD has been completed. Installation and required installation inspection activities have been completed in accordance with design and testing specifications. The Diesel Generator Fuel Oil, Starting Air, Heating and Ventilation, and 125V Battery Systems have been preoperationally tested. The diesel generator sets and supporting auxiliar- shall be operational.	This test will verify the capability of the diesel generator to supply emergency power within the required time while operating in the test mode. The test will demonstrate: 1) That the diesel generator overcurrent relays will trip the diesel generator 6.9 kV ACB only when the diesel generator is in the test mode (i.e., parallel with offsite power); 2) That if the diesel generator receives an emergency start signal while in the test mode, the manual control

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
			lockout will not trip until the diesel generator is located from offsite power; 3) That when the diesel generator is in the test mode and a blackout occurs, the blackout signal will automatically override the diesel generator manual controls and establish the appropriate electrical alignment. Acceptance criteria will be met if the above objectives are satisfactorily completed.
TVA-14A	Diesel Generators and Supporting Auxiliaries (Diesel Generator Fuel Oil System)	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation of all equipment associated with this system has been completed in accordance with design specifications. Required installation inspections, integrity testing activities, and cleaning and flushing activities, have been completed on fuel storage tanks, and fuel oil piping. All pumps, valves, and electrical supplies have been functionally tested. Instrumentation and alarms have been checked, tested, and calibrated. The diesel generator building CO_2 Fire Protection System must be operable before performing tests on the Fuel Oil System. Electrical power supplies have been energized and the associated for service. The required amount of No. 2 diesel fuel has been installed in the proper tanks.	This test will verify the system's ability to transfer fuel oil from the railcar unloading station to fill the yard storage tanks and transfer fuel oil in all the difference operational modes. This test will also verify the systems associated interlocks, controls, and annunciations. Acceptance criteria for the Diesel Generator Fuel Oil System shall be met upon demonstration that the requirements given in FSAR section 9.5.4.2 have been satisfied.
TVA-14B	Diesel Generators and Supporting	The tentative transfer of all the affected equipment from CONST to P PROD has	This test will demonstrate the ability of the air start system controls to maintain the air

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
	Auxiliaries (Diesel Generator Starting Air System)	been completed. Installation of all equipment associated with this system has been completed. Required installation inspections, integrity testing activities, and cleaning and flushing activities have been completed. Electrical power supplies have been energized and associated equipment is available for service.	pressure in the air receiver tanks between 250 psig to 300 psig and provide 200 psig air to the air start motors through pressure reducing valves. This vest will also demonstrate the proper operation of the air start system interlocks and alarms. The ability of the air receivers to provide a sufficient quality of air to allow five diesel starts will be verified as well as the ability to recharge the receivers to 300 psig within 30 minutes.

NOTE: Additional testing of diesel generator auxiliary systems was performed via STI-72, -73, -74 and -75 during 1988 unit 2 restart program.

			Acceptance criteria will be met upon demonstration that the air start system performs in accordance with the requirements of section 9.5.6 of the FSAR.
TVA-14C	Diesel Generators and Supporting Auxiliaries (Diesel Generator Building Heating and Ventilation System)	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation of all equipment associated with this system has been completed in accordance with design specifications. Required installation inspection, integrity testing activities, and cleaning and flushing activities have been completed. Instrumentation and alarms have been checked, tested, and calibrated. Electrical power supplies have been energized and the associated equipment is available for service.	This test will verify that the Diesel Generator Building Heating and Ventilation System maintains an acceptable environment for the protection of the diesel generator equipment. Verification of the proper operation of the control circuits for the air intake dampers and various exhaust fans shall be demonstrated. Acceptance criteria for the DGH&V system will be demonstrated when the design requirements given in FSAR section 9.4.5 have been satisfied.
TVA-14D	Diesel Generators and Supporting Auxiliaries (125-V Control	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installa-	This test is divided into three sections or phases which are performed on each diesel generator set. Phase 1 will be an acceptance test to determine

TABLE 14.1-1 (Sheet 60)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
	and Field Flashing Batteries)	tion inspections of all equipment associated with this system have been completed in accordance with design and testing specifications. All instrumentation and annunciators have been installed, tested, and calibrated.	that the battery meets manufacturer's guaranteed rating. Phase 2 will be a service test to determine if the battery is sized properly to supply the actual system loads. Phase 3 will demonstrate that the charger will recharge the battery to its nominally full charged state from the 30-minute design discharge while supplying normal loads, within a 12-hour period. Acceptance criteria will be satisfied if the batteries meet the above objectives.
TVA-14E	Diesel Generators and Supporting (Diesel Generator Functional Tests)	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation of all equipment associated with this system has been completed in accordance with design specifications. Required installation inspections, integrity testing activities, and cleaning and flushing activities, have been completed. Instrumentation and alarms have been checked, tested, and calibrated. The diesel generator building CO_2 Fire Protection System, Essential Raw Cooling Water System, and AC Distribution System have been preoperationally tested and are available. Preoperational tests 14A-D have been performed.	This test will demonstrate the proper operation of the controls, interlocks, and alarms associated with the diesel generators and the supporting auxiliaries. Also the capability of the diesels to start and run for 24 hours, while loaded to 4,000-kW, without exceeding design specifications will be demonstrated. This test will be deemed acceptable if the diesel performance is in accordance with the manufacturer's testing that was performed on the diesels prior to shipment to TVA.
TVA-15	Vital 120V AC Power System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. All equipment and components required to support operation and testing have either been preoperationally tested or cleared under an IOR. Alarms have	The test will confirm the ability of the 120V AC Vital Power System to automatically switch between the 480V DC power sources while delivering and maximem demand load and maintaining output voltage within acceptable limits. While the system is loaded with an equivalent

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		been installed, tested, and calibrated. Acceptance testing of the 120-Volt vital inverters has been completed. Electrical power supplies have been energized and associated equipment is available for service. Construction checks and tests of the system shall have been completed. Tests of the 125V DC system and the 480V AC supplies should be completed before this test.	maximum deman load, the 480V AC power source will be disconnected and the 125V DC supply to carry the load for at least 10 seconds. Acceptance criteria will be met for the vital 120-Volt AC Power System when the requirements given in FSAR section 8.3.2.1.1 have been demonstrated.
TVA-16A	Vital 125-V DC Power System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections of all equipment associated with this system have been completed in accordance with design and testing specifications. All equipment and components required to support this system during testing have either been preoperationally tested or cleared under an IOR. Required electrical power supplies have been energized and all associated equipment is available for service. Alarms have been installed and tested.	This test will demonstrate the capability of the four separate vital power systems to supply the 125-volt DC power requirements under the worst anticipated operating conditions. Each battery will be discharged for 2 hours, continued to be discharged to a minimum terminal voltage of 105 volts, and then recharged to establish the time required to return to a charged condition. Acceptance criteria for the Vital 125-Volt DC Power System will be met upon demonstration that the requirements given in FSAR section 8.3.2.1.1 have
TVA-16B	*Vital 125-V DC Power System (Measurement of Actual Loads)	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspection of all equipment associated with this system have been completed in accordance with design and testing specifications. All equipment and components required to support this system during testing have either been preoperaionally tested or cleared under an IOR. Required electrical	This test will demonstrate that the actual 125-VC DC system loads are below the design loads for the system. This will be accomplished by recording the majority of the actual system loads on the system during plant start-up. Loads that cannot be measured will be assumed to be equal to design loads. The loads on the 125V DC system will be deemed acceptable if the sum of all system loads,

TABLE 14.1-1 (Sheet 62)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		power supplies have been energized and all associated equipment is available for service.	including those that cannot be measured, is less than the system loading values given in Tables 8.3-23 of the FSAR.
TVA-17	Condenser Circulating Water System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing of all equipment associated with this system have been completed. All systems required to support operation and testing of the CCWS have either been preoperationally tested or cleared under an IOR. Electrical power supplies have been energized. Condensers, intake tunnels, and discharge tunnels have been filled with water and the disharge structure stoplogs have been removed. The vacuum priming and cooling water system must be complete and operable. Monitor which provide warning of flooding of the reactor, auxiliary, and turbine buildings must be operational.	The test verifies that the condenser circulating water (CCW) pumps can be shutdown immediately following a design basis accident (loss of downstream dam) to prevent the forebay pool from being pumped dry. Each CCW pump will be operated to verify correct functioning of pumps and systems. The pumps will be stopped and restarted manually. Both float manually. Both float level switches provided in each CCW pump pit designed to automatically stop the CCW pumps will be operated manually through elevation 668.0 to simulate the design basis accident. Acceptance criteria for the CCWS will be met upon demonstration that the requirements given in FSAR section 10.4.5.1 have been satisfied.
TVA-18A	Essential Raw Cooling Water System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing activities have been completed in accordance with design and testing specifications. Instrumentation and alarms have been checked, tested and calibrated. All components and equipment required to support operation and/or testing of the ERCW system have either been preoperationally tested or are cleared under an IOR.	This test shall verify the operability of the Essential Raw Cooling Water (ERCW) System including components, instrumentation and control equipment, and applicable alarms and setpoints. Only the ERCW pumps, strainers, main headers for both units, the component cooling heat exchangers, and associated valves will be included in this test. Minimum header flow requirements must be met for both one and two pump operation and proper control of the components will also be checked.

TABLE 14.1-1 (Sheet 63)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		The process computer has electrical power and is available for service to monitor temperature sensors, which have been connected. All electrical supplies have been energized and the associated equipment is available for service.	Acceptance criteria will be met for the ERCW system when the system requirements stated in FSAR section 9.2.2.2 have been satisfied.
TVA-18B	Essential Raw Cooling Water System-Components	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing activities of all equipment associated with this system have been completed in accordance with design and testing specifications. All equipment and components required to support operation and/or testing of the ERCW system has either been preoperationally tested or cleared under an IOR. Electrical power and control air is available to all components requiring such. Instrumentation and alarms have been installed, tested, and calibrated. The ERCW headers are pressurized and the system has been properly filled and vented.	This test shall verify the proper operation of the valves associated with the individual components in the ERCW system and check for flow through the coolers and heat exchangers served by ERCW. The system components are divided into groups, which will include all ERCW components, piping, and valves including the first isolation valves to other associated components to be tested separately. This test shall also verify proper operation of alarms and monitor lights for the associated ERCW equipment. Acceptance criteria for the ERCW system components will be met when the requirements given in FSAR section 9.2.2.2 have been satisfied.
TVA-18C	Essential Raw Cooling Water System - Flow Balance	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing activities of all equipment associated with the ERCW system have been completed in accordance with design and testing specifications. All equipment and components re-	This test shall verify proper balancing of the ERCW system in the various modes which are most demanding of the system. One and two ERCW pump flows,as well as one auxiliary ERCW pump flow are attained for each train on ERCW headers and components. All components are checked for having sufficient water flow for all tested modes in which they are needed.

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		quired to support the ERCW system have either been preoperationally tested or cleared under an IOR. Electrical power supplies have been energized and all associated equipment is available for service.	The ERCW System flow balance will be deemed acceptable when the requirements given in FSAR section 9.2.2.2 have been satisfied.
TVA-18D1	Essential Raw Cooling Water System - Pumping Station Functional Test	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing activities have been completed in accordance with design and testing specifications. Instrumentation and alarms have been checked, tested and calibrated. All components and equipment required to support operation and/or testing of the ERCW System have either been preoperatested or are cleared under an IOR. The process computer has electrical power and is available for service to monitor temperature sensors, which have been connected. All electrical supplies have been energized and the associated equipment is available for service.	This test shall verify operability of the essential raw cooling water system, including components, instrumentation & control equipment associated with the new pumping station. Testing includes operational performance of ERCW strainers, traveling screens and screen wash pumps, control and operation of system valves, and verification of instrumentation of alarm setpoints. Operational and response time testing of ERCW pumps Q-A, K-A, M-B and and response time testing of ERCW pumps Q-A, K-A, M-B and N-B is also included. Control logic for ERCW pumps has been previously tested in preoperational test TVA-18C, unit 1. Operational performance of ERCW pumps J-A, R-A, L-B and P-B will be tested in Preoperational test TVA-18D2. The system flow balance and steady state piping vibration will be performed in preoperational test TVA-18C, unit 2 after the new pumps are qualified. Acceptance criteria will be met for the ERCW system when the system when the system requirements stated in FSAR section 9.2.2.2 have been satisfied.

TABLE 14.1-1 (Sheet 65)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
TVA-18D2	Essential Raw Cooling Water System - Pump Performance Test	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing activities have been completed in accordance with design and testing specifications. Instrumentation and alarms have been checked, tested, and calibrated. All components and equipment required to support operation and/or testing of the ERCW system have either been preoperationally tested or are cleared under an IOR. The process computer has electrical power and is available for service to monitor temperature sensors, which have been connected. All electrical supplies have been energized and the associated equipment is available for service.	This test shall verify proper operation of ERCW Pumps J-A, R-A, L-B and P-B at the new pumping station. Testing including verification that pump performance meet design ratings at several flow rates, and verification that pump response times to safety injection signals are within design limits. Control for ERCW pumps has been previously tested in Preoperational Test TVA-18C, Unit 1. Operational performance of ERCW Pumps Q-A, K-A, M-B and N-B has been tested in Preoperational Test TVA-18D1. The system flow balance and steady state piping vibration testing will be performed in Preoperational Test TVA-18C, Unit 2 after the new pumps are qualified. Acceptance criteria will be met for the ERCW system when the system requirements stated in FSAR section 9.2.2.2 have been satisfied.
TVA-19	Auxiliary Essential Raw Cooling Water System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. All system required to support operation and testing of the AERCW system have either been preoperationally tested or cleared under an IOR. Control air and electrical power is available to all components requiring such. Heat tracing for the AERCW system is available for service, as required. Flushing and hydrostatic testing of system is complete. Construction testing of pumps, valves, and control circuits, and instrumentation and alarm calibration have been completed. Testing of the essen-	The test verifies the operability of the cooling towers and recirculation system of the essential raw cooling water system including components, instrumentation and control equipment, and applicable alarms and setpoints. Specifically, the test includes: 1) Manual and automatic operation of the auxiliary ERCW pumps, cooling tower makeup pump, traveling water screens, cooling tower fans and all motor and air operated valves from the control room and local panels. 2) Flow tests to demonstrate acceptable cooling water

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		tial raw cooling water system should be completed before starting this test.	flow rates during various system modes of operation. AERCW system performance will be deemed acceptable if the requirements given in section 9.2.2 of the FSAR have been have been satisfied.
TVA-20A	Component Cooling System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspection, integrity testing, and cleaning and flushing activities have been completed in accordance with design and testing specifications. Instrumentation and alarms have been installed, tested, and calibrated. All equipment and components required for operation and/or testing of the componentes cooling system (CCS) has either been preoperationally tested or cleared under an IOR. Electrical power supplies have been energized and control air is available to all components requiring such. Demineralized Water and Essential Raw Cooling Water Systems are available to supply water to all components requiring such.	This test will verify the proper operation of the CCS pumps, the Seal Leakage Return Unit (SLRU) pumps, and alarms, valves, and surge tanks. Pumps and valves will be tested in both automatic and manual modes. The CCS surge tank level alarms are also checked for proper actuation. Acceptance criteria for this portion of CCS test will be met upon demonstration that the system requirements given in FSAR section 9.2.1.2 have been satisfied.
		The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing activities of all equipment associated with the CCS have been completed in accordance with design and testing specifications. All components and equipment	The test will verify the proper operation of the CCS motor- and air-operated valves and the CCS Thermal Barrier Booster Pumps (TBBP). The reactor coolant pump thermal barrier containment isolation valves are checked for closure on a thermal barrier flow differential signal. The unit 1 equipment will be tested for receiving a minimum flow rate with the system set up in an

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		required for operation and/or testing of this system have either been preoperationally tested or cleared under an IOR. Instrumentation and alarms have been checked, tested, and calibrated. Electrical power and control air are available to all components requiring such. Demineralized Water and Essential Raw Cooling Water Systems are available to provide water to the surge tanks, heat exchangers, pumps, and coolers.	actual operating mode. The pumps will then be tested for providing minimum flow in any operation mode. The unit 2 pumps also be tested to being able to supply the Unit 1 equipment in the initial shutdown mode. Minimum flow requirements for the Gas Stripper and Boric Acide Package B will also be verified. A heat balance shall be performed on the CCS heat exchangers. Acceptance criteria for this portion of CCS testing will be met when the requirements given in FSAR section 9.2.1.2 have been satisfied.
TVA-21A	Containment Spray System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing activities have been completed in accordance with design and testing specifications. System instrumentation has been installed and calibrated. An adequate source of clean, dry compressed air of clean, dry compressed air is available for testing of the containment spray and RHR spray nozzles. A final filter and dry/moisture separator have been installed just prior to air test connections.	This test shall verify that the nozzles for the Containment Spray and Residual Heat Removal System are not plugged and will pass air freely. This test will be deemed acceptable if all CSS and RHR nozzles are unobstructed for flow through them.
TVA-21B	Containment Spray System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation inspections, integrity testing and cleaning and flushing activities have been completed in accordance	This test will demonstrate the capability of the CSS to perform as designed. This test includes the following: 1) Pumps will be operated at reduced flow through the minimum flow recirculation

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		with design and testing specifications. The Essential Raw Cooling Water and Component Cooling Systems have either been preoperationally tested or cleared under an IOR. Instrumentation and alarms have been checked, tested, and calibrated. Electrical power supplies have been energized and associated equipment is available for service.	and essentially rated flow through the test line to the refueling water storage tank. Pump performance will be verified by comparing test values of developed head and flow with manufacturer's data. 2) Valve interlocks in pump suction lines between the containment sump and refueling water storage tank will be verified to be operable in accordance with the latest revision TVA schematic diagram. 3) Capability for manual operation of the system from both the main and auxiliary control rooms will be verified. All control room indications of system status will be checked. CSS performance will be deemed acceptable if the requirements given in section 6.2.2.2 of the FSAR have been satisfied.
TVA-22	Auxiliary Feedwater System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. All systems required to support operation and testing of the AFS have either been preoperationally tested or cleared under an IOR. Flushing, cleaning, and hydrostatic testing have been completed. Construction testing of system components and instrumentation testing of system components and instrumentation calibration have been completed. Condensate storage tank must be filled with makeup quality water	The tests will demonstrate the capability of the auxiliary feedwater system to perform designed, specifically the test includes: 1) Each of the electric motor-driven pumps and the steam turbine-driven pump are tested in both the minimum flow recirculation mode and at essentially rated flow conditions. Pump performance will be evaluated by comparing measured flow and and head data against manufacturer's data. Pumps will be tested for deliverance of rated flow within one minute following certain events,

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		and the standpipe must be installed. Auxiliary boiler must be operational to provide a source of steam to the turbine-driven pump. Electrical power and control air must be available to components as required for testing. Temporary strainers have been installed for initial pump operation.	such as loss of external power, safety injection signal, low-low steam generator water levels, trip of the Main Feedwater pumps. 2) Both cold functional and hot functional testing will be conducted. Cold functional tests will be limited to minimum flow recirculation pump tests. Hot functional tests will be those conducted while the reactor coolant system and steam generators are at essentially operating temperatures and pressures, and will include pump tests conducted over a range of steam generator pressures. 3) All level-control valves and pressure-control valves and their associated instrumentation and control circuits will be tested to demonstate correct operation. 4) Certain system control and logic circuitry tests will be performed to demonstrate correct operation. Included will be tests to verify that suction line valves to the essential raw cooling water supply proper response to simulated initiation signlas. Acceptance criteria for the performance of the Auxiliary Feedwater System will be met when the system functional requirements given in 10.4.7.2 have been satisfied.

TABLE 14.1-1 (Sheet 70)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
TVA-23A	Auxiliary System Thermal Expansion - Main Steam	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections and integrity testing for supports, restraints, and hangers have been completed in accordance with design and testing specificaitons. All measuring devices have been installed and inspected. All related pressure transmitters, indicators, and modulators have been checked, tested, and calibrated and are available for service. All of the W-1.2 prerequisites have been completed and the RCS is at ambient temperature. All systems necessary for the Reactor Coolant System Heatup are operational. The secondary steam system will be complete to the point of receiving and dumping steam.	The test objective is to verify that no interferences occur due to thermal expansion during system heatup or due to contraction during system cooldown Measurements will be made at the steady state conditions and all piping will be observed for possible interferences. This test will be performed throughout Hot Functional Testing. The acceptance criteria is that the main steam piping system will expand without interference or obstruction from ambient to operating conditions, and during cooldown will return to ambient conditions without interference or obstruction.
TVA-23B	*Auxiliary Systems Thermal Expansion - Feedwater	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections and integrity testing for supports, restraints, and hangers have been completed in accordance with design and testing specifications. All measuring devices, located inside the Reactor Building Crane Wall, have been installed and inspected.	The test objective is to verify that no interferences occur due to thermal expansion during system heatup or due to contraction during cooldown. Measurements will be made at the steady state conditions and all piping will be monitored or observed for possible interferences. This test will be performed throughout power ascension testing after fuel loading. The acceptance criteria is that the feedwater piping system will expand without interference or obstruction from ambient to operationg conditions, and during cooldown will return to ambient conditions wihtout interference or obstruction.

TABLE 14.1-1 (Sheet 71)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
TVA-25	Fire Protection System	The tentative transfer of all affected equipment from CONST to P PROD has been completed. Installation and required installation inspection, integrity testing, and cleaning and flushing have been compelted. Electrical power and control air is available to all components requiring such. The AERCW pumping station has been completed to the extent that it can receive a discharge of water from the FPS. Heat tracing for this system has been installed and checked. Instrumentation and controls have been installed, tested, and calibrated.	This test will demonstrate the functional readiness of the high pressure fire protection system. Included in this test will be system response to various fire actuation alarms, measurement of pressure differential across mainline strainers, and verificaiton that check valves separating the Class I (seismic designed) porfrom the remainder of the system are operable. High Pressure Fire Protection System performance will be deemed acceptable when the system requirements given in FSAR section 9.5.1 have been satisfied.
TVA-26	Compressed Air System - (Excluding Control Air)	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing activities have been completed. Control air and electrical power is available to all components requiring such. Essential Raw Cooling Water is available to the main station air compressor intercoolers and aftercoolers. Instrumentation and alarms have been installed, tested, and calibrated.	This test will demonstrate that the stationary air compressors & associated criteria requirements. Verification that the service air isolation valve, the cooling water isolation valves, annunciators, and indicator lights operate according to design criteria requirements will be made. System pressures and temperatures will also be checked for criteria compliance. Compressed air system performance will be deemed acceptable when the requirements of section 9.3.1 of the FSAR have been satisfied.
TVA-27	Control Air System (Auxiliary Compressed Air System)	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Instrumentation and annunciators have been installed, tested and calibrated. Essential	This test verifies the operability of the Control Air System including components, instrumentation and control equipment, and applicable alarms and setpoints. The control air dryers will be placed

TABLE 14.1-1 (Sheet 72)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		Raw Cooling Water is available to the auxiliary air compressor intercoolers and aftercoolers. All control air lines have been cleaned and applicable pressure and leak rate tests completed. Electric AC and DC power will be available as required. Testing of the stationary air compressors and associated equipment have been completed.	into service and capability to maintain dewpoint at desired level demonstrated. Actuation of the dewpoint alarm at the established setpoint will be demonstrated. Automatic isolation of air supply to service air supply to control air system pressure falls below specified level will be verified. Operability of isolation valves between the two subsystems shall be verified. Start of the auxiliary air compressors when Control Air System pressure decreases to specified level and associated control room alarm will be demonstrated. Acceptance criteria for the Control Air System will be met when design requirements given in FSAR section 9.3.1 have been satisfied. (The control air system is called the auxiliary compressed air system in the FSAR.)
TVA-28	Water Quality and Sampling System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, and cleaning and flushing activities have been completed in accordance with design and testing specifications. Instrumentation and alarms have been installed, tested, and calibrated. Electrical power and control air are available as required. Installation of all sample from the remote sample points to the local	The test demonstrates the capability of the sampling system to provide a representative sample from specified sample points associated with the NSSS and supporting auxiliary systems. Primarily, the test includes those sampling facilities and process analyzers located in the auxiliary building sampling area (hot sample room). Testing shall include: 1) Verification that sample flow rates and temperatures can be regulated to desired values.

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		stations have been completed and hydrostatically tested. Demineralized water, component cooling water, essential raw cooling water, and raw cooling water are available.	2) Perform standardization and operational tests on all hot sample room analyzers. Perform functional tests on analyzer indicator and recorder, and verify annunciation on recorder setpoints. 3) Verification that sample isolation valves function properly in response to an electrical signal or loss of power. 4) Demonstration of the capability to adequately sample the reactor coolant and steam generator blowdowns under simulated design basis flood conditions. Verifications that ERCW is supplied to the proper heat exchangers. 5) Verification of proper operation of the Hydrogen Monitor and hot sample cubical ventilation system. Water quality and sampling system performance will be deemed acceptable when the requirements given in section 9.3.2 of the FSAR have been satisfied.
TVA-29	Steam Generator Blowdown System and Verification Feedwater Quality	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing activities have been completed. Electrical power and control air are available to all components requiring such. Instrumentation and annunciation have been checked, tested,	The overall objective of this test is to verify that the blow down system operates properly in the normal mode of operation at the maximum and minimum steam generator blowdown flow rates. All three modes of operation used in discharging water from the flash tank should be verified. The feedwater quality shall be tested and verified to be within required specifications for hot functional operation. Also the

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		and calibrated. All systems required to support operation and testing of the Steam Generator Blowdown System have either been pre-operationally tested or cleared under an IOR. The sample system for the blowdown and feedwater systems must be operational. The steam generators must be at hot functional test conditions and the secondary chemical treatment system must be operable to maintain secondary water quality within the limits for the hot functional tests with chemical feed systems operable. The full flow condensate demineralizer system must be in operation to accept blowdown.	secondary chemical treatment system shall be demonstrated to be operating properly. Inlet and outlet temperatures for the blowdown heat exchangers will be periodically recorded and samples of the system influent will be collected for analysis. Operation of protective devices will be verified using simulated input signals. These include devices for over pressure, high temperature, and high pH protection. Verification of proper operation of pumps, valves, and radiation monitors shall also be made. Acceptance criteria for this test will be that the system achieves a 90 percent recovery factor and conforms to the design specifications given in FSAR section 10.4.8.
TVA-30	Condenser Vent System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing and cleaning and flushing activities have been completed. The Control Air System has either been preoperationally tested or cleared under an IOR. Instrumentation and alarms have been installed, tested, and calibrated. Electrical power supplies have been energized and are available for service.	This test will verify the capability of the system to restrict radioactive emissions to as low as practicable levels. Verification of all filter differential pressures and in-place leak and efficiency tests of filters will demonstrate adequacy of filter installation and design. Proper operation of filter system protective devices, the exhaust headers, and related interlocks will be verified. System performance will be deemed acceptable if the design requirements given in FSAR section 9.4.4.2.3 have been satisfied.
TVA-31A	Process Radiation Monitoring	The tentative transfer of all the affected equipment from CONST to P PROD has	This test will verify proper operation of each check source, instrumentation, pumps indica-

	System (Off-Line Gamma Scintillation Liquid Monitors)	been completed. Installation and required installation inspection of all equipment associated with this system have been completed in accordance with design and testing specifications. All components and equipment required to support operation an testing of the radiation monitoring system have either been preoperationally tested or cleared under an IOR. All instrumentation and alarms have been installed, tested, and calibrated. Electrical power supplies have been energized and the associated equipment is available for service. Each flow control valve for the designated radiation monitors has been adjusted to its desired flow rate.	tors, and control valves and also verify that flow requirements are met. Verification will also be made that on a low flow, or a loss of power, a malfunction alarm will occur for each respective monitor. All interlocks and annunciators will be tested on each monitor. Acceptance criteria will be that the monitors respond to check sources in accordance with calibration data, sample flowrates meet design flow requirements, all annunciators and alarms function properly, and the requirements given in FSAR section 11.4.2.1 for liquid monitors are met.
TVA-31B	Process Radiation Monitoring System (Off-Line Particulate Total-Gas, and Iodine Monitors)	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections of all equipment associated with this system have been completed in accordance with design and testing specifications. All components and equipment required for operation and testing of this system have either been preoperationally tested or cleared under an IOR. Instrumentation and alarms have been checked, tested, and calibrated. Electrical power supplies have been energized and all associated equipment is available for service. Each flow control valve for	This test will verify proper operation of each check source, instrumentation, pumps, and control valves, and verify that flow requirements are met. Verification that on a low monitor flow, a loss of power, or a filter tape break, a malfunction alarm will occur for each respective monitor. All interlocks and annunciators will be tested. Acceptance criteria will be that the monitors respond to check source in accordance with calibration data and sample floor rates meet design requirements, as given in FSAR section 11.4.2.2.4 for off-line monitors.

TABLE 14.1-1 (Sheet 76)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		the designated monitors has been adjusted to its desired flow rate.	
TVA-31C	Process Radiation Monitoring System (Gaseous Monitors - Total Gas)	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections for all equipment associated with this system have been completed in accordance with design and testing specifications. All components and equipment required to support operation and testing of this system have either been properationally tested or cleared under an IOR. Instrumentation and alarms have been installed, tested, and calibrated. Each flow control valve for the designated radiation monitor has been adjusted to its desired flow rate. Electrical power supplies have been energized and associated equipment is available for service.	Each off-line monitor assembly consists of a beta scintillation detector, a preamplifier, appropriate control valves, indicators, and instrumentation. This test shall verify proper operation of each check source, instrumentation, pumps, indicators, and control valves and verify that flow requirements are met. Verification will also be made that on a low monitor flow or a loss of power, a malfunction alarm will occur for each respective monitor. All interlocks and annunciators will be tested for instrument upscale and downscale radiation indicator trips. Acceptance criteria will be that the monitors respond to check sources in accordance with calibration data, sample flow rates meet design requirements, all annunciators and alarms function properly, and the requirements given FSAR sections 11.4.2.2.5 and 11.4.2.2.6 for the off-line gaseous monitors are met.
TVA-31D	Process Radiation System (Off-Line Gaseous Monitors)	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections of all equipment associated with this system have been completed in accordance with design specifications. All components and equipment required to support operation and testing of this system have either been preoperationally tested or cleared under	Each monitor assembly consists of a Geiger-Mueller tube with a preamplifier and appropriate indicators and instrumentation. Each check source will be tested for proper operation and instrument response. Verification will also be made that on a loss of power, a malfunction alarm occurs for each receptive monitor. Interlocks and annunciators will also be tested for initiation on upscale and downscale radiation indicator trips.

TABLE 14.1-1 (Sheet 77)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		an IOR. Instrumentation and alarms have been installed, tested and calibrated. Electrical power supplies have been energized and all associated equipment is available for service.	Acceptance criteria will be that the monitors respond to check sources in accordance with calibration data, sample flow rates meet design requirements, all annunciators and alarms function properly, and the requirements given in FSAR section 11.4.2.2.3 for the GM detectors are met.
TVA-32A	Area Radiation Monitoring System - Area Monitor	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections have been completed in accordance with design and testing specifications. All components and equipment required to support operation and testing of the radiation monitoring system radiation monitoring system have either been preoperationally tested or cleared under an IOR. Instrumentation and alarms have been installed, tested, and calibrated. Electrical power supplies have been energized and all associated equipment is available for service. The flow control valves for each particulate radiation monitor have been adjusted to their proper setpoints.	The area radiation monitor system consists of radiation monitors which use a Geiger-Mueller tube as a sensing element. This test will verify proper operation of each check source, pumps, indicators, and control valves and verify that flow requirements to particulate monitors are met. This test will also verify that on a low monitor flow, loss of power, or a filter tape break, a malfunction alarm occurs for each respective monitor. Acceptance criteria will be that the monitors respond to check sources in accordance with calibration data, sample flow rates meet design requirements, all annunciators and alarms function properly, and the requirements given in FSAR section 12.1.4 are met.
TVA-32B	Area Radiation Monitoring System - Radiation Survey Monitors	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections have been completed in accordance with design and testing specifications. All components and equipment re-	This test will verify that the laboratory radioactivity counting equipment, laundry monitor, portal monitors, and local hand and foot monitors function in a manner which ensure accurate and reliable monitoring and personal safety. Response to the appropriate check source

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		quired to support operation and testing of radiation monitoring system have either been preoperationally tested or cleared under an IOR. Instrumentation, alarms, and counting instruments have been installed, tested, and calibrated.	signals will be verified and the proper initiation of the annunciation functions for high and low trips will be checked. Acceptance criteria will be that the monitors respond to check sources in accordance with calibration data and that system alarms function properly.
TVA-33	Environs Radiation Monitoring System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections have been completed. The PAX Telephone System and the Annunciator System have either been preoperationally tested or cleared under an IOR. Instrumentation and alarms have been installed, tested, and calibrated. Electrical power supplies have been energized.	This test will verify and document the capability of the local and perimeter environmental radiation monitors to perform their design function. Each unit will be tested individually to verify local and control room indication response. All alarms and high and low setpoints will be checked. Acceptance criteria will be that the radiation monitors respond to their check source in accordance with calibration data, and all annunciators, alarms, and recorders function per design.
TVA-34	Nitrogen Supply System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning activities have been completed. Instrumentation and alarms have been checked, tested, and calibrated. Electrical power and control air is available to all components requiring such. The system, including nitrogen bottles, manifold pressure regulators, and control valves is	This test will verify the operability of the Nitrogen System and its components. Capability of the high-pressure section of the system to supply nitrogen at 650 to 675 psig to the accumulators will be verified. The low-pressure section will be tested for automatic switching capability upon low pressure signals and the capability to supply nitrogen at 100 psig to served components will be demonstrated. All applicable alarms and setpoints will be verified.

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		operational.	Acceptance criteria will be that the requirements for the Nitrogen Supply System given in the FSAR section 9.5.9 have been satisfied.
TVA-35A	Powerhouse CO_2 Fire Protection System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning activities of all equipment associated with this system have been completed in accordance with design and testing specification. All systems required to support operation and testing of the powerhouse CO_2 fire protection system have either been preoperationally tested or cleared under an IOR. Instrumentation and alarms have been checked, tested, and calibrated. All pyrotonics fire detection components have been installed, tested, and loop checked by test representatives. Control, turbine and service building HVAC systems are in service. Electrical power supplies have been energized and all associated equipment is available for service.	This test will verify that for the CO_2 fire protection for powerhouse will supply adequate quantities and concentrations of carbon dioxide to essential areas which are designate Class I conditions. The applicable portions of the system will be tested throughout all design operational modes (i.e., automatic, manual, and electric operation). Testing will be conducted by actually releasing CO_2 into the specified hazard areas and measuring resulting concentrations. Proper operation of applicable alarms, timers, and associated controls will be verified. Acceptance criteria for the Powerhouse CO_2 Fire Protection System will be verification that the system requirements given in FSAR section 9.5.1 have been satisfied.
TVA-35B	Diesel Building CO_2 Fire Protection System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning activities for all equipment associated with this system have been completed in accordance with design and testing specifications. All systems required to support operation and testing of the CO_2 fire protection system have either been preoperationally tested or	This test will verify that the CO_2 fire protection system for the diesel generator building is capable of supplying adequate quantities and concentrations of CO_2 to essential areas. CO_2 will be released into each hazard area and the CO_2 concentrations will be verified. The applicable portions of the system will be tested throughout all design operational of applicable alarms, timers, and associated Acceptance criteria will be

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		cleared under an IOR. Instrumentation and alarms have been installed, tested, and calibrated. All pyrotonics fire detection components have been installed, tested, and loop checked by test representatives. Diesel generator building heating and ventilating systems are in service. Electrical power supplies have been energized and all associated equipment is available for service.	that the system requirements given in FSAR section 9.5.1 have been satisfied for the diesel generator building.
TVA-36	Emergency Lighting System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections have been completed. All systems required to support operation and testing of the Emergency Lighting System have either been preoperationally tested or cleared under an IOR. Electrical supplies have been energized and all associated equipment is available for service.	The test is to confirm that the emergency DC lighting system satisfies design requirements. Test will consist of interrupting the standby lighting sources and providing illumination solely from the emergency system. Footcandle level data will be taken at selected locations. Acceptance criteria will be that the emergency system immediately provides minimum illumination levels in area essential to safe shutdown of the plant when other lighting sources are unavailable. Also the requirements given in FSAR section 9.5.3 must be satisfied.
TVA-37	Hydrogen System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning activities have been completed. All systems required to support operation and testing of the Hydrogen System have either been preoperationally tested or cleared under an IOR.	Test objective is to verify the operability and safety of the system. The system capability to automatically isolate the system in case the a line break will be demonstrated. All control valves will be tested for proper pressure maintenance at served components. These valves will be verified to close on a sudden increase of pressure.

TABLE 14.1-1 (Sheet 81)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		Instrumentation and alarms have been installed, tested, and calibrated. Electrical power and control air is available to all components requiring such. Proper amounts of nitrogen are available onsite to facilitate testing.	Acceptance criteria for the Hydrogen System will be that the requirements given in FSAR section 9.5.8 have been satisfied. (Note that ventilation requirements for the volume control tank rooms are addressed in test TVA-9C.)
TVA-38	Main Feedwater System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing activities have been completed. Instrumentation and alarms have been installed, tested, and calibrated. Electrical power and control air are available to all components requiring such. The Main Feedwater System has been filled and vented so the feedwater isolation and bypass valves will not be cycled dry.	This test will demonstrate the engineered safety features as of the Main Feedwater System by verifying that the feedwater flow to all steam generators can be stopped within the time required for safe shutdown of the unit. Manual control of the safety-related feedwater valves and their response time of closure will be tested. Feedwater isolation upon receipt of a simulated hi-hi steam injection signal, or reactor trip along with a low T-average will be verified. A trip signal to the main feed pump turbines and hotwell pumps due to a simulated safety injection signal or high-high steam generator level signal will be verified. System performance will be deemed acceptable when the criteria given in FSAR section 10.4.7.1.3 have been satisfied.
TVA-40	Main Steam System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing activities of the main steam system piping and components have been completed. Instrumentation and annunciators have been	The test will demonstrate that main steam flow from all steam generators can be stopped within a specified time period by closure of all main steam isolation valves and main steam isolation bypass valves. The test will verify capability of valves to be tripped closed in response to simulated input signals denoting either high-high containment pressure or

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		installed, tested, and calibrated. Electrical power and control air is available to all components requiring such. The brush recorders for measuring the closure times of the MSIVs have been calibrated and are operational.	high steam line flow in coincidence with either low steam line pressure or low-low TAVG. The valves will be tripped closed by simulated signals from each power train to demonstrate main steam line isolation capability in the event of total loss of one power train. The partial closure feature of main steam isolation valves will also be demonstrated. Acceptance criteria for the main steam system will be met when the isolated timing requirements given in FSAR section 10.3.2.1 have been satisfied.
TVA-41	Containment Isolation System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections have been completed. Electrical power shall be available to all components and control air shall be available for air-operated isolation valves. This test will be performed before fuel loading. NOTE: Additional testing on certain containment isolation valves was performed during the unit 2 restart test program via STI-20 and -81.	The test verifies capability of the system to isolated the containment upon receipt of actuation signals generated by either the solid-state protection system or main control room switches. Specifically, the test includes the following: 1) Manual operation of each containment isolation valve using control room switches. The following will be verified: valve change of position, position light indication, and valve closing time. 2) Simulated output signals from the solid-state protection system will be used to actuate the containment isolation valves which function automatically in response to containment isolation phases A and B, and containment vent isolation signals.

TABLE 14.1-1 (Sheet 83)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
			3) Air-operated containment isolation valves will be demonstrated to change to proper "fail-safe" position upon loss of either control air or electrical power. Acceptance criteria for the test will be that the system satisfies design functional requirements specified in FSAR section 6.2.4.
TVA-42	Turbine and Generator Control and Protection System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Instrumentation and alarms have been installed, tested, and calibrated. All systems required to support operation and testing have either been preoperationally tested or cleared under an IOR. Raw cooling water is available to all heat exchangers. Electrical power and control air are available to all components requiring such. Turbine lube oil system and EH hydraulic fluid system have been completely installed, flushed, tested, and are available for operation. Normal turbine protective systems (hydraulic, mechanical, electrical, and electronic) have been installed, tested, and are ready for zero speed operation. Reactor protection system has been completed, tested, and is operational.	The test demonstrates that turbine protective systems are actuated both from reactor protection system inputs and from the various turbine protective trips. Applicable reactor protection system input signal (i.e., P-4 reactor trip signals, steam generator hi-hi level, and safety injection) will be simulated and proper functioning of the turbine protection system will be verified. The test will demonstrate that: 1) Tripping the control emergency trip fluid causes trip closure of all control and intercept valves and all non-return valves. 2) Tripping the stop emergency trip fluid causes tripping of all stop and reheat stop valves and also tripping of the control emergency trip fluid system. 3) Tripping of the auto stop oil causes tripping of both the control and stop emergency trip fluid systems. Verification that auto stop oil is tripped by various turbine hazard condition monitors and interface sensors will be demonstrated.

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
TVA-43A	Cranes and Heavy Equipment 175-Ton Polar Crane	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. The polar crane has been erected and inspected, and electrical power is available.	This test will demonstrate that the safety features of the 175-ton polar crane are functioning properly. Testing will verify: 1) The ability of each hoist brake to independently stop a rated load from full lowering speed within a distance of six inches. 2) The ability of the emergency dynamic hoist braking systems to control speed of a load with the electric brakes manually held open. 3) Proper operation of the geared hoist upper and lower travel limit switches. 4) Counterweight level limit switches limit upward travel of hoists. 5) Proper operation of hoist overspeed switches. 6) Proper operation of the warning horn. 7) Proper performance of hoists with a rated load. Acceptance criteria for this test shall be that the 175-ton polar crane performs in accordance with industry accepted testing specifications for cranes. 4) The overspeed protection control feature on the turbine speed/load control system functions properly. System acceptance criteria will be met when the requirements given in FSAR section 10.2.2

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
			for the turbine-generator control and protection system have been satisfied.
TVA-43B	Cranes and Heavy Equipment 125-Ton Auxiliary Building Crane	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. The auxiliary building crane has been erected and inspected and electrical power is available.	This test will demonstrate that the safety features of the 125-ton crane are functioning properly. Testing will demonstrate: 1) Proper functioning of each spent fuel pit stop limit switch while operating the crane on the east, west, and notrh sides of the spend fuel pit. 2) Proper operation of the movable, administratively controlled, trolley bumper stops. 3) Proper brake settings for all brakes on the crane. 4) The amount of trolley and bridge skewing. 5) Proper operation of the hoist overspeed switch. 6) The amount of trolley hook travel. Acceptance criteria for this test will be that the 125-ton auxiliary crane's movement can be restricted over the spent fuel pit satisfactorily and the crane performs in accordance with industry accepted testing specifications.
TVA-44	Liquid Waste Drains, Collection, and Transfer Facilities	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and	The test demonstrates that all drains are clear and capable of draining of the required rate. Each drain will be visually inspected and any trash or solid waste material removed. Any convenient source of clean

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		flushing activities have been completed. All systems required to support operation and testing of this system have either been preoperationally tested or cleared under an IOR. The auxiliary building and reactor building floor and equipment drain sumps must be capable of receiving and transferring drainage. All drain collector tanks must be capable of receiving liquid waste. Transfer pumps associated with these tanks should be operable. Instrumentation has been installed, tested, and calibrated. Control air, electrical power, and demineralized water are available to all components requiring such.	water will be used to deliver water to drains at specified rates. Drain flow rates will be measured and visually observed if possible. Set-points for sump level alarms and pump actuation will be checked by filling and draining the sumps. System performance will be deemed acceptable when the requirements given in section 11.2.5 of the FSAR have been satisfied.
TVA-45A	Station Drainage System (Turbine Building Station Sump)	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. All components and equipment required to support operation and testing of this system have either been preoperationally tested or cleared under an IOR. Instrumentation and the pump level alarm have been installed, tested, and calibrated. A source of raw water near the station pump will be available. Electrical power supplies have been energized.	This test demonstrates the ability of the sumps and associated pumps located in the turbine building to receive and adequately discharge the various non-radioactive waste liquids generated in this building. Automatic and manual operation of all pumps will be checked and all control and alarms will be tested for proper operation. Acceptance criteria for this system will be met when the operation of the pumps, valves, and alarms in all operational modes is in accordance with section 9.3.3 of the FSAR.
TVA-45B	Station Drainage System - Service Building	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installa-	This test will verify the capability of the sumps and associated sump pumps located in the control and service buildings to receive and

		tion inspections, integrity testing, and cleaning and flushing activities have been completed in accordance with design and testing specifications. All components and equipment required to support operation and testing of this system have either been preoperationally tested or cleared under an IOR. Instrumentation and alarms have been installed, tested and calibrated. A temporary source of raw water is available to the Service and Control Building sumps. Electrical power supplies have been energized and all associated equipment is available for service.	adequately discharge the nonradioactive liquid waste generated in these buildings. Verification of pump controller action and setpoints will be made as well as manual and automatic operation of the pumps. All controls and alarms will be checked for proper operation. Acceptance criteria for this test will be that the operation of the station drainage system to the sumps for the control and service buildings, is in accordance with design and testing specifications given given in section 9.3.3 of the FSAR.
TVA-46	Primary Makeup Water System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing activities have been completed. The Demineralized Water Distribution and Makeup Water Treatment Systems have either been preoperationally tested or cleared under an IOR. Instrumentation and alarms have been checked, tested, and calibrated. Control air and electrical power supplies are available to all components requiring such. Primary makeup water has been filled to normal operating level with makeup quality water.	This test demonstrates the capability of the system to supply makeup water to the required points in the reactor and auxiliary buildings. The test includes flow-rate measurements to demonstrate pump capabilities and adequacy of distribution piping, and checking of alarms and indicated PMWT levels. Acceptance criteria will be that the PMWS satisfies the requirements given in FSAR section 9.3.4.2.2.

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
TVA-49	Status Monitoring System	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections have been completed. Electrical power supplies have been energized.	This test will demonstrate the capability of the SMS to show available protection systems and to continuously monitor safety related plant equipment status. It will verify that the status of any system which has been bypassed or inadvertently made inoperable will be indicated to the operator by an indicating lamp and on a cathode ray tube, CRT display. Also demonstrated will be the capability to manually enter into the SMS the status of devices not automatically monitored. Proper CRT display and timing for devices having a grace time will be verified. Acceptance criteria for this test will be that the requirements given in FSAR section 7.1.4.2 have been satisfied.
TVA-50	Reactor Coolant Pressure Boundary (RCPB) Leakage Detection	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections, integrity testing, and cleaning and flushing of all associated equipment have been completed. Instrumentation and annunciators have been installed, tested, and calibrated. Electrical power is available to each leakage detection instrument, control panels M-10, M-5, and M-6, and other associated equipment as required.	This test will only check part of the RCPB leakage detection system: that part consisting of the humidity detectors located in the containment upper and lower compartments, and that part consisting of the reactor vessel flange leakoff valve and temperature detector. The capability of these detectors to alarm at an indication of RCPB leakage will be demonstrated. Acceptance criteria for the RCPB Leakage Detection System will be that the requirements given in FSAR section 5.2.7 have been satisfied.
TVA-51	Flood Protection Provisions	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installa-	This test will demonstrate the operational capability of, along with vibrational tests for, the Auxiliary Charging

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		tion and required installation inspections, integrity testing, and cleaning and flushing activities have been completed. Essential Raw Cooling Water is available to the Containment Cooling System and ice condenser coolers. Demineralized water is available to the auxiliary boration makeup tank. Electrical power supplies have been energized.	System. The portable diesel forebay makeup pumps flow capability will be verified. Also the spool piece connections of core cooling will be tested for ease of installation. Installation of temporary jumper cables will also be simulated. Acceptance criteria for this test will be that the requirements given in FSAR sections 9.3.6 and 2.4A.2.2 have been satisfied.
TVA-52	Seismic Instrumentation	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections for all seismic instrumentation have been completed. Instrumentation and annunciators have been installed, tested, and calibrated.	The seismic instrumentation is necessary to monitor the behavior of Category I structures, systems, and components should the plant experience a seismic event. This test shall ensure that the instrumentation is installed, calibrated, and functioning properly. Acceptance criteria for this test will be that the seismic instrumentation satisfies the design requirements given in FSAR section 3.7.4
TVA-53	Equipment for Replacement of Radwaste Filter Elements	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installation and required installation inspections and cleaning activities have been completed in accordance with design and testing specifications. Electrical power supplies have been energized. The filters necessary for testing of the handling equipment have either been preoperationally	This test shall demonstrate the adequacy of the equipment and instructions for replacement and safe handling of filter cartridges located in the auxiliary building. The equipment to be tested consists of special handling tools, hatch shield plate and tool plug, transfer cask, motorized dolly, drum casks, and the filter seals. The acceptance criteria will be that the handling tools,

TABLE 14.1-1 (Sheet 90)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		tested or cleared under an IOR and are in place in their housings.	equipment, and instructions are adequate safety margins for radiological protection of personnel during future filter handling operations.
TVA-54	Main Control Room Meteoro-logical Tower Data	The tentative transfer of all the affected equipment from CONST to P PROD has been completed. Installa-tion and required installa-tion inspections have been completed in accordance with design and testing specifi-cations. The Computer Demultiplexer for environ-mental monitoring has been functionally tested. Instrumentation has been installed, tested, and calibrated.	The Main Control Room Meteoro-logical Data System will be tested for its capability to perform its required functions. This test will demonstrate that certain meteorological param-eter collected at the onsite meteorological facility are continuously and accurately recorded in the main control room. This test encompasses functional testing of only that equipment required for trans-mitting certain meteorological data from the meteorological facility to the control room. These data are wind speed and direction at the 46- and 10- meter (m) levels and vertical temperature difference between the 46- and 10-m and the 91- and 10-m levels. Acceptance criteria for the Main Control Room Meteorolo-gical Data System will be that the requirements given in FSAR section 2.3.3 have been satisfied.
TVA-55	Vibration and Loose Paris Monitoring Systems	Electronics checkout must be made prior to hot functional testing but the signature profiles will be made during hot functional testing.	Verify the ability of the vib-ration and loose parts monitor-ing system to detect and record alarm conditions on any of the detection channels associated with major Reactor Coolant System components. Generate initial signature profiles on the reactor pressure vessel, steam generators, and reactor coolant pumps.

TABLE 14.1-1 (Sheet 91)

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
TVA-56	ESFAS Reset (Unit 1 Only)	Tentative transfer of all affected equipment from CONST to NUC PR has been completed. Installation and required inspection activities have been completed. All components and equipment required to support operation and testing have been preoperationally tested. Various plant conditions are required for testing the devices included in this test.	This test will verify the state of all devices that receive an Engineered Safety Features Actuation Signal (ESFAS) after the actuation signal is reset. Individual slave relays in the Solid State Protection System will be manually actuated to produce the ESFAS. Proper emergency states for the actuated equipment will then be verified, the ESFAS will be reset, and the equipment states will be checked again to verify the proper emergency position has been retained.
TVA-57	ERCW Pumping Station Heating and Ventilating System	Confirmation that construction activities are complete. Correct electrical power and connections to fans, dampers, heaters, and control circuits shall be assured. Proper lubrication of fans and motors shall be cleaned to remove all foreign debris that might cause damage to the system or the exhaust fans are its components. Controls shall be installed, tested, operational, and adjusted according to manufacturer's instructions. Data shall have been submitted to and approved by EN DES to include but not be limited to: A. Air flow rates in cfm for each portion of each system. B. Fan static pressure in inches of water for each system taken from near fan inlet and fan discharge. C. Operating data from each fan to include fan rpm, motor rpm, motor voltage, and motor current in amperes.	The test objective is to demonstrate the following capabilities: A. The supply and exhaust fans for the electrical and mechanical equipment rooms are controlled from a local control switch near each supply fan started from auxiliary contacts on the supply fan motor starter. B. Motor-operated dampers mounted in the air stream of each fan will automatically open or close when the fans are started or stopped. C. A multistage duct heater is installed in the discharge air stream of each equipment room supply fan. Each heater is controlled by a step controll operated from a thermostat sensing the unheated air temperature. D. The unit heaters located in the mechanical and electrical equipment rooms are properly controlled by built-in thermostats.

LIST OF PREOPERATIONAL TESTS

Test No.	Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		D. Dry bulb and wet bulb temperature for fresh air.	
TVA-66	Interim Controlled Hydrogen Ignition System (Unit 2 Only)	The tentative transfer of all affected equipment from CONST to NUC PR has been completed. Installation and required installation inspection activities have been completed. All components and equipment required to support operation and testing have been preoperationally tested or cleared under an IOP.	This test verifies that the system will provide ignition sources of a specified temperature. Each igniter is energized and the voltage and surfacer temperature of the igniter is recorded. The acceptance criteria for the igniters is: A. The AC voltage at the output of each igniter transformer, is no greater than 14 volts and no less than 12 volts. B. The temperature of each igniter is at least 1500°F

* All or portions of this pre-operational test are to be completed after fuel loading.

LIST OF STARTUP TESTS UNIT 1

Title of Test	Test Prerequisites	Summary of Testing and Acceptance Criteria
I. Core-Loading Program		
SU-6.2 Core-Loading Pre requisites	Hot functional test program completed. Plant being readied for core loading.	The objective of this instruction is to ensure the operability of equipment and systems necessary for a safe and expeditious core loading. Temporary neutron monitoring channels to be utilized during core loading will be checked and demonstrated to be operable.
SU-6.3 Reactor Systems Sampling Prior to and During Core Loading	Reactor vessel head removed and vessel water level is above the centerline of the outlet nozzles in preparation for core loading. Reactor cooling system and connected auxiliary systems have been borated to specified concentrations. The CVCS System, RHR System, Safety Injection System, and component cooling system are in service with RHR System circulating coolant through the vessel.	The test verifies correct and uniform boron concentration, prior to core loading, in all parts of the reactor coolant system and directly connected auxiliary systems and verifies equipment status and plant conditions during core loading to ensure that planned conditions are being maintained.
SU-6.1 Initial Core Loading	Nuclear instrumentation and communications required for core loading installed and verified operational. Reactor vessel is ready to receive fuel and required fuel handling tools are available for use. Startup test SU-6.2 has been completed and RHR System is in service. Equipment door and at least one door in each personnel airlock are closed. At least	The instruction establishes the conditions under which installation of the initial nuclear fuel charge is to be accomplished and specifies the sequence of events which constitutes the initial core-loading program. The instruction includes a core-loading sequence which specifies the loading in a step-by-step fashion with the appropriate precautions and prerequisites for each step listed.

TABLE 14.1-2 (Sheet 2)

LIST OF STARTUP TESTS UNIT 1

	one flow path for emergency boration is available. All required preloading tests have been completed and the requirements of SU-6.3 have been satisfied.	
II. Precritical Testing (Tests to be completed after Core Loading)		
Preoperational Tests:		
Pressurizer Spray and Heater Capability and Continuous Spray Flow Setting	See Table 14.1-1	
Reactor Coolant System Flow Measurement	See Table 14.1-1	
Reactor Coolant Flow Coastdown	See Table 14.1-1	
Resistance Temperature Detector Bypass Loop Flow Verification	See Table 14.1-1	
Rod Drive Mechanism Timing	See Table 14.1-1	
Rod Control System	See Table 14.1-1	
Rod Drop Time Measurements	See Table 14.1-1	
Rod Position Indication System	See Table 14.1-1	
Incore Movable Detectors	See Table 14.1-1	
Adjustment to Reactor and Turbine Control Systems	See Table 14.1-1	
STARTUP TESTS		

TABLE 14.1-2 (Sheet 3)

LIST OF STARTUP TESTS UNIT 1

Title of Test	Test Prerequisites	Summary of Testing and Acceptance Criteria
SU-1.0 Plant Measurements-Operational and Baseline Data	Reactor Core loaded in preparation for startup testing	The test implements a program of gathering and analyzing baseline and operational data. Radiation surveys are performed at various steps during the power escalation to determine radiation dose-levels at preselected locations throughout the plant to evaluate the adequacy of plant shielding. A chemical and radio- chemical program of sampling and analysis will be implemented coincident with core loading. Specified analyses will be performed at major steps of the startup program to gather baseline chemical/radio- chemical data and to demonstrate that plant water chemistry requirements can be maintained. Coincident with initial criticality an, effluent monitoring and analysis program will be implemented to ensure that plant effluents potentially containing radioactive materials are monitored and the effluent monitors are calibrated and operational.
III. Initial Criticality and Low Power Testing		
SU-7.1 NSSS Startup Sequence	Installation of nuclear steam supply system, all components of turbine steam system, and supporting control and auxiliary systems is complete. All pre-operational testing except as outlined in this sequence shall have been successfully completed or specifically waived for this sequence of tests. Reactor Coolant System at ambient temperature and borated to required concentration. Adequate makeup water available for extensive dilution. Concentrated boric acid	This instruction prescribes the sequence of operations constituting the plant startup testing program. The sequence of operations is presented in tabular form as the NSSS Startup Sequence, in which detailed instructions, specific plant conditions, and test procedures are included.

TABLE 14.1-2 (Sheet 4)

LIST OF STARTUP TESTS UNIT 1

Title of Test	Test Prerequisites	Summary of Testing and Acceptance Criteria
	available in sufficient quantity for extensive boration. All special test equipment required for this testing sequence is available and operational.	
SU-7.2 Initial Criticality	Plant at hot shutdown with at least 2000 ppm boron in the RCS. The source and intermediate range nuclear instrumentation channels are operational with 3 of 4 power range channels in operation.	The objective is to bring the reactor critical for the first time from the plant conditions specified. All rods are withdrawn except the last controlling group, which is left partially inserted for control once criticality is achieved by boron dilution. At preselected points in rod withdrawal and boron dilution, data is taken and inverse count rate plots made to enable extrapolating to the expected critical point. When the inverse count rate ratio reaches a preselected value, dilution is stopped and the system allowed to mix. If criticality is not achieved during mixing, bank D control rods are withdrawn until criticality is achieved.
SU-7.3 Nuclear Design Check Tests	Plant at zero power. These tests are run as part of the zero power physics test program. The RCC control selector switch is on bank control. The temperature is 547 + 0, -5°F and pressure is 2235 $\pm$ 50 psig.	The test establishes the boron concentration endpoint with various rod configurations, determines the isothermal temperature coefficient of reactivity, and determines the neutron flux distribution at various rod distributions. The boron endpoints are measured by determining the boron concentration of the coolant system with the rods partially inserted. The rod is then quickly pulled and reinserted with no boron adjustment. The change in reactivity is measured and the end- point calculated. The isothermal moderator temperature coefficient is determined by heating the coolant system at a constant rate

TABLE 14.1-2 (Sheet 5)

LIST OF STARTUP TESTS UNIT 1

Title of Test	Test Prerequisites	Summary of Testing and Acceptance Criteria
		and then cooling down at a constant rate. The total temperature swing is about 5°F. The temperature versus reactivity is plotted and the slope of the lines generated is the isothermal moderator temperature coefficient. The neutron flux distribution is determined by inserting miniature flux detectors into core locations with the flux indicated on strip chart recorders.
*SU-7.4 Rod and Boron Worth Measurements During Boron Dilution *SU-7.5 Rod and Boron Worth Measurements During Boron Addition	Reactor just critical at zero power. Rod banks positioned as specified in startup sequence (SU-7.1). RCC control on bank control. Reactor coolant system pressure at 2235 ± 50 psig; coolant system temperature at 547 ± 5°. Flux signal from one power range detector connected to reactivity computer.	The test determines the differential and integral worth of the RCC banks, and determines the differential boron worth over the range of the RCC banks. The nuclear design predictions for Rod Cluster Control Assembly (RCCA) group differential worths are validated. Rods are inserted or with drawn as boron is constantly added or diluted. The worth of the rods is compensated for by boron. Rod movement will cause step changes in reactivity which are measured on a reactivity computer. Differential boron worth measurements are made by increasing or decreasing reactor coolant boron concentration. Compensation for reactivity effect of boron concentration change will be made by withdrawing or inserting, respective control rods to maintain moderator average temperature and power level constant and observing the result-and accumulated change in core reactivity corresponding to these successive rod movements. Both of these measurements are done simultaneously.
SU-7.6 Rod Cluster Con-	Reactor just critical at zero	The test determines the worth of the

TABLE 14.1-2 (Sheet 6)

LIST OF STARTUP TESTS UNIT 1

Title of Test	Test Prerequisites	Summary of Testing and Acceptance Criteria
trol Assembly (RCCA) Pseudo Ejection at Zero Power	power. Rod banks positioned as specified in startup sequence (SU-7.1). RCC control on bank control Reactor coolant system pressure at 2235 ± 50 psig; coolant system temperature at 547 ± 5°. Flux signal from one power range channel connected to reactivity signal.	most reactive RCC unit ejected from the fully inserted RCC banks, with the RCC configuration which occurs at zero power; determines the just critical boron concentration with the most reactive rod fully withdrawn; and determines the neutron flux distribution at essentially zero power with the most reactive rod fully withdrawn. A reference flux map is taken with the most reactive rod in bank. The lift coils of all rods in the bank, except the most reactive one, are then disconnected. The rod is then slowly withdrawn compensating for the reactivity added with boron. The worth of the rod, the boron end- point, and the flux maps are taken with the rod in the ejected position as in startup tests SU-7.3, SU-7.4, and SU-7.5.
SU-7.7 Minimum Shutdown Verification and Stuck Rod Worth Measurement	Reactor just critical at zero power. All control banks are fully inserted and all shutdown banks and the part-length bank are fully withdrawn. Reactor coolant system pressure at 2235 ± 50 psig; coolant system temperature at 547 ± 5°F. RCC control on bank control. Flux signal from one power range channel connected to the reactivity computer.	The test verifies the minimum shutdown boron concentration with the most reactive RCC unit fully withdrawn and all other full length RCC units fully inserted. All rod banks are inserted into the core while boron is being diluted until shutdown bank A is just a few steps withdrawn and the most reactive RCCA is fully withdrawn. The boron is allowed to mix thoroughly and the boron concentration end point is determined. The plant is brought back to zero power with all shutdown banks withdrawn and all control banks inserted.

TABLE 14.1-2 (Sheet 7)

LIST OF STARTUP TESTS UNIT 1

Title of Test	Test Prerequisites	Summary of Testing and Acceptance Criteria
SU-1.0 Plant Measurements- Operational and Baseline Data.	Reactor core loaded in preparation for startup testing.	The test implements a program of gathering and analyzing baseline and operational data. Radiation surveys are performed at various steps du ing the power escalation to determine radiation dose-levels at preselected locations throughout the plant to evaluate the adequacy of plant shielding. A chemical and radio- chemical program of sampling and analysis will be implemented coincident with core loading. Specified analyses will be performed at major steps of the startup program to gather baseline chemical/radiochemical data and to demonstrate that plant water chemistry requirements can be maintained. Coincident with initial criticality, and effluent monitoring and analysis program will be implemented to ensure that plant effluents potentially containing radioactive materials are monitored and the effluent monitors are calibrated and operational.
SU-8.1 Power Coefficient and Integral Power Defect Measurements During Power Level Increase.	Plant at power level specified by startup sequence (SU-7.1). RCC banks positioned as required by starting sequence. RCC selector on manual control. Reactivity computer input flux signal is sum of power range channels through isolation amplifier.	The test measures the differential power coefficient of reactivity and measures the integral power defect. The generator electrical load is decreased and increased at a rate of approximately one-percent power is adjusted to match the gen- erator load by moving the controlling RCC banks. These movements are recorded on the reactivity computer. The total reactivity added divided by power increase is the differential power coefficient of reactivity.
SU-8.2 RCCA Pseudo Ejection and RCCA Above Bank Position Measurements	Reactor at stable power level as specified in startup sequence (SU-7.1). RCC bank configurations	The test determines the neutron flux distribution and temperature distribution with an RCCA unit above bank; demonstrates

TABLE 14.1-2 (Sheet 8)

LIST OF STARTUP TESTS UNIT 1

Title of Test	Test Prerequisites	Summary of Testing and Acceptance Criteria
	as required by startup sequence. Equilibrium xenon established prior to initiation of test. RCC selector on bank control.	the excore instrumentation response to an RCCA unit above bank, and determines the neutron flux distribution and temperature distribution when an RCCA unit has been "ejected" from the controlling RCC configuration. With the plant at the power level specified in the startup sequence, a reference flux map is taken with the rods in a normal configuration. A selected RCCA is moved out of the core by disconnecting the lift coils on the banks and lifting the one rod which has not been disconnected. Thermocouple maps, excore detector currents, flux maps, boron data, and calorimetric data are taken with the rod out of bank. The core is then returned to initial conditions.
SU-8.3 Static RCCA Drop and RCCA Below Bank Position Measurements	Reactor at stable power level as specified in startup sequence (SU-7.1). RCC bank configuration as required by startup sequence. Equilibrium xenon established prior to initiation of test. RCC selector on bank control.	The test obtains thermocouple maps partial moveable detector (M/D) maps, and excore detector response with an RCCA below bank position Thermocouple maps, partial M/D maps, and excore detector response for the dropped rod configuration are also obtained. The test is performed in a similar fashion to the rod above bank position measurement (SU-8.2) except the RCCA is diluted into the core instead of withdrawal by boration.
SU-8.4 Incore - Exore Detector Calibration	Plant is stable at power level specified in startup sequence (SU-7.1). RCC selector is on manual control Controlling RCC bank positioned as required by startup sequence.	The test determines a relationship between incore and excore generated axial offsets and I. Moveable detector maps, excore detector currents, thermocouple maps, and Calorimetric data are taken with the reactor having an axial power imbalance ranging from zero to large negative and positive values. The axial offsets are accomplished by a xenon oscillation initiated by bank D. From the

TABLE 14.1-2 (Sheet 9)

LIST OF STARTUP TESTS UNIT 1

Title of Test	Test Prerequisites	Summary of Testing and Acceptance Criteria
		data taken, the relationship between the excore and incore detectors is determined and the offset
and circuits are calibrated.		
SU-8.5 Nuclear and Temperature Instrumentation Calibration and Thermal Power Measurement	The Nuclear Instrumentation System is aligned for 100 percent power. Sensor for measuring feedwater temperature to each steam generator shall be installed, independent of the signals to the computer. The plant will be at various power levels.	The objectives of this test are to obtain data for: 1) Determining nuclear instrumentation channel overlap; 2) Verifying linearity and uniform detector outputs under flat power conditions; 3) Determining operational settings of instrument compensating voltages and test current values; 4) Setting power and intermediate range detector voltages; 5) Calculating thermal power in order to set power range channels; 6) Aligning WT and WT average instrumentation; 7) Setting overtemperature and overpower WT instrument trip points; 8) Verifying calibration of RTD's under isothermal conditions and determining installation corrections for each RTD for use in calibrating process instrumentation. The detector trip setpoints are initially set at conservative values.

TABLE 14.1-2 (Sheet 10)

LIST OF STARTUP TESTS UNIT 1

Title of Test	Test Prerequisites	Summary of Testing and Acceptance Criteria
		After initial criticality and during escalation into the intermediate and power ranges, detector currents are taken to verify overlap between the source, intermediate, and power range channels. This data is collected until the overlaps are firmly established. During low power escalation, the power range detector currents are monitored and compared with the intermediate range currents to verify response of the power range detectors. The power range channels will be calibrated based on a calorimetric measurement across the steam generator. The power delivered by each steam generator will be determined by measurement of feed-water flow, feedwater temperature, and steam pressure. WT and WT setpoints are established by comparing WT incore with the RTD readings at isothermal conditions. The WT instrumentation is set at 0.0°F in this case.
SU-9.1 Load Swing Tests	The following systems have been checked and placed in automatic control: 1) Reactor rod control 2) Steam generator level control 3) Pressurizer pressure control 4) Pressurizer level control 5) Steam dump control (T average mode) All control rods positioned as specified in the startup sequence (SU-7.1). Plant must be	The objective of this test is to verify the nuclear plant transient response, including automatic control systems performance, when step-load changes are introduced at the turbine generator. Step-load changes will be initiated from steady-state conditions at approximately 30-percent, 75-percent, and 100-percent power. The plant is at steady-state conditions and the turbine governor valves are rapidly repositioned for a 10-percent load decrease. Plant parameters are monitored on high-speed strip chart recorders. A new equilibrium condition is reached and the load is increased back to the

TABLE 14.1-2 (Sheet 11)

LIST OF STARTUP TESTS UNIT 1

Title of Test	Test Prerequisites	Summary of Testing and Acceptance Criteria
	able to deliver 30 percent, 75 percent, or 100 percent of rated capacity as required.	original condition.
		The recordings are analyzed for control systems behavior, and requirements for realignment.
SU-9.3 Large Load Reduction Tests	The following systems have been checked and placed in automatic control: 1) Reactor Rod Control System 2) Pressurizer Level Control System 3) Pressurizer Pressure Control System 4) Steam Generator Level Control System 5) Steam Pump Control System (T average control mode)	The objectives of this test are: 1) To verify the ability of the primary and secondary plant and the Automatic Reactor Control Systems to sustain a 50-percent step-load reduction from 75-percent and 100-percent of full power 2) To evaluate the interaction between the control systems 3) To evaluate test data to determine if possible setpoint changes are required in the control systems in order to improve transient response.
SU-9.3 Large Load Reduction Tests	The plant is in steady-state condition at the required power level with controlling bank positioned as required by SU-7.1.	These tests are performed to determine mine if the reactor or turbine will trip and to verify that safety valves do not lift, turbine speed responds normally, and the steam dump system functions correctly. The turbine governor valves are repositioned for a 50-percent load change. Plant parameters are recorded on a high- speed strip chart recorder.
SU-9.4 Plant Trip From 100 Percent Power	Plant is a 100 percent power with control bank D positioned as required by SU-7.1. The following	This test is performed in two parts with each part being a separate test. Part A

TABLE 14.1-2 (Sheet 12)

LIST OF STARTUP TESTS UNIT 1

Title of Test	Test Prerequisites	Summary of Testing and Acceptance Criteria
	systems are functioning properly and have been placed in automatic control: 1) Rod Control System; 2) Steam Generator Level Control System; 3) Pressurizer Pressure Control System; 4) Pressurizer Level Control System; 5) Steam Dump Control System (T average control mode).	The objectives of this test are: 1) To verify capability of the primary and secondary plant to sustain a trip from 100 percent power and to bring the plant to stable conditions following the transient; 2) To determine the overall response time of the reactor coolant hot leg RTD's; and 3) To evaluate the data resulting from this test to determine possible changes in control system setpoints in order to improve transient response. The plant is tripped from a steady-state, 100-percent power level by manually tripping the turbine. The following criteria will be used to determine successful test completion. 1) Pressurizer and steam generator safety valves do not lift; 2) Safety injection is not initiated and turbine trips; 3) The overall RTD response time does not exceed a specified time; 4) Nuclear Flux drops to 15 percent within 2.5 seconds after turbine trip 5) All full-length RCCA's release and drop. Part B 1) To verify the ability of the automatic control and protection systems to sustain a net electrical load loss without exceeding turbine design overspeed; 2) To evaluate the data resulting from this test to determine

TABLE 14.1-2 (Sheet 13)

LIST OF STARTUP TESTS UNIT 1

Title of Test	Test Prerequisites	Summary of Testing and Acceptance Criteria
		possible changes in control system setpoints in order to improve transient responses. The main generator breakers are opened with the plant at 100 percent steady state power. The following criteria will be used to determine successful completion of the test. 1) The turbine will not exceed the manufacturer's design overspeed. 2) Safety injection is not initiated.
SU-9.5 Rod Group Drop and Plant Trip	The plant shall be operating at a steady-state level of 50 percent.	This test is to confirm that the negative rate trip circuit will trip the reactor as a result of dropping two rods in a group that is most difficult to detect by the power range detectors. Also, to obtain preliminary data for systems response to plant trip before performing the turbine trip and reactor trip from 100 percent.
SU-1.0 Plant Measurements Operational and Baseline Data	See test description under Phase II testing.	
SU-1.1 Loss of Offsite Power	Power level greater than or equal to 10% rated generator output. The following are ready for emergency start: 1) Emergency diesel generators 2) Auxiliary feedwater pumps The reactor protection and safeguards systems are fully operational.	This test demonstrates the ability of the reactor systems, the reactor control and protection systems, the auxiliary feedwater pumps and the emergency power system to sustain a loss of turbine generator coincident with loss of offsite power and to place the plant in a safe shutdown condition. The offsite power circuits to the primary systems are interrupted, the turbine and reactor are tripped and the auxiliary feedpumps and diesel generators start. Acceptance criteria are: 1) The diesel generators shall start and accept the emergency power system load.

TABLE 14.1-2 (Sheet 14)

LIST OF STARTUP TESTS UNIT 1

Title of Test	Test Prerequisites	Summary of Testing and Acceptance Criteria
		2) Reactor trip and turbine trip shall occur. 3) Auxiliary feedwater pump start.
SU-1.2A Shutdown From Outside the Control Room	Power level shall be greater than or equal to 10% rated generator output Emergency start: 1) Emergency diesel generators 2) Auxiliary feedwater pumps Power level shall be greater than or equal to 10% rated generator output The reactor protection and safe guards systems are fully operational.	This test verifies that following a reactor trip the unit can be maintained in the hot standby condition. The reactor auxiliary feedwater pumps and the emergency power system to sustain a loss of turbine generator coincident with loss of offsite power and to place the plant in a safe shutdown condition. The offsite power circuits to the primary systems are interrupted, the turbine and reactor are tripped and the auxiliary feedpumps and diesel generators start. Acceptance criteria are: 1) The diesel generators shall start and accept the emergency power system load. 2) Reactor trip and turbine trip shall occur. 3) Auxiliary feedwater pump start. This test verifies that following a reactor trip the unit can be maintained in the hot standby condition. The reactor and turbine are tripped from outside the main control room. Other necessary operator action to safely shutdown and maintain the plant are done from the auxiliary control room or from local control points. The acceptance criteria from this test is successful shutdown of the plant from outside the control room by the normal complement.

TABLE 14.1-2 (Sheet 15)

LIST OF STARTUP TESTS UNIT 1

Title of Test	Test Prerequisites	Summary of Testing and Acceptance Criteria
SU-1.2B Cooldown from Outside the Control Room	Plant in Mode 3 at 547°F. Unit control is from the main control room with the unit in a stable condition. This prerequisite may be disregarded if this test is to follow immediately after performing SU-1.2A.	This test shall verify that the unit can be cooled down through Mode 3 and 50°F into Mode 4 from outside the main control room. The demonstration of remote cooldown need not be performed in conjunction with the remote shutdown demonstration. It will be performed when most convenient situation arises.
SU-10.1 NSSS Acceptance Test	The plant is at 100-percent power. All preoperational tests have been completed. All startup physics testing is complete.	The NSSS is operated for 300 continuous hours at rated thermal output to verify that the plant is acceptable. Operation of plant systems and components are verified and monitored during this time period.
SU-10.2 Steam Generator Moisture Carryover Measurement	The Power level is at 100% of full power.	The test objective is to determine the moisture carryover performance of the steam generators. This measurement is obtained by using Sodium-24 as the source. The acceptance criteria is that the moisture carryover measured be less than or equal to the warranted value of .25% by weight.
*Automatic Steam Generator Level Control	See Table 14.1-1	
*Dynamic Automatic Steam Dump Control	See Table 14.1-1	
*Calibration of Steam and Feed water Flow Instrumentation at Power	See Table 14.1-1	

*Preoperational tests completed during startup test program.

The test implements a program of gathering and analyzing baseline and operational data. Radiation surveys are performed at various steps during the power escalation to determine radiation dose-levels at preselected locations throughout the plant to evaluate the adequacy of plant shielding. A chemical and radiochemical program of sampling and analysis will be implemented coincident with core loading. Specified analyses will be performed at major steps of the startup program to gather baseline chemical/radiochemical data and to demonstrate that plant water chemistry requirements can be maintained. Coincident with initial criticality, and effluent monitoring and analysis program will be implemented to ensure that plant effluents potentially containing radioactive materials are monitored and the effluent monitors are calibrated and operational.
IV. Power Level Escalation Testing		

TABLE 14.1-3 (Sheet 8)

LIST OF STARTUP TESTS UNIT 2

Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
SU-8.1 Power Coefficient and Integral Power Defect Measurements During Power Level Increase (cont'd.)	Plant at power level specified by startup sequence (SU-7.1). RCC banks positioned as required by starting sequence. RCC selector on manual control. Reactivity computer input flux signal is sum of power range channels through isolation amplifier. erator load by moving the controlling RCC banks. These movements are recorded on the reactivity computer. The total reactivity added divided by power increase is the eifferential power coefficient of reactivity.	The test measures the differential power coefficient of reactivity and measures the integral power defect. The generator electrical load is decreased and increased at a rate of approximately one-percent per minute. The reactor power is adjusted to match the gen-
SU-8.3 Static RCCA Drop and RCCA Below Bank Position Measurements	Reactor at stable power level as specified in startup sequence (SU-7.1). RCC bank configuration as required by startup sequence. Equilibrium xenon established prior to initiation of test. RCC selector on bank control.	The test obtains thermocouple maps partial moveable detector (M/D) maps, and excore detector response with an RCCA below bank position Thermocouple maps, partial M/D maps, and excore detector response forthe dropped rod configuration are also obtained. With the plant at the power level specified in the startup sequence, a reference flux map is taken with the rods in a normal configuration. A selected RCCA is moved into the core by disconnecting the lift coils on the bank and inserting the one rod which has not been disconnected. During the rod insertion, a reactor coolant boron dilution is used to compensate for temperature changes.
SU-8.4 Incore - Exore Dectector Calibration	Plant is stable at power level specified in startup sequence (SU-7.1). RCC selector is on manual control Controlling RCC bank	The test determines a relationship between incore and excore generated axial offsets and I. Moveable detector maps, excore detector cur-

TABLE 14.1-3 (Sheet 9)

LIST OF STARTUP TESTS UNIT 2

Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
	positioned as required by startup sequence.	rents, thermocouple maps, and Calorimetric data are taken with the reactor having an axial power imbalance ranging from zero to large negative and positive values. The axial off- sets are accomplished by a xenon oscillation initiated by bank D. From the data taken, the relationship between the excore and incore detectors is determined and the offset and I circuits are calibrated.
SU-8.5 Nuclear and Temperature Instrumentation Calibration and Thermal Power Measurement	The Nuclear Instrumentation System is aligned for 100 percent power. Sensor for measuring feedwater temperature to each steam generator shall be installed, independent of the signals to the computer. The plant will be at various power levels.	The objectives of this test are to obtain data for: 1) Determining nuclear instrumentation channel overlap; 2) Verifying linearity and uniform detector outputs under flat power conditions; 3) Determining operational settings of instrument compensating voltages and test current values; 4) Setting power and intermediate range detector voltages; 5) Calculating thermal power in order to set power range channels; 6) Aligning WT and WT average instrumentation; 7) Setting overtemperature and overpower WT instrument trip points; 8) Verifying calibration of RTD's under isothermal conditions and determining installation corrections for each RTD for use in calibrating process instrumentation.

TABLE 14.1-3 (Sheet 10)

LIST OF STARTUP TESTS UNIT 2

Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		The detector trip setpoints are initially set at conservative values. After initial criticality and during escalation into the intermediate and power ranges, detector currents are taken to verify overlap between the source, intermediate, and power range channels. This data is collected until the overlaps are firmly established. During low power escalation, the power range detector currents are monitored and compared with the intermediate range currents to verify response of the power range detectors. The power range channels will be calibrated based on a calorimetric measurement across the steam generator. The power delivered by each steam generator will be determined by measurement of feed-water flow, feedwater temperature, and steam pressure. WT and WT setpoints are established by comparing WT incore with the RTD readings at isothermal conditions. The WT instrumentation is set at 0.0°F in this case.
SU-9.1 Load Swing Tests	The following systems have been checked and placed in automatic control: 1) Reactor rod control 2) Steam generator level control 3) Pressurizer pressure control 4) Pressurizer level control 5) Steam dump control (T average mode)	The objective of this test is to verify the nuclear plant transient response, including automatic control systems performance, when step-load changes are introduced at the turbine generator. Step-load changes will be initiated from steady-state conditions at approximately 30-percent, 75-percent, and 100-percent power. The plant is at steady-state conditions and the turbine governor valves are rapidly repositioned for a 10-percent load decrease. Plant

Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
	All control rods positioned as specified in the startup sequence (SU-7.1). Plant must be able to deliver 30 percent, 75 percent, or 100 percent of rated capacity as required.	parameters are monitored on high-speed strip chart recorders. A new equilibrium condition is reached and the load is increased back to the original condition. The recordings are analyzed for control systems behavior, and requirements for realignment.
SU-9.3 Large Load Reducino Tests	The following systems have been checked and placed in automatic control: 1) Reactor Rod Control System 2) Pressurizer Level Control System 3) Pressurizer Pressure Control System 4) Steam Generator Level Control System 5) Steam Pump Control System (T average control mode) The plant is in steady-state condition at the required power level with controlling bank positioned as required by SU-7.1.	The objectives of this test are: 1) To verify the ability of the primary and secondary plant and the Automatic Reactor Control Systems to sustain a 50-percent step-load reduction from 75-percent and 100-percent of full power 2) To evaluate the interaction between the control systems 3) To evaluate test data to determine if possible setpoint changes are required in the control systems in order to improve transient response. These tests are performed to determine if the reactor or turbine will trip and to verify that safety valves do not lift, turbine speed responds normally, and the steam dump system functions correctly. The turbine governor valves are repositioned for a 50-percent load change. Plant

TABLE 14.1-3 (Sheet 12)

LIST OF STARTUP TESTS UNIT 2

Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		parameters are recorded on a high-speed strip chart recorder.
SU-9.4 Plant Trip From 100 Percent Power	Plant is a 100 percent power with control bank D positioned as required by SU-7.1. The following systems are functioning properly and have been placed in automatic control: 1) Rod Control System; 2) Steam Generator level Control System; 3) Pressurizer Pressure Control System; 4) Pressurizer Level Control System; 5) Steam Dump Control System (T average control mode).	The objectives of this test are: 1) To verify capability of the primary snd secondary plant to substain a trip from 100 percent power and to bring the plant to stable conditions following the transient; 2) To determine the overall response time of the reactor coolant hot leg RTD's; and 3) To evaluate the data resulting from this test to determine possible changes in control system setpoints in order to improve transient response. The plant is tripped from a steady-state, 100-percent power level by manually tripping the turbine. The following criteria will be used to determine successful test completion. 1) Pressurizer and SG safety valves do not lift; 2) Safety injection is not initiated and turbine trips; 3) The overall RTD response time does not exceed a specified time; 4) Nuclear Flux drops to 15 percent within 2.5 seconds after turbine trip 5) All full-length RCCA's release and drop.
SU-1.0 Plant Measurements Operational and	See test description under Phase II testing.

Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
Baseline Data		
SU-1.2A Shutdown From Outside the Control Room	Power level shall be greater than or equal to 10% rated generator output Emergency start: 1) Emergency diesel generators 2) Auxiliary feedwater pumps The reactor protection and safeguards systems are fully operational.	This test verifies that following a reactor trip the unit can be maintained in the hot standby condition. The reactor auxiliary feedwater pumps and the emergency power system to sustain a loss of turbine generator coincident with loss of offsite power and to place the plant in a safe shutdown condition. The offsite power circuits to the primary systems are interrupted, the turbine and reactor are tripped and the auxiliary feedpumps and diesel generators start. Acceptance criteria are: 1) The diesel generators shall start and accept the emergency power system load. 2) Reactor trip and turbine trip shall occur. 3) Auxiliary feedwater pump start.
SU-1.2A Shutdown From Outside the Control Room	Power level shall be greater than or equal to 10% rated generator output	This test verifies that following a reactor trip the unit can be maintained in the hot standby condition. The reactor and turbine are tripped from outside the main control room. Other necessary operator action to safely shutdown and maintain the plant are done from the auxiliary control room or from local control points.

TABLE 14.1-3 (Sheet 14)

LIST OF STARTUP TESTS UNIT 2

Title of Test	Test Prerequisites	Test Objectives Summary of Testing and Acceptance Criteria
		The acceptance criteria from this test is successful shutdown of the plant from outside the control room by the normal complement.
SU-10.1 NSSS Acceptance Test	The plant is at 100-percent power. All preoperational tests have been completed. All startup physics testing is complete.	The NSSS is operated for 300 continuous hours at rated thermal output to verify that the plant is acceptable. Operation of plant systems and components are verified and monitored during this time period.
SU-10.2 Steam Generator Moisture Carryover Measurement	The Power level per SU 7.1.	The test objective is to determine the moisture carryover performance of the steam generators. This measurement is obtained by using Sodium-24 as the source. The acceptance criteria is that the moisture carryover measured be less than or equal to the warranted value of 0.25% by weight.

FIGURE 14.1-4 STARTUP TEST SEQUENCE - UNIT 2

14.2 AUGMENTATION OF PLANT STAFF FOR INITIAL TESTS AND OPERATIONS (HISTORICAL)

Manpower requirements during the planning, coordination, and conduct of the initial test program necessitate that the normal operating staff be provided with technical assistance and, in some instances, direct augmentation from other organizations both within and outside of TVA. The distinction between assistance and augmentation is made so as to clearly note those instances where supplemental personnel are assigned to full-time duties with the plant staff in the implementation and conduct of the test program.

Members of the plant staff with key responsibilities for the initial testing program are identified in Paragraphs 14.1.1.1 and 14.1.1.2.

14.2.1 Organizational Functions, Responsibilities, and Authorities

The organizational functions of the various organizations and special groups involved in the preoperational and startup test programs are briefly discussed in Section 14.1 with regard to authorities and responsibilities for the preparation and review of detailed test instructions, the conduct of tests, and the review of test results. These organizational functions are classified as either "assistance" wherein the applicable organization acts as a technical consultant and provides test program review services to the plant staff or as "augmentation" wherein the applicable organization provides full-time personnel on a temporary basis to supplement the plant staff during the testing program.

14.2.1.1 Augmenting Organizations

Division of Nuclear Power (NUC PR) Preoperational Test Section

The NUC PR preoperational test section consists of system oriented engineers functioning under the direction of the section supervisor who acts as the preoperational test program coordinator. As discussed in Section 14.1, individual engineers within this group are designated as the "test director" for specific preoperational tests. As test directors, they are responsible for preparation of detailed test instructions, directing the conduct of the test, evaluation of test results, and final documentation for all tests so assigned. This group devotes its full-time activities to the preoperational test program.

Since certain portions of the preoperational test program cannot be completed until after fuel loading, the "test directors" are also considered as augmenting personnel during the startup test program. Additionally, certain members of the test group will have completed those preoperational tests for which they are responsible prior to the initial core loading and will be utilized during the startup test program as dictated by manpower requirements.

Reactor Engineering, Mechanical, and Electrical and Instrument and Controls Branches

Within the Division of Nuclear Power, the Reactor Engineering, Mechanical, and Electrical and Instrument and Controls Branch provides a variety of engineering services to generating plants. During nuclear plant startup, these services include providing test engineers technical guidance during testing and assistance in the analysis of test results as required.

These branches include the NSSS Engineering and Analysis Group, the Chemical Group, the Instrument and Controls Equipment Group, the Performance and Test Group, and a Reactor

Analyses Group. During startup testing and initial plant operation, personnel from these sections are assigned on a full or part-time basis to augment the normal plant operating staff. While so assigned, these personnel function under the supervision of the plant results supervisor as described in Subsection 14.1.1 and are responsible for the preparation of detailed startup test instructions, technical direction during conduct of the tests, and evaluation and final documentation of test results.

14.2.1.2 Assisting Organizations

Functional assistance in lieu of full-time assignment of personnel is provided by the following organizations:

Division of Construction (CONST)

The Division of Construction is responsible for completion of installation of plant systems and provides assistance to NUC PR during the preoperational and startup test programs. CONST also augments the plant staff by providing the necessary craft manpower for mechanical and electrical maintenance activities after systems have been accepted by NUC PR for testing and operation. CONST personnel assigned such duties will function under the technical direction of the plant maintenance supervisor.

Division of Engineering Design (EN DES)

The Division of Engineering Design is responsible for providing scoping documents describing the preoperational testing required for all systems within the TVA scope of supply. Further, as described in Section 14.1, OE will review all preoperational test instructions and, on a selective basis, startup test instructions for adequacy of testing and will review and approve all preoperational test results and, on a selective basis, startup test results for compliance with design requirements. They will provide all design information necessary for preparation of detailed test instructions; provide onsite technical guidance as necessary during preparation for and conduct of tests; and provide assistance in the evaluation of any design deficiencies discovered as a result of testing.

Radiological Health Staff

The Radiological Health Staff reviews selected test instructions and provides onsite technical assistance, if necessary, during conduct of testing on systems specifically designed for environmental and radiation protection. During initial plant operation, the division provides technical guidance in the areas of personnel radiation protection and environmental monitoring.

Westinghouse Electric Corporation (W)

Westinghouse Electric Corporation will review test instructions applicable to the Nuclear Steam Supply System (NSSS) prior to implementation. During initial testing and operation of the NSSS, Westinghouse will provide, through the Westinghouse site manager, competent personnel qualified for the various phases of the test program who will technically assist the plant staff. Westinghouse will participate in the review of NSSS test results.

14.2.2 Interrelationships and Interfaces

The working interrelationships and organizational interfaces of all groups which provide either direct augmentation or functional assistance to the plant staff are shown in Figures 14.2.2-1 and 14.2.2-2 for the preoperational and startup test programs, respectively.

14.2.3 Personnel Functions, Responsibilities, and Authorities

The key augmenting personnel for the preoperational test program are the members of the NUC PR Preoperational Test Section. The functions, responsibilities, and authorities of the "test directors" within this group are described in Subsection 14.1.1.

Key augmenting personnel positions during the startup test program are the staff engineer positions shown in Figure 14.2.2-2. The functions, responsibilities, and authorities of these positions are discussed in Paragraph 14.2.1.1.

14.2.4 Personnel Qualifications

Qualifications of appointees to key augmenting positions for the pre-operational and startup test programs will be kept in the plant master file. The files will also contain the key qualifications for the supervisors of the various sections.

15.0 ACCIDENT ANALYSES

A new main feedwater Leading Edge Flow Meter (LEFM) system was installed in SQN Units 1 and 2. The LEFM resulted in a 1.3% reduction in the calorimetric uncertainty of the secondary side power measurement. TVA took advantage of this reduction by making an equivalent 1.3% upgrade in rated thermal power. The new rated thermal power is 3455 MWt and the new calorimetric uncertainty is 0.7%. However, the value of rated thermal power plus calorimetric uncertainty is identical before and after the power level upgrade. Before the power level upgrade, the rated thermal power plus calorimetric uncertainty was 102% of 3411 MWt = 3479 MWt and after the power level upgrade it is 100.7% of 3455 MWt = 3479 MWt.

All FSAR Chapter 15 LOCA and non-LOCA safety analyses were evaluated relative to the power level upgrade. Transient analyses that assumed an initial core power of 102% of rated thermal power or greater were unaffected by the power level upgrade. Safety analyses performed at zero power conditions were also unaffected by the power level upgrade. The remainder of the Chapter 15 safety analyses were either insensitive to power level considerations or were bounded by other events. The key factor in the evaluation of the FSAR Chapter 15 events is a 1.3% power level upgrade coincident with an equivalent reduction in calorimetric uncertainty. Therefore, none of the Chapter 15 events were reanalyzed for the power level upgrade.

FSAR Chapter 15 LOCA and non-LOCA analyses were evaluated for the Unit 1 and Unit 2 replacement steam generators. The analyses (see Reference 28 and Reference 29) demonstrate that the acceptance criteria continue to be met subsequent to the steam generator replacement. The analysis for the OSGs continues to be applicable to the RSGs for tube plugging level up to 15 percent.

15.1 CONDITION I - NORMAL OPERATION AND OPERATIONAL TRANSIENTS

Condition I occurrences are those which are expected frequently or regularly in the course of power operation, refueling, maintenance, or maneuvering of the plant. As such, Condition I occurrences are accommodated with margin between any plant parameter and the value of that parameter which would require either automatic or manual protective action. In as much as Condition I occurrences occur frequently or regularly, they must be considered from the point of view of affecting the consequences of fault conditions (Conditions II, III and IV). In this regard, analysis of each fault condition described is generally based on a conservative set of initial conditions corresponding to the most adverse set of conditions which can occur during Condition I operation.

A typical list of Condition I events is listed below:

1. Steady state and shutdown operations

    a. Power operation (~15 to 100 percent of full power)

    b. Start up (or standby) (critical, 0 to 15 percent of full power)

    c. Hot shutdown (subcritical, Residual Heat Removal System isolated)

    d. Cold shutdown (subcritical, Residual Heat Removal System in operation)

    e. Refueling

2. Operation with permissible deviations

Various deviations which may occur during continued operation as permitted by the plant Technical Specifications must be considered in conjunction with other operational modes. These include:

a. Operation with components or systems out of service

b. Leakage from fuel with cladding defects

c. Activity in the reactor coolant

   i. Fission products

   ii. Corrosion products

   iii. Tritium

d. Operation with steam generator leaks up to the maximum allowed by Technical Specifications.

e. Operation with loss of one (redundant) DC system as permitted by Technical Specifications.

3. Operational transients

a. Plant heatup and cooldown (up to 100°F/hour) for the Reactor Coolant System; 200°F/hour for the pressurizer.

b. Step load changes (up to ± 10 percent)

c. Ramp load changes (up to 5 percent/minute)

d. Load rejection up to and including design load rejection transient

15.1.1 Optimization Of Control Systems

A setpoint study was performed in order to simulate performance of the reactor control and protection systems. Emphasis was placed on the development of a control system which will automatically maintain prescribed conditions in the plant even under the most conservative set of reactivity parameters with respect to both system stability and transient performance.

For each mode of plant operation, a group of optimum controller setpoints was determined. In areas where the resultant setpoints were different, compromises based on the optimum overall performance were made and verified. A consistent set of control system parameters was derived satisfying plant operational requirements throughout the core life and for power levels between 15 and 100 percent. The study comprised an analysis of the following control systems: Rod cluster control assembly, steam dump, steam generator level, pressurizer pressure and pressurizer level.

15.1.2 Initial Power Conditions Assumed In Accident Analyses

15.1.2.1 Power Rating

Table 15.1.2-1 lists the principal power rating values which are assumed in analyses performed in this section. Two ratings are given:

1. The guaranteed Nuclear Steam Supply System thermal power output. This power output includes the thermal power generated by the reactor coolant pumps.

2. The Engineered Safety Features design rating. The Westinghouse supplied Engineered Safety Features are designed for a thermal power higher than the guaranteed value in order not to preclude realization of future potential power capability. This higher thermal power value is designated as the Engineered Safety Features design rating. This power output includes the thermal power generated by the reactor coolant pumps.

Where initial power operating conditions are assumed in accident analyses, the "guaranteed Nuclear Steam Supply System thermal power output" plus allowance for errors in steady state power determination is assumed. Where demonstration of adequacy of the containment and Engineered Safety Features are concerned, the "Engineered Safety Features design rating" plus allowance for error is assumed. The thermal power values for each transient analyzed are given in Table 15.1.2-2.

15.1.2.2 Initial Conditions

For accident evaluation, the initial conditions are obtained by adding maximum steady state errors to rated values. The following steady state errors are considered:

1.	Core power	+ 0.7 percent allowance calorimetric error based on LEFM on feedwater header (Reference 27)
2.	Average Reactor Coolant System temperature	+ 4°F allowance for deadband and measurement error*
3.	Pressurizer pressure	+ 30/-42 psi allowance for steady state fluctuations and measurement error**

*A uniform temperature distribution between 578.2°F and 583°F was used in the realistic large break loss-of-coolant accident analysis consistent with the realistic analysis methodology.

**Pressurizer pressure transmitters associated with this function have a thermal non-repeatability bias only associated with abnormal and accident operating temperatures. This bias is not applied to the low end of the pressurizer operating range for DNB calculations because they are performed for normal operating conditions where the bias does not exist. For normal operating conditions, the control system uncertainty of ±30 psi without the thermal non-repeatability bias applies (Reference 30).

Installation of the LEFM effectively reduces the 2% calorimetric error to 0.7%. However, the results presented in Chapter 15 continue to be based on 2% error because they are based on the original rated thermal power of 3411 MWt. 102% of the original rated thermal power of 3411 MWt is equivalent to 100.7% of the upgraded rated thermal power of 3455 MWt.

The text of Chapter 15 contains several references to a rated thermal power of 3411 MWt in combination with a calorimetric uncertainty of 2%. Unless indicated otherwise, plots and results related to reactor power are reported in terms of the original rated thermal power and calorimetric uncertainty. In the interest of brevity, the references to the original rated thermal power and calorimetric uncertainty were left unchanged since the power level upgrade is exactly balanced by a reduction in calorimetric uncertainty.

The magnitude of the errors, not the absolute temperatures, are about the same.

The outer surface of the fuel rod at the hot spot operates at a temperature of approximately 660°F for steady state operation at rated power throughout core life due to the onset of nucleate boiling. Initially (beginning of life), this temperature is that of the cladding metal outer surface. During operation over the life of the core, the buildup of oxides and crud on the fuel rod surface causes the cladding surface temperature to increase. Allowance is made in the fuel center melt evaluation for this temperature rise. Since the thermal hydraulic design basis limits DNB, adequate heat transfer is provided between the fuel cladding and the reactor coolant so that the core thermal output is not limited by considerations of the cladding temperature. These temperatures are calculated using the Westinghouse fuel rod model (Reference 1) which has been reviewed and approved by the NRC.

15.1.2.3 Power Distribution

The transient response of the reactor system is dependent on the initial power distribution. The nuclear design of the reactor core minimizes adverse power distribution through the placement of control rods and operation instructions. The power distribution may be characterized by the radial factor $F_{\Delta H}$ and the total peaking factor F_q. The peaking factor limits are given in the technical specifications.

For transients which may be DNB limited, the radial peaking factor is of importance. The radial peaking factor increases with decreasing power level due to rod insertion. This increase in $F_{\Delta H}$ is included in the core limits illustrated in Figure 15.1.3-1. All transients that may be DNB limited are assumed to begin with $F_{\Delta H}$ consistent with the initial power level defined in the technical specifications. The axial power shape used in the DNB calculation is the 1.55 chopped cosine as discussed in Subparagraph 4.4.3.2.2.

For transients which may be overpower limited, the total peaking factor F_q is of importance. The value of F_q may increase with decreasing power level such that full power hot spot heat flux is not exceeded, i.e., F_q * Power = design hot spot heat flux. All transients that may be overpower limited are assumed to begin with a value of F_q consistent with the initial power level as defined in the technical specifications.

Analyses of transients which are overtemperature limited must use a variable radial peak ($F_{\Delta H}$); see Section 15.1.3.

15.1.3 Trip Points And Time Delays To Trip Assumed In Accident Analyses

A reactor trip signal acts to open two trip breakers connected in series feeding power to the control rod drive mechanisms. The loss of power to the mechanism coils causes the mechanisms to release the rod cluster control assemblies which then fall by gravity into the core. There are various instrumentation delays associated with each trip function, including delays in signal actuation, in opening the trip breakers, and in the release of the rods by the mechanisms. The total delay to trip is defined as the time delay from the time that trip conditions are reached to the time the rods are free and begin to fall. Limiting trip setpoints assumed in accident analyses and the time delay assumed for each trip function are given in Table 15.1.3-1. Reference is made in that table to overtemperature and overpower ΔT trip shown in Figure 15.1.3-1.

For analyses which rely on the overtemperature ΔT trip for core protection, a variable radial peak ($F_{\Delta H}$) must be used as part of the design peak during DNBR calculations. A variable design peak $F_{\Delta H}$ is employed such that the safety limit lines—lines for which the DNBR is equal to the safety analysis limit in the design hot channel for thermal design flow—are equal to the overtemperature ΔT lines. The variable design peak $F_{\Delta H}$ is shown in Figure 15.1.3-2.

Accident analyses which assume the S/G Low-Low Water Level trip signal to initiate protection functions may be affected by the Environmental Allowance Modifier (EAM) and the Trip Time Delay (TTD) (References 18 and 19) systems, which were developed to reduce the incidence of unnecessary feedwater related reactor trips.

The EAM system permits plant operation with a relatively low setpoint for the S/G Low-Low Water Level trip, which does not include the full environmental error allowance. The EAM will automatically enable a higher Low-Low level trip setpoint, which includes the full environmental error allowance, whenever an adverse containment environment is indicated by a rise in containment pressure.

The TTD imposes a system of pre-determined delays upon the S/G Low-Low level reactor trip and auxiliary feedwater initiation. The values of these delays are based upon (1) the prevailing power level at the time the Low-Low level trip setpoint is reached, and by (2) the number of steam generators in which the Low-Low level trip setpoint is reached. The TTD delays the reactor trip and auxiliary feedwater actuation in order to provide time for corrective action by the operator or for natural stabilization of shrink/swell water level transients. The TTD is primarily designed for low power or startup operations.

The overtemperature ΔT setpoints shown in Figure 15.1.3-1 along with all other evaluated DNBR's were calculated assuming approximately 4 percent margin in the critical heat flux calculation, as discussed in Paragraph 4.4.2.1.

The difference between the limiting trip point assumed for the analysis and the nominal trip point represents an allowance for instrumentation channel error and setpoint error. During preoperational start-up tests, it was demonstrated that actual instrument errors and time delays are equal to or less than the assumed values.

High and low power range neutron flux trip setpoints allow for a 2% calorimetric uncertainty and the installation of the LEFM effectively reduces the calorimetric uncertainty to 0.7%. As a result of the reduction in calorimetric uncertainty and equivalent upgrade in rated thermal power, the safety analysis high and low power range neutron flux trip setpoints will be redefined based on the new power level. The power range neutron flux (high setting) will be defined as 116.5% of 3455 MWt and the power range neutron flux (low setting) will be defined as 34.6% of 3455 MWt. Redefining these setpoints makes additional analysis unnecessary because the new values are equivalent, in terms of total megawatts, to the current licensing basis at 3411 MWt (116.5% of 3455 MWt = 118% of 3411 MWt and 34.6% of 3455 MWt = 35% of 3411 MWt).

The text of Chapter 15 contains references to high and low power range neutron flux trip setpoints of 118% and 35% of the original rated thermal power, respectively. Unless indicated otherwise, plots and results of transients that modeled these trips used the original setpoint definitions. In the interest of brevity, the references to the original setpoints were left unchanged since the new setpoints represent identical values in terms of total megawatts.

15.1.4 Instrumentation Drift And Calorimetric Error - Power Range Neutron Flux

The instrumentation drift and calorimetric errors used in establishing the maximum overpower setpoint are presented in References 17 and 27.

The calorimetric error is the error assumed in the determination of core thermal power as obtained from secondary plant measurements. The total ion chamber current (sum of the top and bottom sections) is calibrated (set equal) to this measured power on a periodic basis. The secondary power is obtained from measurement of feedwater flow, feedwater inlet temperature to the steam generators and steam pressure. High accuracy instrumentation is provided for these measurements with accuracy tolerances much tighter than those which would be required to control feedwater flow.

15.1.5 Rod Cluster Control Assembly Insertion Characteristic

The negative reactivity insertion following a reactor trip is a function of the acceleration of the rod cluster control assemblies and the variation in rod worth as a function of rod position.

With respect to accident analyses, the critical parameter is the time of insertion up to the dashpot entry or approximately 85 percent of the rod cluster travel. For accident analyses it is conservatively assumed that the insertion time to dashpot entry is 2.7 seconds. The rod cluster control assembly position versus time assumed in accident analyses is shown in Figure 15.1.5-1.

Figure 15.1.5-2 shows the fraction of total negative reactivity insertion for a core where the axial distribution is skewed to the lower region of the core. An axial distribution which is skewed to the lower region of the core can arise from a xenon oscillation or can be considered as representing a transient axial distribution which would exist after the rod cluster control assembly bank had already traveled some distance after trip. This lower curve is used as input to all point kinetics core models used in transient analyses.

There is inherent conservatism in the use of this curve in that it is based on a skewed distribution which would exist relatively infrequently. For cases other than those associated with xenon oscillations significant negative reactivity would have been inserted due to the more favorable axial distribution existing prior to trip.

The normalized rod cluster control assembly negative reactivity insertion versus time is shown in Figure 15.1.5-3. The curve shown in this figure was obtained from Figures 15.1.5-1 and 15.1.5-2. A total negative reactivity insertion following trip of 4 percent $\Delta k/k$ is assumed in the transient analyses except where specifically noted otherwise. This assumption is conservative with respect to the calculated trip reactivity worth available as shown in Table 4.3.2-3.

The normalized rod cluster control assembly negative reactivity insertion versus time curve for an axial power distribution skewed to the bottom (Figure 15.1.5-3) is used in transient analyses. Where special analyses require use of three dimensional or axial one dimensional core models, the negative reactivity insertion resulting from reactor trip is calculated directly by the reactor kinetic code and is not separable from other reactivity feedback effects. In this case, the rod cluster control assembly position versus time of Figure 15.1.5-1 is used as code input.

15.1.5.1 Fuel Assembly Bowing

Exposure dependent distortion has been experienced in the shapes of Mark-BW fuel assemblies. This distortion develops primarily as lateral displacement of the assembly cross section along its axis, such that an assembly can take on a slight “S” or “W” shaped bowing along its length. In rodded assemblies this bowing can increase control rod insertion times due to increases in friction between control rods and their guide tubes. In the interim while this condition is corrected, monitoring and engineering calculations are performed to measure assembly distortion, to conservatively predict the insertion times of individual control rods, and to determine any affects on safety analysis assumptions or results.

Experience has shown that control rods can be expected to reliably arrive at the dashpot within the maximum time allowed per Technical Specification 3.1.4, SR 3.1.4.3, and per Figures 15.1.5-1 and 15.1.5-3. However, the potential exists that one or more control rods could, over the period of an operating cycle, become slow to settle (STS), meaning that the rod would not complete the remaining travel from dashpot entry to the fully inserted position within the time indicated in Figures 15.1.5-1 and 15.1.5-3. As stated in Section 15.1.5 above, in safety analyses the critical parameter is the time of insertion up to the dashpot entry. Evaluations have shown that safety analysis acceptance criteria can be met even when multiple control rods stop at the dashpot entry, resulting in incomplete rod insertion (IRI).

Monitoring of fuel assembly bowing is achieved through analysis of (1) drag test results, (2) post-irradiation examinations, and (3) rod drop time surveillance test results. Drag tests measure the friction forces that resist withdrawal of a control rod assembly from a fuel assembly. These tests can be performed while the assembly is located in the reactor core or the spent fuel pool. Post irradiation examinations measure any actual bowing distortion in spent fuel assemblies. Rod drop time surveillances measure the elapsed time to dashpot entry and beyond. Rod drop surveillance testing is required prior to each operating cycle per procedure and can also be performed during forced outages to supplement monitoring data or to validate projections.

Correlations and trends in monitoring data are analyzed to conservatively project any increases in rod insertion times over the course of each operating cycle. All rods at risk of becoming STS during a cycle are evaluated for their combined affect on the assumptions and outcomes in all applicable Chapter 15 events. All rods at risk of becoming STS are conservatively assumed to be IRIs stuck at the dashpot entry. Results of these evaluations must show that all applicable safety analysis acceptance criteria are met.

15.1.6 Reactivity Coefficients

The transient response of the reactor system is dependent on reactivity feedback effects, in particular the moderator temperature coefficient and the Doppler power coefficient. These reactivity coefficients and their values are discussed in detail in Chapter 4.

In the analysis of certain events, conservatism requires the use of large reactivity coefficient values whereas in the analysis of other events, conservatism requires the use of small reactivity coefficient values. Some analyses such as loss of reactor coolant from cracks or ruptures in the Reactor Coolant System do not depend on reactivity feedback effects. The values used are given in Table 15.1.2-2; reference is made in that table to Figure 15.1.6-1 which shows the upper and lower Doppler power coefficients, as a function of power, used in the transient analysis. The justification for use of conservatively large versus small reactivity coefficient values is treated on an event by event basis. To facilitate comparison, individual sections in which justification for the use of large or small reactivity coefficient values is to be found are referenced below:

Condition II Events		Section
1.	Uncontrolled Rod Cluster Control Assembly Bank Withdrawal From a Subcritical Condition	15.2.1
2.	Uncontrolled Rod Cluster Control Assembly Bank Withdrawal At Power	15.2.2
3.	Rod Cluster Control Assembly Misalignment	15.2.3
4.	Uncontrolled Boron Dilution	15.2.4
5.	Partial Loss of Forced Reactor Coolant Flow	15.2.5
6.	Startup Of An Inactive Reactor Coolant Loop	15.2.6
7.	Loss of External Electrical Load And/Or Turbine Trip	15.2.7
8.	Loss of Normal Feedwater	15.2.8
9.	Loss Of All Off-Site Power To The Station Auxiliaries (Station Blackout)	15.2.9
10.	Excessive Heat Removal Due to Feedwater System Malfunctions	15.2.10
11.	Excessive Load Increase Incident	15.2.11
12.	Accidental Depressurization of the Reactor Coolant System	15.2.12
13.	Accidental Depressurization of Main Steam System	15.2.13
14.	Spurious Operation of the Safety Injection System At Power	15.2.14

Condition III Events

1.	Complete Loss of Forced Reactor Coolant Flow	15.3.4
2.	Single Rod Cluster Control Assembly Withdrawal, At Full Power	15.3.6

Condition IV Events

1.	Rupture of A Steam Pipe Rupture of A Feedwater Pipe	15.4.2.1 15.4.2.2
2.	Single Reactor Coolant Pump Locked Rotor	15.4.4
3.	Rupture Of A Control Rod Drive Mechanism Housing (Rod Cluster Control Assembly Ejection)	15.4.6

15.1.7 Fission Product Inventories

15.1.7.1 Activities in the Core

The design basis LOCA source terms are based on an average 1000 EFPD reactor core with an enrichment of 5% U235. The reactor core inventory analysis was performed with the ORIGIN-S computer code (Ref. 19a) by Oak Ridge National Laboratory. The fraction of reactor core releases into the containment are based on TID-14844 (Ref. 2) methodology which consists of an instantaneous release of 100% of the noble gases, 50% of the halogens, and 1% of the solids in the fission product inventory. These isotopes are given in Table 15.5.3.8. The subset of these isotopes which are important from a health hazards point of view are given in Table 15.5.3-5. The isotopes included in Table 15.5.3-5 are the isotopes controlling from considerations of inhalation dose (iodines) and from external dose due to immersion (noble gases).

15.1.7.2 Activities in the Fuel Pellet Cladding Gap

The computed gap activities (Table 15.1.7-1) are based on buildup in the fuel from the fission process and diffusion to the gap at rates dependent on the operating temperature. The temperature dependence is accounted for by determining the core fuel fraction operating within each of nine temperature regions (Table 15.1.7- 2), each with a release rate to the gap dependent of the mean fuel temperature within that region. Since the temperature distribution changes during core life, the highest expected values are used. The temperature dependence of the diffusion coefficient, D′, for Xe and Kr in UO_2, follows the Arrhenius law:

$$D'(T) = D'(1673)\exp - \left[\frac{E}{R}\left(\frac{1}{T} - \frac{1}{1673}\right)\right]$$

where

D′(T)	= diffusion coefficient at temperature T, sec^{-1}
D′(1673)	= 1×10^{-11} sec^{-1}, diffusion coefficient at 1673°K

E = 82 kilocalories/mole, activation energy

R = 1.99×10^{-3} kilocalories/mole - °K, gas constant

T = temperature, °K

The above expression is valid for temperatures above 1100°C. Below 1100°C fission gas release occurs mainly by two temperature independent mechanisms, recoil and knock out, and is predicted by using D' at 1100°C. The value used for D' (1673°K), based on data at burnups greater than 10^{19} fissions/cc, accounts for possible fission gas release by other mechanisms as well as pellet cracking during irradiation.

The diffusion coefficient for iodine isotopes was conservatively assumed to be the same as for Xe and Kr. Toner and Scott (Reference 4) observed that iodine diffuses in UO_2 at about the same rate as Xe and Kr and has about the same activation energy. Data reported by Belle (Reference 5) indicate that the iodine diffuses at slightly slower rates than Xe and Kr.

With the diffusion coefficient determined for the fuel temperature region of interest, the fraction of radioactive fission gas which crosses the fuel boundary into the fuel rod gap is found from:

$$f = 3\sqrt{\frac{D'}{\lambda}} \quad \mathrm{Coth}\sqrt{\frac{\lambda}{D'}} - \sqrt{\frac{D'}{\lambda}}$$

Where:

f = fraction of a given radioactive fission gas in fuel rod gap

λ = fission gas decay constant, sec^{-1}

D' = diffusion coefficient, Sec^{-1}

The above expression is the steady-state solution of the diffusion equation in spherical geometry as given by Booth (Reference 6).

Table 15.1.7-1 lists the total core activities as well as activities present in the gap for each pertinent isotope obtained using the above equations and the fuel temperature distribution given in Table 15.1.7-2.

The activities in the reactor coolant, as well as in the volume control tank, pressurizer and gaseous waste processing system, are given in Chapter 11 including the data on which the computation of these activities are based.

15.1.8 <u>Residual Decay Heat</u>

Residual heat in a subcritical core consists of:

1. Fission product decay energy,

2. Decay of neutron capture products, and

3. Residual fissions due to the effect of delayed neutrons.

These constituents are discussed separately in the following paragraphs.

15.1.8.1 Fission Product Decay

For short times (< 10^3 seconds) after shutdown, data on yields of short half life isotopes is sparse. Very little experimental data is available for the γ-ray contributions and even less for the β-ray contribution. Several authors have compiled the available data into a conservative estimate of fission product decay energy for short times after shutdown, notably Shure (Reference 7), Dudziak (Reference 8), and Teage. Of these three selections, Shure's curve is the highest and it is based on the data of Stehn and Clancy (Reference 9) and Obenshain and Foderaro (Reference 10).

The fission product contribution to decay heat which has been assumed in the accident analyses is the curve of Shure increased by 20 percent for conservatism. This curve with the 20 percent factor included is shown in Figure 15.1.8-1.

15.1.8.2 Decay of U-238 Capture Products

Betas and gammas from the decay of U-239 (23.5 minute half-life) and Np-239 (2.35 day half-life) contribute significantly to the heat generation after shutdown. The cross section for production of these isotopes and their decay schemes are relatively well known. For long irradiation times their contribution can be written as:

$$P_1/P_o = \frac{E_{\gamma 1} + E_{\beta 1}}{200\ \text{Mev}} \quad c(1+a)\, e^{-\lambda_1 t} \quad \text{watts/watts}$$

$$P_2/P_o = \frac{E_{\gamma 2} + E_{\beta 2}}{200\text{Mev}}\, c(1+a) \left[\frac{\lambda_2}{\lambda_1 - \lambda_2} \left(e^{-\lambda_2 t} - e^{-\lambda_1 t}\right) + e^{-\lambda_2 t} \quad \text{watts / watts} \right]$$

Where:

P_1/P_o is the energy from U-239 decay

P_2/P_o is the energy from Np-239 decay

t is the time after shutdown (seconds)

c (1+a) is the ratio of U-238 captures to total fissions = 0.6(1+.2)

λ_1 = the decay constant of U-239 = 4.91 x 10^{-4} seconds $^{-1}$

λ_2 = the decay constant of Np-239 decay = 3.41 x 10^{-6} seconds $^{-1}$

$E_{\gamma 1}$ = total γ-ray energy from U-239 decay = .06 Mev

$E_{\gamma 2}$ = total γ-ray energy from Np-239 decay = .30 Mev

$E_{ß1}$ = total ß-ray energy from U-239 decay = 1/3 x 1.18 Mev

$E_{ß2}$ = total ß-ray energy from Np-239 decay = 1/3 x 0.43 Mev

(Two-thirds of the potential ß-energy is assumed to escape by the accompanying neutrinos.)

This expression with a margin of 10 percent is shown in Figure 15.1.8-1. The 10 percent margin, compared to 20 percent for fission product decay, is justified by the availability of the basic data required for this analysis. The decay of other isotopes, produced by neutron reactions other than fissions, is neglected.

15.1.8.3 Residual Fissions

The time dependence of residual fission power after shutdown depends on core properties throughout a transient under consideration. Core average conditions are more conservative for the calculation of reactivity and power level than actual local conditions as they would exist in hot areas of the core. Thus, unless otherwise stated in the text, static power shapes have been assumed in the analyses and these are factored by the time behavior of core average fission power calculated by a point model kinetics calculation with six delayed neutron groups.

For the purpose of illustration only a one delay neutron group calculation, with a constant shutdown reactivity of -4 percent $\Delta k/k$, is shown in Figure 15.1.8-1.

15.1.8.4 Decay Heat Following Loss of Coolant Accident

For a large break loss-of-coolant accident the core is rapidly shut down by void formation such that heat generation comes from fission product decay. The decay heat assumed by the analysis is based on the 1979 ANS standard for decay heat from U235 with fully saturated decay chains, corresponding to infinite operation, assuming 200 MeV per fission. Differing from the base Reference 67 evaluation model approach, the uncertainty for the decay heat parameter is set to zero and no sampling is done on this parameter. The choice of infinite operation with pure U235 fission product decay heat provides a base model that is conservative relative to the decay heat for finite operation For the S-RELAP5 calculation, the heat is conservatively assumed to be generated within the fuel pellet.

15.1.9 Computer Codes Utilized

Summaries of some of the principal computer codes used in transient analyses are given below. Other codes, in particular, very specialized codes in which the modeling has been developed to simulate one given accident, which consequently has a direct bearing on the analysis of the accident itself, are either summarized or referenced in their respective accident analyses sections. The codes used in the analyses of each transient have been listed in Table 15.1.2-2.

15.1.9.1 FACTRAN

FACTRAN calculates the transient temperature distribution in a cross section of a metal clad UO_2 fuel rod and the transient heat flux at the surface of the clad using as input the nuclear power and the time-dependent coolant parameters (pressure, flow, temperature, density). The code uses a fuel model which exhibits the following features simultaneously:

1. A sufficiently large number of radial space increments to handle fast transients such as rod ejection accidents.

2. Material properties which are functions of temperature and a sophisticated fuel-to-clad gap heat transfer calculation.

3. The necessary calculations to handle post-DNB transients: film boiling heat transfer correlations, zirconium alloy water reaction and partial melting of the materials.

The gap heat transfer coefficient is calculated according to an elastic pellet model (refer to Figure 15.1.9-1). The thermal expansion of the pellet is calculated as the sum of the radial (one-dimensional) expansions of the rings. Each ring is assumed to expand freely. The cladding diameter is calculated based on thermal expansion and internal and external pressures.

If the outside radius of the expanded pellet is smaller than the inside radius of the expanded clad, there is no fuel-clad contact and the gap conductance is calculated on the basis of the thermal conductivity of the gas contained in the gap. If the pellet's outside radius so calculated is larger than the clad inside radius (negative gap), the pellet and the clad are pictured as exerting upon each other a pressure sufficiently important to reduce the gap to zero by elastic deformation of both. This contact pressure determines the gap heat transfer coefficient.

FACTRAN is further discussed in Reference 11.

15.1.9.2 MARVEL

The MARVEL code is used to determine the detailed transient behavior of multi-loop pressurized water reactor systems caused by prescribed initial perturbations in process parameters. The code is useful in predicting plant behavior when different conditions are present in the loops. For analytical purposes, the physical, thermal and hydraulic characteristics of a multi-loop plant are represented by two "equivalent" loops. The perturbation is considered to occur in one of the equivalent loops which may represent one or more physical loops. The other equivalent loop thus represents in lumped form, the remaining loops in the plant.

The code simulates the coolant flow through the reactor vessel, hot leg, cold leg, steam generator plus the pressurizer surge line. Neutron kinetics, fuel-clad heat transfer and the rod control system characteristics are modeled. Simulation of the Reactor Trip System, Engineered Safety Features (Safety Injection) and Chemical and Volume Control System is provided.

MARVEL also has the capability of calculating the transient value of DNB ratio based on the input from the core limits illustrated on Figure 15.1.3-1. The core limits represent the minimum value of DNBR as calculated for a typical or thimble cell.

MARVEL is further discussed in Reference 12.

15.1.9.3 LOFTRAN

The LOFTRAN program is used for studies of transient response of a pressurized water reactor system to specified perturbations in process parameters. LOFTRAN simulates a multi-loop system by a lumped parameter single loop model containing reactor vessel, hot and cold leg piping, steam generator (tube and shell sides) and the pressurizer. The pressurizer heaters, spray, relief and safety valves are also considered in the program. Point model neutron kinetics, and reactivity effects of the moderator, fuel, boron and rods are included. The secondary side of the steam generator utilizes a homogeneous, saturated mixture for the thermal transients and a water level correlation for indication and control. The reactor protection system is simulated to include reactor trips on neutron flux, overpower and overtemperature reactor coolant delta-T, high and low pressurizer pressure, low RCS flow, and high pressurizer level. Control systems are also simulated including rod control, steam dump, feedwater control and pressurizer pressure control. The Safety Injection System including the accumulators is also modeled.

LOFTRAN is a versatile program which is suited to both accident evaluation and control studies as well as parameter sizing.

LOFTRAN also has the capability of calculating the transient value of DNB ratio based on the input from the core limits illustrated on Figure 15.1.3-1. The core limits represent the minimum value of DNBR as calculated for typical or thimble cell. LOFTRAN is further discussed in Reference 13.

15.1.9.4 LEOPARD

The LEOPARD computer program determines fast and thermal spectra, using only basic geometry and temperature data. The code optionally computes fuel depletion effects for a dimensionless reactor and recomputes the spectra before each discrete burnup step.

LEOPARD is further described in Reference 14.

15.1.9.5 TURTLE

TURTLE is a two-group, two-dimensional neutron diffusion code featuring a direct treatment of the nonlinear effect of xenon, enthalpy, and Doppler. Fuel depletion is allowed.

TURTLE was written for the study of azimuthal xenon oscillations, but the code is useful for general analysis. The input is simple, fuel management is handled directly, and a boron criticality search is allowed.

TURTLE is further described in Reference 15.

15.1.9.6 TWINKLE

The TWINKLE program is a multi-dimensional spatial neutron kinetics code, which was patterned after steady-state codes presently used for reactor core design. The code uses an implicit

finite-difference method to solve the two-group transient neutron diffusion equations in one, two and three dimensions. The code uses six delayed neutron groups and contains a detailed multi-region fuel-clad-coolant heat transfer model for calculating pointwise doppler and moderator feedback effects. The code handles up to 2000 spatial points, and performs its own steady state initialization. Aside from basic cross-section data and thermal-hydraulic parameters, the code accepts as input basic driving functions such as inlet temperature, pressure, flow, boron concentration, control rod motion, and others. Various edits provide channelwise power, axial offset, enthalpy, volumetric surge, pointwise power, fuel temperatures, and so on.

The TWINKLE code is used to predict the kinetic behavior of a reactor for transients which cause a major perturbation in the spatial neutron flux distribution.

TWINKLE is further described in Reference 16.

15.1.9.7 THINC

The THINC code is described in Section 4.4.3.1.

15.1.9.8 RELAP5/MOD2-B&W

RELAP5/MOD2-B&W is a BWNT adaptation of the Idaho National Engineering Laboratory code RELAP5/MOD2. The code, developed for best-estimate transient simulation of pressurized water reactors, has been modified to include models required for licensing analysis. Modeling capabilities are associated with the analysis of large and small break LOCAs, as well as operational transients defining the safety envelope of a reactor. The latter class of transients include Anticipated Transient Without Scram, Loss of Offsite Power, Loss of Feedwater, and Loss of RCS Flow transients. The code has been benchmarked extensively to existing experimental data for regulatory approval of its use in analyzing LOCA and Non-LOCA transients. RELAP5/MOD2-B&W is documented in topical BAW-10164 (Reference 20).

15.1.9.9 S-RELAP5

This code is used for the system calculation for analysis of large break LOCAs. The field equations are basically the same form as RELAP5/MOD2 with the addition of full two-dimensional momentum equations. This two dimensional capability is only applied within the reactor vessel in the Realistic Large Break LOCA methodology, but can be applied anywhere in the reactor coolant system through input. The S-RELAP5 code structure was modified to be essentially the same as RELAP5/MOD3. The coding for reactor kinetics, control systems, and trip systems was also replaced from RELAP5/MOD3. Initial fuel conditions are supplied by the realistic fuel performance code, RODEX3A. To be consistent, the fuel deformation and conductivity models from RODEX3A were included in S-RELAP5. Capability to interface with a concurrent calculation of containment backpressure using the ICECON code was added. S-RELAP5 is documented in topical report EMF-2100 (P) (Reference 21).

15.1.9.10 RODEX3A

RODEX3A calculates fuel rod performance for Realistic Large Break LOCA analysis. In particular, the initial operating temperature of the fuel pellets (as stored energy) and the internal fuel rod gas pressure are provided as functions of fuel exposure and power history. RODEX3A is documented in topical report ANF-90-145(P)(A) (Reference 22).

15.1.9.11 LYNXT

LYNXT is approved by the NRC and provides the capability for single-pass core thermal-hydraulic analysis for both steady state and transient conditions. It also has the capability to analyze

conditions with high lateral flow and/or recirculating flow, such as encountered in the analysis of a steamline break with reactor coolant pumps off. The single pass LYNXT model has been extensively benchmarked to multi-pass analyses and appropriate experimental data. LYNXT is used almost exclusively for determining core flow redistribution and for predicting the DNB performance of various fuel designs.

LYNXT has been qualified for the BWC, BHTP, BWU-N, Biasi, BWCMV, BWCMV-A, B&W2 and W3 correlations by data base analysis. In each case, where this evaluation has been performed, LYNXT supported the licensed DNBR limit for the respective CHF correlation. Some of the features of LYNXT include:

1) Reverse/recirculating flow option
2) Exit pressure profile boundary condition and transient pressure drop boundary condition
3) Generalized DNBR subroutine
4) Internal code generation of the axial power shape
5) Transient radial and axial power shapes input capability
6) Dynamic gap conductance fuel model
7) ANSI Fortran 77 and self-contained
8) Enhancements to the conducting wall model to allow rectangular and cylindrical walls

LYNXT is described in topical report BAW-10156 (Reference 23).

15.1.9.12 TACO3

The TACO3 code, with its Fuel Rod Gas Pressure Criteria, is a state-of-the-art methodology for fuel rod thermal performance analysis. This package applies to fuel rod burnups to 62,000 MWd/mtU, with possible extrapolation to 65,000 MWd/mtU. The TACO3 fuel performance code is a major evolution in the prediction of fuel rod performance. TACO3 uses best-estimate models benchmarked to an extensive data base of fuel performance data from numerous industry sponsored experimental programs. TACO3 uses a complete set of new thermal and mechanical models, as well as new fuel and cladding material relations. Several models represent advances in the state-of-the-art. The TACO3 fuel temperature predictions have less uncertainty than other comparable codes. The NRC has reviewed and approved TACO3. TACO3 predicts the following as a function of burnup:

- Centerline Fuel Melt
- Fuel Rod Internal Gas Pressure
- LOCA Analysis Initialization Parameters
- Cladding Strain
- Creep Collapse Analysis Initialization Parameters

TACO3 uses best-estimate inputs to provide best-estimate predictions. Statistical evaluations are performed to estimate uncertainties and provide conservative results for use in licensing evaluations. Code and power prediction uncertainties and manufacturing variations are considered for internal gas pressure uncertainties. Statistical parameters obtained from the analysis of an extensive code benchmark database evaluate fuel temperature uncertainties. Transient fission gas release and cladding oxide effects are also represented to provide appropriate conservatism. TACO3 is described in topical report BAW-10162 (Reference 24).

15.1.9.13 NEMO (BAW-10180-A)

NEMO is a nodal neutronics code used to calculate power distributions and perform reactivity analyses of pressurized water reactors (PWRs). The nodal balance equation is solved to determine the neutron flux, source, relative power density (which includes pin power reconstruction to obtain detailed pin power profiles), and reactivity of the core. NEMO employs a two-group nodal expansion method to determine the currents and fluxes at the surface of each node in the core. Two or three dimensional problems can be analyzed with thermal-hydraulic feedback and isotopic depletion. Microscopic cross sections are required for the isotopic depletion calculation and are obtained from pre-calculated cross section database files. Interpolation of these cross section tables, one for each fuel enrichment/burnable poison combination, is performed versus a six-dimensional space of independent variables: burnup, boron, xenon, moderator specific volume, fuel temperature, and a spectral parameter.

NEMO has been applied to a wide array of problem solutions, including: development of reload fuel assembly loading patterns, calculation of startup physics control rod worths and reactivity coefficients and defects, core maneuvering analyses, core follow, provide input parameters to safety analysis evaluation, and generation of neutron flux signal to power factors for online measurement systems. A detailed description of NEMO is given in topical report BAW-10180 (Reference 25).

15.1.10 Loss Of One (Redundant) DC System

15.1.10.1 Identification of Causes

The plant DC System serves as a power source for DC pump motors, controls, and instrumentation. A description of this system and its redundant design are presented in Subsection 8.3.2. The loss of one DC System will be defined for the purposes of this analysis as the loss of one battery and one battery charger.

15.1.10.2 Analysis of Effects and Consequences

As discussed in Subsection 8.3.2, the plant has been designed so that the loss of one DC System will not affect the safe operation of the plant.

15.2 CONDITION II - FAULTS OF MODERATE FREQUENCY

These faults at worst result in the reactor shutdown with the plant being capable of returning to operation. By definition, these faults (or events) do not propagate to cause a more serious fault, i.e., Condition III or IV category. In addition, Condition II events are not expected to result in fuel rod failures or Reactor Coolant System overpressurization.

For the purposes of this report the following faults have been grouped into this category:

1. Uncontrolled rod cluster control assembly bank withdrawal from a subcritical condition.

2. Uncontrolled rod cluster control assembly bank withdrawal at power.

3. Rod cluster control assembly misalignment.

4. Uncontrolled boron dilution.

5. Partial loss of forced reactor coolant flow.

6. Start-up of an inactive reactor coolant loop.

7. Loss of external electrical load and/or turbine trip.

8. Loss of normal feedwater.

9. Loss of offsite power to the station auxiliaries.

10. Excessive heat removal due to feedwater system malfunctions.

11. Excessive load increase.

12. Accidental depressurization of the Reactor Coolant System.

13. Accidental depressurization of the Main Steam System.

14. Spurious Operation of Safety Injection System at power.

An evaluation of the reliability of the Reactor Protection System actuation following initiation of Condition II events has been completed and is presented in Reference 1 for the relay protection logic. Standard reliability engineering techniques were used to assess likelihood of the trip failure due to random component failures. Common-mode failures were also qualitatively investigated. It was concluded from the evaluation that the likelihood of no trip following initiation of Condition II events is extremely small (2×10^{-7} derived for random component failures).

The solid state protection system design has been evaluated by the same methods as used for the relay system and the same order of magnitude of reliability is provided.

Hence, because of the high reliability of the protection system no special provision is proposed to be taken in the design to cope with the consequences of Condition II events without trip.

15.2.1 Uncontrolled Rod Cluster Control Assembly Bank Withdrawal From A Subcritical Condition

15.2.1.1 Identification of Causes and Accident Description

A rod cluster control assembly withdrawal accident is defined as an uncontrolled addition of reactivity to the reactor core caused by withdrawal of rod cluster control assemblies resulting in a power excursion. Such a transient could be caused by a malfunction of the reactor control or control rod drive systems. This could occur with the reactor either subcritical, at hot zero power or at power. The "at power" case is discussed in Subsection 15.2.2.

Although the reactor is normally brought to power from a subcritical condition by means of rod cluster control assembly withdrawal, initial startup procedures with a clean core call for boron dilution. The maximum rate of reactivity increase in the case of boron dilution is less than that assumed in this analysis (Subsection 15.2.4, Uncontrolled Boron Dilution).

The rod cluster control assembly drive mechanisms are wired into preselected bank configurations which are not altered during reactor life. These circuits prevent the assemblies from being withdrawn in other than their respective banks. Power supplied to the banks is controlled such that no more than two banks can be withdrawn at the same time. The rod cluster control assembly drive mechanisms are of the magnetic latch type and coil actuation is sequenced to provide variable speed travel. The maximum reactivity insertion rate analyzed in the detailed plant analysis is that occurring with the simultaneous withdrawal of the combination of the two control banks having the maximum combined worth at maximum speed.

The neutron flux response to a continuous reactivity insertion is characterized by a very fast rise terminated by the reactivity feedback effect of the negative Doppler coefficient. This self limitation of the power burst is of primary importance since it limits the power to a tolerable level during the delay time for protection action. Should a continuous rod cluster control assembly withdrawal accident occur the transient will be terminated by the following automatic features of the Reactor Protection System:

1. Source Range High Neutron Flux Reactor Trip - actuated when either of two independent source range channels indicates a neutron flux level above a preselected manually adjustable setpoint. This trip function may be manually bypassed when either intermediate range flux channel indicates a flux level above a specified level. It is automatically reinstated when both intermediate range channels indicate a flux level below a specified level.

2. Intermediate Range High Neutron Flux Reactor Trip - actuated when either of two independent intermediate range channels indicates a flux level above a preselected manually adjustable setpoint. This trip function may be manually bypassed when two of the four power range channels are reading above approximately 10% of full power and is automatically reinstated when three of the four channels indicate a power below this value.

3. Power Range High Neutron Flux Reactor Trip (Low Setting) - actuated when two out of the four power range channels indicate a power level above approximately 25% of full power. This trip function may be manually bypassed when two of the four power range channels indicate a power level above approximately 10% of full power and is automatically reinstated when three of the four channels indicate a power level below this value.

4. Power Range High Neutron Flux Reactor Trip (High Setting) - actuated when two out of the four power range channels indicate a power level above a preset setpoint. This trip function is always active.

5. Power Range High Positive Neutron Flux Rate Trip - actuated when the positive rate of change of neutron flux on two out of four nuclear power range channels indicate a rate above the preset setpoint. This trip function is always active.

In addition, control rod stops on high intermediate range flux level (one of two) and high power range flux level (one out of four) serve to discontinue rod withdrawal and prevent the need to actuate the intermediate range flux level trip and the power range flux level trip, respectively.

15.2.1.2 Analysis of Effects and Consequences

The analysis of the uncontrolled RCCA bank withdrawal from subcritical accident is performed in two stages. First a systems analysis is performed which includes the prediction of core power response. In the second stage, forcing functions generated in the systems analysis are subsequently used in sub-channel thermal-hydraulics analyses to determine minimum DNBR for the event.

System and core nuclear response is performed using the RELAP5/MOD2- B&W computer code (Reference 12). The RELAP5/MOD2-B&W code simulates the neutron kinetics, reactor coolant system and steam system thermal-hydraulics. The power response for the uncontrolled RCCA bank withdrawal from subcritical event is generated with the RELAP5/MOD2-B&W point kinetics model utilizing conservatively bounding reactivity feedback inputs.

System flow, pressure, core inlet temperature, and core kinetics responses resulting from the system analysis are transferred to the LYNXT computer code (Reference 13). LYNXT is used to generate core sub-channel fluid response, hot-pin heat flux, and location-specific DNBR. LYNXT studies determine a radial peaking limit that, in conjunction with the core power response, yields an acceptable margin to DNB for the RCCA bank withdrawal from subcritical event. Adherence to the peaking limit is assured by the use of three-dimensional neutronics computer simulation - NEMO (Reference 16) as part of each fuel cycle design.

In order to give conservative results for a startup accident, the following assumptions are made concerning the initial reactor conditions:

1. Since the magnitude of the power peak reached during the initial part of the transient for any given rate of reactivity insertion is strongly dependent on the Doppler coefficient, conservatively low values are used. The least negative, or lower, Doppler curve of Figure 15.1.6-1 is utilized in this analysis.

2. Contribution of the moderator reactivity coefficient is negligible during the initial part of the transient because the heat transfer time between the fuel and the moderator is much longer than the neutron flux response time. After the initial neutron flux peak, the succeeding rate of power increase can be affected by the moderator reactivity coefficient. Since the moderator reactivity coefficient must be negative at all times in plant life any reactivity feedback to a core heatup would be negative, a mitigative response. A conservative value of 0 pcm/°F is therefore utilized in this analysis.

3. The reactor is assumed to be initially critical at hot zero power. This assumption is more conservative than that of a lower initial system temperature. The higher system temperature yields a larger fuel-water heat transfer coefficient, larger specific heats, and a less negative (smaller absolute magnitude) Doppler coefficient all of which tend to reduce the Doppler feedback effect thereby increasing the neutron flux peak.

4. Reactor trip is assumed to be initiated by power range high neutron flux (low setting). The most adverse combination of instrument and setpoint errors, as well as delays for trip signal actuation and rod cluster control assembly release, is taken into account. A 10 percent increase is assumed for the power range flux trip setpoint raising it from the nominal value of 25 percent to 35 percent. Since the rise in the neutron flux is so rapid, the effect of errors in the trip setpoint on the actual time at which the rods are released is negligible. In addition, the reactor trip insertion characteristic is based on the assumption that the highest worth rod cluster control assembly is stuck in its fully withdrawn position. See Subsection 15.1.5 for rod cluster control assembly insertion characteristics.

5. The maximum positive reactivity insertion rate assumed (57 pcm/s) is greater than that for the simultaneous withdrawal of the combination of the two control banks having the greatest combined worth at maximum speed (45 inches/min). Control rod drive mechanism design is discussed in Subsection 4.2.3.

6. The initial power level was assumed to be below the power level expected for any shutdown condition. The combination of highest reactivity insertion rate and lowest initial power produces the highest peak heat flux.

7. Two reactor coolant pumps are assumed to be operational.

Results

Use of a BOL delayed neutron fraction effectively slows the neutron flux response, allowing closer coupling to the increase in lagging core thermal power. Use of BOL parameters, therefore, result in the most limiting RCCA withdrawal from subcritical event response. Figures 15.2.1-1 through 15.2.1-3 show the transient behavior for this event.

Figure 15.2.1-1 is a graph of the nuclear power transient predicted in the systems analysis with RELAP5/MOD2-B&W. Nuclear power is normalized to the rated thermal power of 3455 MWth. The nuclear power overshoots the rated thermal power for a very short time period. As a result, the fuel thermal response is limited.

Core thermal power predicted in the systems analysis with RELAP5/MOD2-B&W is normalized to rated thermal power and plotted in Figure 15.2.1-2. The benefit of the fuel thermal lag behind the nuclear power response is demonstrated in this plot. Thermal power peaks significantly below rated thermal power.

An adequate margin to DNB is indicated by the results of the LYNXT DNB study. In addition, the study demonstrates that the hot-pin fuel temperature response is acceptable and that the peak centerline temperature is significantly less than the fuel melt temperature. A plot of the peak fuel and cladding temperature response is shown in Figure 15.2.1-3.

The time sequence of events for the RCCA withdrawal from subcritical event is shown in Table 15.2-1.

15.2.1.3 Conclusions

The system analysis for the RCCA withdrawal accident from subcritical event demonstrates that the systems responses are well within relevant material and component limits. The corresponding core sub-channel thermal-hydraulics analysis results in a minimum DNBR above the safety limit. In addition, fuel thermal responses are well within material limits. All acceptance criteria are, therefore, met for this event.

The RCCA Withdrawal from Subcritical event has been evaluated with respect to the CENP-Westinghouse steam generator replacement at Sequoyah Unit 1 and Unit 2. The evaluation concludes that the parameters important to the consequences of this event are not adversely affected by the RSG.

15.2.2 Uncontrolled Rod Cluster Control Assembly Bank Withdrawal At Power

15.2.2.1 Identification of Causes and Accident Description

Uncontrolled rod cluster control assembly bank withdrawal at power results in an increase in the core heat flux. Since the heat extraction from the steam generator lags behind the core power generation until the steam generator pressure reaches the relief or safety valve setpoint, there is a net increase in the reactor coolant temperature. Unless terminated by manual or automatic action, the power mismatch and resultant coolant temperature rise would eventually result in DNB. Therefore, in order to avert damage to the cladding the Reactor Protection System is designed to terminate any such transient before the DNBR falls below the safety limit.

The automatic features of the Reactor Protection System which prevent core damage following the postulated accident include the following:

1. Power range neutron flux instrumentation actuates a reactor trip if two out of four channels exceed an overpower setpoint.

2. Reactor trip is actuated if any two out of four ΔT channels exceed an overtemperature ΔT setpoint. This setpoint is automatically varied with axial power imbalance, coolant temperature and pressure to protect against DNB.

3. Reactor trip is actuated if any two out of four ΔT channels exceed an overpower ΔT setpoint. This setpoint is automatically varied with axial power imbalance to ensure that the allowable heat generation rate (kW/ft) is not exceeded.

4. A high pressurizer pressure reactor trip actuated from any two out of four pressure channels which is set at a fixed point. This set pressure is less than the set pressure for the pressurizer safety valves.

5. A high pressurizer water level reactor trip actuated from any two out of three level channels which is set at a fixed point.

In addition to the above listed reactor trips, there are the following rod cluster control assembly withdrawal blocks:

1. High neutron flux (one out of four)

2. Overpower ΔT (two out of four)

3. Overtemperature ΔT (two out of four)

The manner in which the combination of overpower and overtemperature ΔT trips provide protection over the full range of Reactor Coolant System conditions is described in Chapter 7. This includes a

plot (also shown as Figure 15.1.3-1) representing typical allowable reactor coolant loop average temperature and ΔT for the design power distribution and flow as a function of primary coolant pressure. The boundaries of operation defined by the overpower ΔT trip and the overtemperature ΔT trip are represented as "protection lines" on this diagram. The protection lines are drawn to include all adverse instrumentation and setpoint errors so that under nominal conditions trip would occur well within the area bounded by these lines. The utility of this diagram is in the fact that the limit imposed by any given DNBR can be represented as a line. The DNB lines represent the locus of conditions for which the DNBR equals the safety limit. All points below and to the left of DNB line for a given pressure have a DNBR greater than the safety limit. The diagram shows that DNB is prevented for all cases if the area enclosed within the maximum protection lines is not traversed by the applicable DNBR line at any point. This diagram is valid also for Cycle 9 reload fuel supplied by the B&W Fuel Company.

The area where DNBR is greater than the safety limit, and power less than the overpower limit (power, pressure and temperature) is bounded by the combination of reactor trips: high neutron flux (fixed setpoint); high pressure (fixed setpoint); low pressure (fixed setpoint); overpower and overtemperature ΔT (variable setpoints).

Power distribution analyses of rod withdrawal accidents from reduced power conditions are described in WCAP-8403 (Reference 10). Radial peaking factors under various rodded conditions used in the accidents are shown in Table 3-1 from Reference 10. The axial power shapes preceding and during the withdrawal accidents are not included here explicitly because of the very large number involved. However, the results from the axial calculations are synthesized with the radial peaking factors using the techniques described in Section 4.3, and then plotted in the form of a "flyspeck." The results indicate that the control bank malfunction flyspeck and the boration/dilution flyspeck reach a smaller maximum linear heat generation rate than the limiting value of 21 kW/ft. Considerable margin is available for conservatism.

15.2.2.2 <u>Analysis of Effects and Consequences</u>

<u>Method of Analysis</u>

This transient is analyzed using the RELAP5/MOD2-B&W code (Reference 12). The RELAP5/MOD2-B&W code is a thermal-hydraulic code that simulates the neutron kinetics, Reactor Coolant System, pressurizer, pressurizer relief and safety valves, steam generators and steam generator safety valves. The code calculates the system parameters by performing a semi-implicit solution of conservation of mass, energy and momentum over two fluids (liquid and vapor). The system and core power responses generated by RELAP5/MOD2-B&W are used to determine the hot channel DNBR by applying the statistical core design methodology (Reference 14) with the LYNXT computer code (Reference 13).

In order to obtain conservative values of DNBR the following assumptions are made:

1. Initial conditions of maximum core power (including instrumentation errors) and use of statistical core design methodology that accounts for measurement and control band uncertainties on all critical parameters.

2. Reactivity Coefficients - Two cases are analyzed:

    a. Minimum Reactivity Feedback. The most positive moderator coefficient is assumed, corresponding to the beginning of core life. The least negative Doppler power coefficient is assumed, consistent with the beginning of core life.

b. Maximum Reactivity Feedback. The largest negative moderator coefficient allowed by the Technical Specifications of the plant is assumed. The largest negative Doppler power coefficient is assumed, consistent with the end of core life.

3. The reactor trip on high neutron flux is assumed to be actuated at a conservative value of 118% of nominal full power. The ΔT trips include all adverse instrumentation and setpoint errors, while the delays for the trip signal actuation are assumed at their maximum values.

4. The rod cluster control assembly trip insertion characteristic is based on the assumption that the highest worth assembly is stuck in its fully withdrawn position.

5. The maximum positive reactivity insertion rate is greater than that for the simultaneous withdrawal of the combination of the two control banks having the maximum combined worth at maximum speed.

Results

Figures 15.2.2-1 through 15.2.2-3 show the transient response to a rapid rod cluster control assembly withdrawal incident starting from full power. Reactor trip on high neutron flux occurs shortly after start of the accident. Since this is rapid with respect to the thermal time constants of the plant, small changes in T_{avg} and pressure result and a large margin to DNB is maintained.

The transient response for a slow control rod assembly withdrawal from full power is shown in Figures 15.2.2-4 through 15.2.2-6. Reactor trip on overtemperature ΔT occurs after a longer period and the rise in temperature and pressure is consequently larger than for rapid rod cluster control assembly withdrawal.

Figure 15.2.2-7 shows the minimum DNBR as a function of reactivity insertion rate from initial full power operation for the minimum and maximum reactivity feedback. It can be seen that two reactor trip channels provide protection over the whole range of reactivity insertion rates. These are the high neutron flux and the overtemperature ΔT channels. The minimum DNBR is never less than the safety limit. The minimum DNBR values shown in Figure 15.2.2-7 are from LYNXT calculations.

A typical sequence of events for both a large and a small reactivity insertion rate may be found in Table 15.2-1.

15.2.2.3 Conclusion

The high neutron flux and overtemperature ΔT trip channels provide adequate protection over the entire range of possible reactivity insertion rates, i.e., the minimum value of DNBR is always larger than the safety analysis limit.

The RCCA Withdrawal at Power has been evaluated with respect to the CENP-Westinghouse steam generator replacement at Sequoyah Unit 1 and Unit 2. The evaluation concludes that the parameters important to the consequences of this event are not adversely affected by the RSG.

15.2.3 Rod Cluster Control Assembly Misalignment

15.2.3.1 Identification of Causes and Accident Description

Rod cluster control assembly misalignment accidents include:

1. A dropped full-length assembly;
2. A dropped full-length assembly bank;
3. Statically misaligned full length assembly.

Each rod cluster control assembly has a position indicator channel which displays position of the assembly. The displays of assembly positions are grouped for the operator's convenience. Fully inserted assemblies are further indicated by a rod bottom light. Group demand position is also indicated.

RCCAs are always moved in preselected banks, and the banks are always moved in the same preselected sequence. Each bank of RCCAs is divided into two groups. The rods comprising a group operate in parallel through multiplexing thyristors. The two groups in a bank move sequentially such that the first group is always within one step of the second group in the bank.

A definite schedule of actuation (or deactuation of the stationary gripper, movable gripper, and lift coils of a mechanism) is required to withdraw the RCCA attached to the mechanism. Mechanical failures are in the direction of insertion or immobility.

A dropped assembly or assembly bank is detected by:

1. Sudden drop in the core power level as seen by the Nuclear Instrumentation System;
2. Asymmetric power distribution as seen on out of core neutron detectors or core exit thermocouples;
3. Rod bottom light(s);
4. Rod deviation alarm;
5. Rod position indication.

Misaligned assemblies are detected by:

1. Asymmetric power distribution as seen on out of core neutron detectors or core exit thermocouples;
2. Rod deviation alarm;
3. Rod position indicators.

The resolution of the rod position indicator channel is ± 5 percent of span (± 7.2 inches). Deviation of any assembly from its group by twice this distance (10 percent of span, or 14.4 inches) will not cause

power distributions worse than the design limits. The deviation alarm alerts the operator to rod deviation with respect to group demand position in excess of 5 percent of span.

If one or more rod position indicator channels should be out of service, detailed operating instructions shall be followed to assure the alignment of the non-indicated assemblies. The operator is also required to take action, as required by the Technical Specifications.

15.2.3.2 Analysis of Effects and Consequences

Method of Analysis

1. One or More Dropped RCCAs from the Same Group

   For evaluation of the dropped RCCA event, the transient system response is calculated using the LOFTRAN code (Reference 4). The LOFTRAN code is described in section 15.1.9.3.

   Statepoints are calculated and nuclear models are used to obtain a hot channel factor consistent with the primary system conditions and reactor power. By incorporating the primary conditions from the transient and the hot channel factor from the nuclear analysis, the DNBR design basis is shown to be met using the THINC code (See Section 4.4.3.4.1). The transient response, nuclear peaking factor analysis, and DNBR design basis confirmation are performed in accordance with the methodology described in Reference 5.

2. Statically Misaligned RCCA

   Steady state power distributions are analyzed using the computer codes as described in Table 4.1-2. The peaking factors are then used as input to the THINC code to calculate the DNBR.

Results

1. One or More Dropped RCCAs

   Single or multiple dropped RCCAs within the same group result in a negative reactivity insertion that may be detected by the power range negative neutron flux rate trip circuitry. If detected, the reactor is tripped within approximately 2.7 seconds following the drop of the RCCAs. The core is not adversely affected during this period since power is decreasing rapidly. Following reactor trip, normal shutdown procedures are followed. The operator may manually retrieve the RCCA by following approved operating procedures.

   For those dropped RCCAs that do not result in a reactor trip, power may be reestablished either by reactivity feedback or control bank withdrawal. Following a dropped rod event in manual rod control, the plant will establish a new equilibrium condition. The equilibrium process without control system interaction is monotonic, thus removing power overshoot as a concern and establishing the automatic rod control mode of operation as the limiting case.

   For a dropped RCCA event in the automatic rod control mode, the rod control system detects the drop in power and initiates control bank withdrawal. Power overshoot may occur due to this

action by the automatic rod controller after which the control system will insert the control bank to restore nominal power. Figures 15.2.3-1 and 15.2.3-2 show a typical transient response to a dropped RCCA (or RCCAs) in automatic control. In all cases, the minimum DNBR remains above the safety analysis limit value. In some cases of automatic bank withdrawal, reactor power can reach and be limited by the power range monitor (PRM) high flux, high setpoint reactor trip. Safety analyses that credit this function generally assume a trip setpoint of 116.5 percent RTP, as indicated in Table 15.1.3-1, and as described in subsections 15.1.3, 15.2.2.2, 4.3.2.2.6, 4.4.2.2.6 and 7.2.2.2.1, and as reflected in Figures 7.2.2-1 and 15.1.3-1. The nominal set point is 109 percent RTP, with a measurement uncertainty of +/-6 percent RTP as calculated under the approved methodology (see subsection 15.1.11, Reference 17). An unallocated margin of 1.5 percent RTP is present in the 116.5 percent RTP analytical limit. To improve DNBR margin in the dropped rod accident, this margin in measurement uncertainty will be applied in dropped rod analyses, allowing the peak power assumption in this accident to be reduced to 115 percent RTP. This lower value is fully supported by margin available in the measurement uncertainty allowance. Additional assurance that this value is conservative is seen in rod control system features that are not credited in modeling of the accident. For example, for the reactor to attain 115 percent RTP in the analyzed scenario it is necessary that a malfunction occur in the rod control system such that rod movement remains functional, but only in the outward direction, without responding to power mismatch feedback that otherwise would stop rod withdrawal and begin rod insertion before reactor power had exceeded RTP. It must also be assumed that the C-11 interlock fails, which otherwise would block automatic withdrawal of Bank D beyond 220 steps, and that the C-2 interlock fails, which stops rod withdrawal, if the C-2 setpoint is exceeded on any one of the four PRMs, before the PRM high flux reactor trip setpoint is reached. It is improbable that this combination of malfunctions would occur simultaneously and concurrently with the initiating failure.

2. Dropped RCCA Bank

A dropped RCCA bank typically results in a reactivity insertion of greater than 500 pcm which will be detected by the power range negative neutron flux rate trip circuitry. The reactor is tripped within approximately 2.7 seconds following the drop of a RCCA bank. The core is not adversely affected during this period since power is decreasing rapidly. Following the reactor trip, normal shutdown procedures are followed to further cool down the plant. Any action required of the operator to maintain the plant in a stabilized condition will be in a time frame in excess of 10 minutes following the incident.

3. Statically Misaligned RCCA

The most severe misalignment situations with respect to DNBR at significant power levels arise from cases in which one RCCA is fully inserted, or where Bank D is fully inserted with one RCCA fully withdrawn. Multiple independent alarms, including a bank insertion limit alarm, alert the operator well before the postulated conditions are approached. The bank can be inserted to its insertion limit with any one assembly fully withdrawn without the DNBR falling below the safety analysis limit value.

The insertion limits in the Technical Specifications may vary from time to time depending on a number of limiting criteria. The full power insertion limits on control Bank D must be chosen to be above that position (which meets minimum DNBR and peaking factors). The full power insertion limit is usually dictated by other criteria. Detailed results will vary from cycle to cycle depending on fuel arrangements.

For this RCCA misalignment, with Bank D inserted to its full power insertion limit and one RCCA fully withdrawn, DNBR does not fall below the safety analysis limit value. This case is analyzed assuming the initial reactor power, pressure, and RCS temperatures are at their nominal values but with the increased radial peaking factor associated with the misaligned RCCA.

For RCCA misalignments with one RCCA fully inserted, the DNBR does not fall below the limit value. This case is analyzed assuming the initial reactor power, pressure, and RCS temperatures are at their nominal values, but with the increased radial peaking factor associated with the misaligned RCCA.

DNBR does not occur from the RCCA misalignment incident and thus the ability of the primary coolant to remove heat from the fuel rod is not reduced. The peak fuel temperature corresponds to a linear heat generation rate based on the radial peaking factor penalty associated with the misaligned RCCA and the design axial power distribution. The resulting linear heat generation is well below that which would cause fuel melting.

Following the identification of an RCCA group misalignment condition by the operator, the operator is required to take action as required by the plant Technical Specifications and operating instructions.

15.2.3.3 Conclusions

For all cases of dropped RCCAs or dropped banks, for which the reactor is tripped by the power range negative neutron flux rate trip, there is no reduction in the margin to core thermal limits and, consequently, the DNB design basis is met. It is shown for all cases which do not result in reactor trip that the DNBR remains greater than the safety analysis limit value and, therefore, the DNB design basis is met.

For all cases of any RCCA inserted, or Bank D inserted to its rod insertion limits with any single RCCA in that bank fully withdrawn (static misalignment), the DNBR remains greater than the safety analysis limit value.

The RCCA Misalignment event has been evaluated with respect to the CENP-Westinghouse steam generator replacement at Sequoyah Unit 1 and Unit 2. The evaluation concludes that the parameters important to the consequences of this event are not adversely affected by the RSG.

15.2.4 Uncontrolled Boron Dilution

15.2.4.1 Identification of Causes and Accident Description

Reactivity can be added to the core by feeding primary grade water into the Reactor Coolant System via the reactor makeup portion of the Chemical and Volume Control System. Boron dilution is a manual operation under strict administrative controls with procedures calling for a limit on the rate and duration of dilution. A boric acid blend system is provided to permit the operator to match the boron concentration of reactor coolant makeup water during normal charging to that in the Reactor Coolant System (RCS). The Chemical and Volume Control System (CVCS) is designed to limit, even under various postulated failure modes, the potential rate of dilution to a value which, after indication through alarms and instrumentation, provides the operator sufficient time to correct the situation in a safe and orderly manner.

The opening of the primary water makeup control valve provides makeup to the RCS which can dilute the reactor coolant. Inadvertent dilution from this source can be readily terminated by closing the control valve or stopping the primary makeup water pump. Makeup water can be added to the RCS at pressure when at least one charging pump and a primary makeup water pump are running.

The rate of addition of unborated makeup water to the RCS when it is not at pressure is limited by the capacity of the primary water supply pumps. Normally, only one primary water supply pump is operating while the other is on standby. With the RCS at pressure, the maximum delivery rate is limited by the control valve.

The boric acid from the boric acid tank is blended with primary grade water in the blender and the composition is determined by the preset flow rates of boric acid and primary grade water on the control board.

In order to dilute, two separate operations are required:

1. The operator must switch from the automatic makeup mode to the dilute mode, and

2. The boric acid to blender flow control switch must be turned to the start position.

Omitting either step would prevent dilution. Information on the status of the reactor coolant makeup is continuously available to the operator by:

1. Status lights on the control board to indicate CVCS operating conditions.

2. CVCS deviations in flow from programmed levels at the boric acid and demineralized water blender.

3. Pressurizer level and pressure would be increasing from prescribed values (at higher than planned dilution flows).

4. Volume control tank level deviation from programmed level.

Thus there are a number of diverse indications available to the operator to indicate inadvertent or excessive dilutions.

15.2.4.2 Analysis of Effects and Consequences

Methods of Analysis

Boron dilution during refueling, startup, and power operation are considered in this analysis. Table 15.2-1 contains the time sequence of events for this accident.

Dilution During Refueling

An uncontrolled boron dilution accident is not credible during refueling. This accident is prevented by administrative controls which isolate the RCS from significant sources of unborated water.

Various valve combinations that are required to be verified closed during refueling operations are specified in Technical Specification 3.9.2, SR 3.9.2.1. These valves will block the significant dilution flow paths which could allow unborated makeup to reach the RCS. Dilution flow paths, such as instrument and sampling sense lines, where the physical size of the connection to the RCS allows sufficient time for operator response based on source range count rate, are considered insignificant. Any makeup which is required during refueling will be borated water supplied either from the refueling water storage tank by the low head safety injection pumps or the centrifugal charging pumps, or from the boric acid tanks via a boric acid transfer pump and a centrifugal charging pump.

Dilution During Startup

In this mode, the plant is being taken from one long-term mode of operation, Hot Standby, to another, Power. Typically, the plant is maintained in the Startup mode only for the purpose of startup testing at the beginning of each cycle. During this mode of operation rod control is in manual. All normal actions required to change power level, either up or down, require operator initiation. Conditions assumed for the analysis are:

1. Dilution flow is the maximum capacity of the makeup water pumps, 300 gpm.

2. A minimum RCS water volume of 9019 ft^3. This corresponds to the active RCS volume excluding the pressurizer and the reactor vessel upper head.

3. The initial boron concentration is assumed to correspond to a conservative maximum value for the critical concentration at the condition of hot zero power, rods to insertion limits, and no Xenon.

4. The critical boron concentration following reactor trip is assumed to correspond to the hot zero power, all rods inserted (minus the most reactive RCCA), no Xenon condition.

Dilution Following Reactor Shutdown

Following reactor shutdown, when in hot standby, hot shutdown, and subsequent cold shutdown condition, and once below the P-6 interlock setpoint, and 10^4 counts per second, the high flux at shutdown alarm setting will be automatically adjusted downward to a nominal value of 3 times the background count rate as the background count rate reduces.

Surveillance testing in accordance with Technical Specification 3.3.9 will ensure that the alarm setpoint is operable. The operator does not depend entirely on this alarm setpoint but has audible indication of increasing neutron flux from the audible count rate drawer and visual indication from counts per second meters for each channel on the main control board and source range drawer.

Dilution at Power

In this mode, the plant may be operated in either automatic or manual rod control. Conditions assumed for the analysis are:

1. Dilution flow at power is the maximum capacity of the makeup water pumps, 300 gpm.

2. A minimum RCS water volume of 9019 ft^3. This corresponds to the active RCS volume excluding the pressurizer and the reactor vessel upper head.

3. The initial boron concentration is the conservative maximum value for the critical concentration at the condition of hot full power, rods to insertion limits, and no Xenon.

4. The critical boron concentration following reactor trip is assumed to correspond to the hot zero power, all rods inserted (minus the most reactive RCCA), no Xenon condition.

15.2.4.3 Conclusions

The time sequence of events during these transients are shown in Table 15.2-1.

For dilution during refueling:

Sufficient dilution of the RCS boron concentration during refueling cannot occur due to administrative controls (see Section 15.2.4.2) and operator response.

The operator has prompt and definite indication of any boron dilution from the audible count rate instrumentation. At all times during fuel movement, the source range audible count rate is on the refueling floor of reactor containment and the main control room. In addition, a high source range flux level at shutdown is alarmed in the control room and in the reactor containment. The count rate increase is proportional to the subcritical multiplication factor.

For dilution during startup:

This mode of operation is a transitory operational mode in which the operator intentionally dilutes and withdraws control rods to take the plant critical. During this mode, the plant is in manual control with the operator required to maintain a high awareness of the plant status. For a normal approach to criticality, the operator must manually initiate a limited dilution and subsequently manually withdraw the control rods, a process that takes several hours. The Technical Specifications require that the operator determine the estimated critical position of the control rods prior to approaching criticality, thus assuring that the reactor does not go critical with the control rods below the insertion limits. Once critical, the power escalation must be sufficiently slow to allow the operator to manually block the source range reactor trip after receiving P-6 from the intermediate range. Too fast a power escalation (due to an unknown dilution) would result in reaching P-6 unexpectedly, leaving insufficient time to manually block the source range reactor trip. Failure to perform this manual action results in a reactor trip and immediate shutdown of the reactor.

For dilution during startup, a cycle specific check demonstrates that the initial and final borons result in more than 15 minutes for operator action from the time of alarm (reactor trip on P-6) to loss of shutdown margin.

For dilution during full power operation:

With the reactor in automatic rod control, the power and temperature increase from boron dilution results in insertion of the control rods and a decrease in the available shutdown margin. The rod insertion limit alarms (LOW and LOW-LOW settings) alert the operator that a dilution event is in process and operators take action to restore margin. A cycle specific check demonstrates that the initial and final borons result in more than 15 minutes for operator action from the time of alarm (LOW-LOW rod insertion limit) to loss of shutdown margin.

With the reactor in manual control and no operator action taken to terminate the transient, the power and temperature rise will cause the reactor to reach the Overtemperature ΔT trip setpoint resulting in a reactor trip. The boron dilution transient in this case is essentially the equivalent to an uncontrolled RCCA bank withdrawal at power. The maximum reactivity insertion rate for a boron dilution is conservatively estimated to be within the range of insertion rates analyzed for the RCCA bank withdrawal at power. A cycle specific check demonstrates that the initial and final borons result in more than 15 minutes for operator action from the time of alarm (overtemperature ΔT) to loss of shutdown margin.

For Dilution Following Reactor Shutdown:

In providing a description of a boron dilution event initiated immediately after scram, it is appropriate to analyze two initial conditions. These are:

1. BOL, Equilibrium Xe

   This will result in the longest time following scram until the Source Range Nuclear Instrumentation System (NIS) is available to provide an indication of a dilution event.

2. BOL, Clean Core

   This will result in a very short time following scram for the source range NIS to become available, however, it yields the most rapid boron dilution (return to criticality) case.

Figure 15.2.4-1 shows the relative change in boron concentration with time for the two cases. The dilution rates are consistent with the time for the two cases. Figure 15.2.4-2 shows the condition of the core consistent with the boron concentrations of Figure 15.2.4-1 and Xe build-up following trip for the Eq Xe cases.

Figure 15.2.4-3 shows the information available to the operator on the core relative power based on the Nuclear Instrumentation System for the Eq Xe case. As shown there is essentially an instantaneous decrease in nuclear power from 100% to 7.5% (< 5 seconds). From 7.5% the standard 80 second period is used until the precursor isotopes have been depleted. From the point shown, an 18-day half life is assumed. For the case without Eq Xe, the NIS stable reading on source range is achieved very rapidly, < 5 minutes as opposed to 21 minutes for the Eq Xe case.

The sequence of events Table 15.2-1 show that for both cases > 15 minutes of operator action time is available. Therefore the acceptance criteria for this event is met. In addition to the High Flux at Shutdown Alarm, there is also the High Pressurizer Level Trip and alarm available. In order to return critical a very large total dilution volume is required. The only means of accommodating this large volume is to allow the pressurizer to start filling. As shown, however, this results in a High Pressurizer Level Alarm very early in the transient.

These two alarms would provide the operator an adequate set of indications that a boron dilution event was in progress and also allow adequate time for operator corrective action.

The Uncontrolled Boron Dilution event has been evaluated with respect to the CENP-Westinghouse steam generator replacement at Sequoyah Unit 1 and Unit 2. The evaluation concludes that the parameters important to the consequences of this event are not adversely affected by the RSG.

15.2.5 Partial Loss of Forced Reactor Coolant Flow

15.2.5.1 Identification of Causes and Accident Description

A partial loss of coolant flow accident can result from a mechanical or electrical failure in a reactor coolant pump, or from a fault in the power supply to the pump. If the reactor is at power at the time of the accident, the immediate effect of loss of coolant flow is a rapid increase in the coolant temperature. This increase could result in DNB with subsequent fuel damage if the reactor is not tripped promptly. The necessary protection against a partial loss of coolant flow accident is provided by the low primary coolant flow reactor trip which is actuated by two out of three low flow signals in any reactor coolant loop. Above approximately 35% power (Permissive 8), low flow in any loop will actuate a reactor trip. Between approximately 10% power (Permissive 7) and the power level corresponding to Permissive 8, low flow in any two loops will actuate a reactor trip. A reactor trip signal from the pump undervoltage relay is provided as an anticipatory signal which serves as a backup to the low flow signal. It functions essentially identically to the low flow trip so that above Permissive 7 an undervoltage relay trip signal from any two pumps will actuate a reactor trip.

The RCPs are normally powered from the Unit Station Service Transformers (USSTRs). The following analysis is bounding for the condition described above.

15.2.5.2 Analysis of Effects and Consequences

Method of Analysis

Partial loss of flow involving loss of two pumps with four loops in operation has been analyzed.

This transient is analyzed by three digital computer codes. First, the LOFTRAN Code (Reference 4) is used to calculate the loop and core flow during the transient, the time of reactor trip based on the calculated flows, the nuclear power transient, and the primary system pressure and temperature transients. The LYNXT Code (Reference 13) is then used to calculate the heat flux transient based on the nuclear power and flow from LOFTRAN. Finally, the THINC Code is used to calculate the departure from DNBR during the transient, based on the heat flux from FACTRAN and the flow from LOFTRAN. The WRB-1 correlation is used for DNBR calculation. Finally, the hot channel DNBR is determined by applying the statistical core design methodology (Reference 14) with the LYNXT computer code (Reference 13).

Typical Initial Conditions

Initial operating conditions assumed are the most adverse with respect to the margin to DNB, i.e., maximum steady state power level, minimum steady state pressure, and maximum steady state coolant average temperature. See Subsection 15.1.2 for explanation of initial conditions. In addition to the initial average temperature condition in Subsection 15.1.2, 1.5°F was added to the initial average temperature for conservatism.

Reactivity Coefficients

A conservatively large absolute value of the Doppler-only power coefficient is used (See Table 15.1.2-2). The total integrated Doppler reactivity from 0 to 100% power is assumed to be 0.016 Δk. The lowest absolute magnitude of the moderator temperature coefficient (0.0 $\Delta k/°F$) is assumed since this results in the maximum hot-spot heat flux during the initial part of the transient when the minimum DNBR is reached.

Flow Coastdown

The flow coastdown analysis is based on a momentum balance around each reactor coolant loop and across the reactor core. This momentum balance is combined with the continuity equation, a pump momentum balance and the pump characteristics and is based on high estimates of system pressure losses.

Results

The calculated sequence of events is shown on Table 15.2-1 for the case analyzed. Figures 15.2.5-1 through 15.2.5-3 show the resulting transient conditions for the 2/4 Partial Loss of Flow analysis. Included in these figures are total RCS flow, faulted loop flow, average and hot channel heat flux, nuclear power, and DNBR, each as a function of time. The minimum DNBR is not less than the safety analysis limit.

15.2.5.3 Conclusions

The analysis shows that the DNBR will not decrease below the safety analysis limit at any time during the transient. Thus there will be no cladding damage and no release of fission products to the Reactor Coolant System.

The Partial Loss of Forced Reactor Coolant Flow event has been evaluated with respect to the CENP-Westinghouse steam generator replacement at Sequoyah Unit 1 and Unit 2. The evaluation concludes that the parameters important to the consequences of this event are not adversely affected by the RSG.

15.2.6 Startup Of An Inactive Reactor Coolant Loop

15.2.6.1 Identification of Causes and Accident Description

The SQN Technical Specification requires that all reactor coolant loops be in operation during plant's startup and power operations except for special test conditions. The following analysis is for a 3 loop operation and will address startup of an inactive reactor coolant loop which may be created due to an operational error.

If the plant is operating with one pump out of service, there is reverse flow through the inactive loop due to the pressure difference across the reactor vessel. The cold leg temperature in an inactive loop is identical to the cold leg temperature of the active loops (the reactor core inlet temperature). If the reactor is operated at power, there is a temperature drop across the steam generator in the inactive loop and, with the reverse flow, the hot leg temperature of the inactive loop is lower than the reactor core inlet temperature.

Starting of an idle reactor coolant pump without bringing the inactive loop hot leg temperature close to the core inlet temperature would result in the injection of cold water into the core which causes a rapid reactivity insertion and subsequent power increase. This event is classified as an ANS Condition II incident (a fault of moderate frequency).

Should the startup of an inactive reactor coolant pump accident occur, the transient will be terminated automatically by a reactor trip on low coolant loop flow when the power range neutron flux (two out of four channels) exceeds the P-8 setpoint, which would have been previously reset for three loop operation.

15.2.6.2 Analysis of Effects and Consequences

Method of Analysis

This transient is analyzed by three digital computer codes. The LOFTRAN Code (4) is used to calculate the loop and core flow, nuclear power and core pressure and temperature transients following the startup of an idle pump. FACTRAN (3) is used to calculate the core heat flux transient based on core flow and nuclear power from LOFTRAN. The THINC Code (see Section 4.4) is then used to calculate the DNBR during the transient based on system conditions (pressure, temperature, and flow) calculated by LOFTRAN and heat flux as calculated by FACTRAN.

Plant characteristics and initial conditions are discussed in Section 15.1.2. In order to obtain conservative results for the startup of an inactive pump accident, the following assumptions are made:

1. Initial conditions of maximum core power and reactor coolant average temperatures and minimum reactor coolant pressure resulting in minimum initial margin to DNB. These values are consistent with the maximum steady state power level allowed with three loops in operation. The high initial power gives the greatest temperature difference between the core inlet temperature and the inactive loop hot leg temperature.

2. Following initiation of startup of the idle pump, flow in the inactive loop reverses and accelerates to its nominal full flow value in approximately 7 seconds.

3. A conservatively large moderator density coefficient (see Section 15.1.6).

4. A conservatively small (absolute value) negative Doppler power coefficient (see Section 15.1.6).

5. The initial reactor coolant loop flows are at the appropriate values for one pump out of service.

6. The reactor trip is assumed to occur on low coolant loop flow when the power range neutron flux exceeds the P-8 setpoint. The P-8 setpoint is conservatively assumed to be 84 percent of rated power which corresponds to the nominal setpoint plus 9 percent for nuclear instrumentation errors.

Results

The results following the startup of an idle pump with the above listed assumptions are shown in Figures 15.2.6-1 through 15.2.6-4. As shown in these curves, during the first part of the transient, the increase in core flow with cooler water results in an increase in nuclear power and a decrease in core average water temperature. The minimum DNBR during the transient is considerably greater than the safety analysis limit. See Section 4.4 for a description of the DNBR design basis.

Reactivity addition for the inactive loop startup accident is due to the decrease in core water temperature. During the transient, this decrease is due both to the increase in reactor coolant flow and, as the inactive loop flow reverses, to the colder water entering the core from the hot leg side (colder temperature side prior to the start of the transient) of the steam generator in the inactive loop. Thus, the reactivity insertion rate for this transient changes with time. The resultant core nuclear power transient, computed with consideration of both moderator and Doppler reactivity feedback effects, is shown on Figure 15.2.6-2.

The calculated sequence of events for this accident is shown on Table 15.2-1. The transient results illustrated in Figures 15.2.6-1 through 15.2.6-4 indicate that a stabilized plant condition, with the reactor tripped, is approached rapidly. Plant cooldown may subsequently be achieved by following normal shutdown procedures.

15.2.6.3 Conclusions

The transient results show that the core is not adversely affected, i.e., there is considerable margin to the DNB safety analysis limit.

Operation of the Sequoyah Nuclear Plant with fewer than 4 RCP's in operation is prohibited (except during special test conditions) by plant Technical Specifications. The startup of an inactive reactor coolant loop event, therefore, is not considered as a safety issue with replacement steam generators.

15.2.7 Loss Of External Electrical Load And/Or Turbine Trip

15.2.7.1 Identification of Causes and Accident Description

Major load loss on the plant can result from loss of external electrical load or from a turbine trip. For either case off site power remains available for the continued operation of plant components such as

the reactor coolant pumps. The case of loss of all AC power (station blackout) is analyzed in Subsection 15.2.9. Following the loss of generator load, an immediate fast closure of the turbine control valves will occur. This will cause a sudden reduction in steam flow, resulting in an increase in pressure and temperature in the steam generator shell. As a result, the heat transfer rate in the steam generator is reduced, causing the reactor coolant temperature to rise, which in turn causes coolant expansion, pressurizer insurge, and RCS pressure rise.

For a turbine trip, the reactor would be tripped directly (unless below approximately 50% power) from a signal derived from the turbine emergency trip header pressure or the turbine stop valve position. The turbine stop valves close on loss of emergency trip header pressure actuated by one of a number of possible turbine trip signals. Turbine-trip initiation signals include:

1. Generator Trip
2. Low Condenser Vacuum
3. Loss of Lubricating Oil
4. Turbine Thrust Bearing Failure
5. Turbine Overspeed
6. Manual Trip

Upon initiation of stop valve closure, steam flow to the turbine stops abruptly. Sensors associated with the stop valves detect the turbine trip and initiate the turbine trip and initiate steam dump and if above 50 percent power, a reactor trip. The loss of steam flow results in an almost immediate rise in secondary system temperature and pressure with a resultant primary system transient.

The automatic steam dump system would accommodate the excess steam generation. Reactor coolant temperatures and pressure do not significantly increase if the steam dump system and pressurizer pressure control system are functioning properly. If the turbine condenser were not available, the excess steam generation would be dumped to atmosphere through the steam generator relief and safety valves. Additionally, main feedwater flow would be lost if the turbine condenser was not available. For this situation feedwater flow would be maintained by the Auxiliary Feedwater System.

The Sequoyah plant is designed to accept a load rejection of 50 percent of its rated electrical load, and signals from the reactor protection system will trip the plant for load rejections in sufficient excess of 50 percent of rated load.

In the event the steam dump valves fail to open following a large loss of load, the steam generator safety valves may lift and the reactor may be tripped by the high pressurizer pressure signal, the high pressurizer water level signal, the overtemperature ΔT signal, or the steam generator Low-Low Level Signal. The steam generator shell side pressure and reactor coolant temperatures will increase rapidly. The pressurizer safety valves and steam generator safety valves are, however, sized to protect the Reactor Coolant System and steam generators against overpressure for all load losses without assuming the operation of the steam dump system, pressurizer spray, pressurizer power operated relief valves, automatic rod cluster control assembly control or direct reactor trip on turbine trip.

The steam generator safety valve capacity is sized to remove the original maximum calculated turbine steam flow from the steam generator without exceeding 110 percent of the steam system design pressure. The pressurizer safety valve capacity is sized based on a complete loss of heat sink with the plant initially operating at the maximum calculated turbine load along with operation of the steam generator safety valves. The pressurizer safety valves are then able to maintain the Reactor Coolant System pressure within 110 percent of the Reactor Coolant System design pressure without direct or immediate reactor trip action.

A more complete discussion of overpressure protection can be found in Reference 8.

Normal power for the reactor coolant pumps is supplied through busses from a transformer connected to the preferred off-site power system.

The following is background on where the 30 second value came from and is based on the original plant design. In the alternate or maintenance power supply configuration, when a generator trip occurs, the busses are automatically transferred to a transformer supplied from external power lines, and the pumps will continue to supply coolant flow to the core. Following any turbine trip where there are no electrical faults which require tripping the generator from the network, the generator remains connected to the network for approximately 30 seconds. The reactor coolant pumps remain connected to the generator, thus ensuring flow for 30 seconds before any transfer is made. The analysis of effects and consequences for this condition is based on the alternate power supply configuration and is bounding.

Should the network bus transfer fail at 30 seconds, a complete loss of forced reactor coolant flow would result. This assumption is made for the analysis of a complete loss of load at approximately 50% power without direct reactor trip. The immediate effect of loss of coolant flow is a rapid increase in the coolant temperature in addition to the increased coolant temperature as a result of the turbine trip. This increase could result in DNB with subsequent fuel damage if the reactor were not tripped promptly.

The following signals provide the necessary protection against a complete loss of flow accident:

1. Reactor coolant pump power supply undervoltage or underfrequency

2. Low reactor coolant loop flow

The reactor trip on reactor coolant pump undervoltage is provided to protect against conditions which can cause a loss of voltage to all reactor coolant pumps, i.e., station blackout. This function is blocked below approximately 10 percent power (Permissive 7).

The reactor trip on reactor coolant pump underfrequency is provided to open the reactor coolant pump breakers and trip the reactor for an underfrequency condition, resulting from frequency disturbances on the major power grid. The trip disengages the reactor coolant pumps from the power grid so that the pump's kinetic energy is available for full coastdown.

The reactor trip on low primary coolant loop flow is provided to protect against loss of flow conditions which affect only one reactor coolant loop. This function is generated by two out of three low flow signals per reactor coolant loop. Between approximately 10 percent power (Permissive 7) and the power level corresponding to Permissive 8, low flow in any two loops will actuate a reactor trip.

15.2.7.2 Analysis of Effects and Consequences

Methods of Analysis

The minimum DNBR for a total loss of load transient is bounded by the value calculated for a complete loss of forced reactor coolant flow (15.3.4). Consequently, the analysis of total loss of load is performed to show the adequacy of the pressure relieving devices on the primary and secondary systems. Two loss of load cases are analyzed. These are a loss of load from 102 percent of full power and a total loss of load from 52 percent of full power.

AREVA reanalyzed the total loss of load from 100 percent rated thermal power plus calorimetric uncertainties for the Cycle 9 reload with AREVA Mark-BW fuel because this event is the limiting overpressure event of the primary and secondary systems. The transient was analyzed using the RELAP5/MOD2-B&W computer program (Reference 12) to generate the time response of the primary system, secondary system and core average power. The reactor was not tripped on the turbine trip, but tripped later on a high pressurizer pressure trip. Main feedwater flow is terminated at the time of turbine trip, with no credit taken for auxiliary feedwater to mitigate the consequences of the transient. In addition, no credit is taken for steam dump and worst case lift tolerance of six percent is assumed for the main steam safety valves. Two of three pressurizer safety valves, each with a lift tolerance of five percent, are assumed to be available to mitigate the primary system pressure transient. Although this is not the limiting event for minimum DNBR, the system and core power responses predicted by RELAP5/MOD2-B&W are used to determine the minimum DNBR for the event by employing the statistical core design methodology of BAW-10170 (Reference 14).

AREVA analyzed the loss of load from 100 percent rated thermal power plus calorimetric uncertainties with credit taken for the operation of pressurizer sprays and the pressurizer power operated relief valves (PORVs). The operation of pressurizer sprays and the pressurizer PORVs result in a delay in reactor trip. By delaying a reactor trip, the mismatch between core power generation and secondary heat removal capability is maximized. This results in a higher peak secondary pressure.

The total loss of load transient from 52 percent of full power is analyzed by employing the detailed digital computer program LOFTRAN. The program simulates the neutron kinetics, Reactor Coolant System, pressurizer, pressurizer relief and safety valves, pressurizer spray, steam generator, and steam generator safety valves. The program computes the pertinent plant variables including temperatures, pressures, and power level. The core limits as illustrated in Figure 15.1.3-1 are used as input to LOFTRAN to determine the minimum DNBR of the typical or thimble cell during the transient. In this analysis, the behavior of the unit is evaluated for a complete loss of steam load from 52 percent of full power without reactor trip. The turbine is assumed to trip without actuating all the sensors for reactor trip on the turbine stop valves. The assumption delays reactor trip until conditions in the RCS result in a trip due to other signals. Thus, the analysis assumes a worst transient. In addition, no credit is taken for steam dump. Main feedwater is terminated at the time of turbine trip, with no credit taken for auxiliary feedwater to mitigate the consequences of the transient.

A fast bus transfer is attempted 30 seconds following the loss of steam load from 52 percent power. The transfer to an external power source is assumed to fail which results in a complete loss of flow transient initiated from the loss of load condition. The loss of flow transient, due to the assumed failure of the fast bus transfer, is analyzed by employing the detailed digital computer codes LOFTRAN (4), FACTRAN (3), and THINC Subparagraph 4.4.3.4. The FACTRAN code calculates the heat flux transient based on the nuclear power and flow from LOFTRAN. Finally, the THINC code calculates the DNBR during the transient based on the heat flux from FACTRAN and flow from LOFTRAN.

Typical assumptions are:

1. Initial Operating Conditions - The initial reactor coolant pressure is set to the nominal value for the 102 percent power case. To maximize the pressure response, the initial primary system average temperature was set to the nominal value minus four degrees for control band and measurement uncertainty. For the loss of load from 52 percent power, the initial reactor power and Reactor Coolant System temperatures are assumed at their maximum values consistent with the power level including allowances for calibration and instrument errors. The initial Reactor Coolant System pressure for this case is assumed at a minimum value that includes allowances for calibration and instrument errors. Table 15.2.7-1 summarizes the initial conditions assumed.

2. Moderator and Doppler Coefficients of Reactivity - Sensitivity calculations show that the maximum primary system pressure is obtained for beginning-of-life conditions. Consequently, for the two loss of load cases analyzed from 100 percent rated thermal power plus calorimetric uncertainty, a moderator coefficient of +7.0 pcm/F (peak primary system pressure case), and +0.0 pcm/F (peak secondary system pressure case), and the least negative Doppler power coefficient are used. The total loss of load from 52 percent power is analyzed for both beginning-of-life and end-of-life conditions. Moderator temperature coefficients of zero at beginning-of-life and a large (absolute value) negative value at end-of-life were used. A conservatively large (absolute value) Doppler power coefficient is used for all cases.

3. Reactor Control - From the standpoint of the maximum pressures attained it is conservative to assume that the reactor is in manual control.

4. Steam Release - No credit is taken for the operation of the steam dump system or steam generator power operated relief valves. The steam generator pressure rises to the safety valve setpoint (plus lift tolerances, where applicable) where steam release through safety valves limits secondary steam pressure near the lift value.

5. Pressurizer Spray and Power Operated Relief Valves - To maximize the primary system pressure response to a total loss of load from 100 percent rated thermal power plus calorimetric uncertainty, no credit is taken for the pressurizer spray or pressurizer PORVs. For the loss of load from 100 percent rated thermal power plus calorimetric uncertainty analyzed to determine peak secondary system pressure, the pressurizer spray and pressurizer PORVs are modeled in order to delay a reactor trip and maximize the secondary system pressure. For the loss of load from 52 percent power, two cases for both the beginning and end-of-life are analyzed:

   a. Full credit is taken for the effect of pressurizer spray and power operated relief valves in reducing or limiting the coolant pressure.

   b. No credit is taken for the effect of pressurizer spray and power operated relief valves in reducing or limiting the coolant pressure. Pressurizer heater operation is assumed since heater operation on high pressurizer water level will tend to increase the maximum surge rate through the pressurizer safety valves.

6. Feedwater Flow - Main feedwater flow to the steam generators is assumed to be lost at the time of turbine trip. No credit is taken for auxiliary feedwater flow since a stabilized plant condition will be reached before auxiliary feedwater initiation is normally assumed to occur. However, the auxiliary feedwater pumps would be expected to start on a trip of the main feedwater pumps. The auxiliary feedwater flow would remove core decay heat following plant stabilization.

7. Reactor Trip - Reactor trip is actuated by the first Reactor Protection System trip setpoint reached with no credit taken for the direct reactor trip on the turbine trip. Trip signals are expected due to high pressurizer pressure, overtemperature ΔT, high pressurizer water level, low reactor coolant loop flow, reactor coolant pump power supply undervoltage, and low-low steam generator water level.

Except as discussed above, normal reactor control system and Engineered Safety Systems are not required to function.

The Reactor Protection System may be required to function following a turbine trip. Pressurizer safety valves and/or steam generator safety valves may be required to open to maintain system pressures below allowable limits. No single active failure will prevent operation of any system required to function.

Results

The transient response for a total loss of load from 100 percent rated thermal power plus calorimetric uncertainties analyzed for peak primary pressure is shown in Figures 15.2.7-1 through 15.2.7-6. Following closure of the turbine stop valves, the primary pressure increases causing a reactor trip on high pressurizer pressure. Control rod insertion terminates the transient. Actuation of the pressurizer safety valves ensures that the primary system pressure remains below the acceptance criterion. Likewise, the main steam safety valves ensure that the secondary system pressure does not exceed 110 percent of design. The DNBR remains above the limit at all times. The sequence of events is shown in Table 15.2-1.

The transient response for a total loss of load from 100 percent rated thermal power plus calorimetric uncertainties analyzed for peak secondary pressure is shown in Figures 15.2.7-1b through 15.2.7-5b. Following closure of the turbine, the primary system pressure increases resulting in actuation of pressurizer sprays and opening of the pressurizer PORVs. Secondary pressure increases and eventually the main steam safety valves lift to limit the pressure increase. The energy mismatch between core power generation and secondary heat removal eventually results in a reactor trip on over-temperature ΔT. Control rod insertion terminates the transient. Actuation of the pressurizer sprays and opening of the pressurizer PORVs maintains primary system pressure below the 110 percent of design pressure. Adequate steam relief through the main steam safety valves ensures secondary system pressure remains below 110 percent of design pressure. Figure 15.2.7-7 shows the transient DNBR response for Advanced W17 HTP fuel. The DNBR remains above the limit at all times. The sequence of events is shown in Table 15.2-1.

The transient responses for a turbine trip from 52% of full power operation are shown for four cases: two cases for minimum reactivity feedback (beginning of core life) and two cases for maximum reactivity feedback (end of core life). These results are shown in Figures 15.2.7-9 through 15.2.7-16. The calculated sequence of events for this accident is shown on Tables 15.2.7-2 and 15.2.7-3.

Figures 15.2.7-9 and 15.2.7-10 show the transient responses for the total loss of steam load with a least negative moderator temperature coefficient assuming full credit for the pressurizer spray and pressurizer power-operated relief valves. No credit is taken for the steam dump. The fast bus transfer is attempted and assumed to fail 30 seconds after the total loss of steam load. The transfer failure results in an undervoltage trip of the reactor and the initiation of the loss of flow transient. The minimum DNBR remains well above the safety analysis limit. The steam generator safety valves limit the secondary steam conditions to saturation at the safety valve setpoint.

Figures 15.2.7-11 and 15.2.7-12 show the responses for the total loss of steam load with a large negative moderator temperature coefficient. All other plant parameters are the same as the above. The minimum DNBR remains well above the safety analysis limit throughout the transient. Pressurizer relief valves and steam generator safety valves prevent overpressurization in primary and secondary systems, respectively.

The turbine trip accident was also studied assuming the plant to be initially operating at 52% of full power with no credit taken for the pressurizer spray, pressurizer power-operated relief valves, or steam dump. The reactor is tripped on the high pressurizer pressure signal. With the plant in the alternate or maintenance auxiliary power supply configuration (generator supplying station power), the fast bus transfer for this case is assumed to fail at 30 seconds after the total loss of load. Figures 15.2.7-13 and 15.2.7-14 show the transients with a least negative moderator coefficient. The neutron flux remains essentially constant at 52% of full power until the reactor is tripped. The DNBR remains above the safety analysis limit throughout the transient. In this case the pressurizer safety valves are actuated and maintain system pressure below 110% of the design value.

Figures 15.2.7-15 and 15.2.7-16 are the transients with maximum reactivity feedback with the other assumptions being the same as in the preceding case. Again, the minimum DNBR remains above the safety analysis limit throughout the transient. In this case, the pressurizer safety valves are momentarily actuated.

Reference 8 presents additional results of analysis for a complete loss of heat sink including loss of main feedwater. This report shows the overpressure protection that is afforded by the pressurizer and steam generator safety valves.

The time sequence of events during this transient is shown in Table 15.2-1.

15.2.7.3 <u>Framatome ANP Safety Evaluation With Replacement Steam Generators</u>

The parameters that affect the peak secondary pressure are the primary-to-secondary heat transfer rate, MSSV characteristics, and the pressure differential between the MSSVs and the peak steam generator pressure location. The peak RCS pressure is a function of the initial secondary pressure, primary-to-secondary heat transfer rate, pressurizer safety valve capacity, and high pressurizer pressure reactor trip setpoint.

An analysis was performed by Framatome ANP to demonstrate that the peak secondary pressure would remain below the acceptance criteria following a loss of electrical load event at Sequoyah Unit 1 with RSGs. The analysis was performed with the RELAP5/MOD2 computer code using a Sequoyah specific plant model.

The RELAP5 peak secondary pressure was obtained using a maximum RCS average temperature and 0% tube plugging in the RSGs. This resulted in a peak steam generator pressure of 1206 psia, which is less than the pressure limit of 1208 psia. Because the acceptance criteria would not be exceeded following a loss of electrical load event at Sequoyah Unit 1 using the RSGs, there is no reduction in the margin of safety associated with the replacement. This conclusion is applicable to Unit 2 because of virtually identical RSG’s installed between Units.

To validate Technical Specification Table 3.7.1-1, partial power cases were also analyzed with different numbers of MSSVs out of service. These analyses yielded secondary pressure below the acceptance limit. Therefore, the Technical Specification table is still valid with the RSGs.

15.2.7.4 Conclusions

Results of the analyses, including those in Reference 8 show that the plant design is such that a total loss of external electrical load without a direct or immediate reactor trip presents no hazard to the integrity of the RCS or the main steam system. Pressure relieving devices incorporated in the two systems are adequate to limit the maximum pressures to within the design limits.

The integrity of the core is maintained by operation of the Reactor Protection System, i.e., the DNBR will be maintained above the safety analysis limit. Thus there will be no cladding damage and no release of fission products to the Reactor Coolant System.

15.2.8 Loss of Normal Feedwater

15.2.8.1 Identification of Causes and Accident Description

A loss of normal feedwater (from pump failures, valve malfunctions, or loss of offsite AC power) results in a reduction in capability of the secondary system to remove the heat generated in the reactor core. If the reactor were not tripped during this accident, core damage would possibly occur from a sudden loss of heat sink. If an alternative supply of feedwater were not supplied to the plant, residual heat following reactor trip would heat the primary system water to the point where water relief from the pressurizer would occur. Significant loss of water from the Reactor Coolant System (RCS) could conceivably lead to core damage. Since the plant is tripped well before the steam generator heat transfer capability is reduced, the primary system variables never approach a DNB condition.

The worst postulated loss of normal feedwater event is one initiated by a loss of offsite AC power which is described in Section 15.2.9. This is due to the decreased capability of the reactor coolant to remove residual core heat as a result of the RCP coastdown.

The following events occur upon loss of normal feedwater (assuming main feedwater pump failures or valve malfunctions):

A. As the steam system pressure rises following the trip, the steam generator power-operated relief valves are automatically opened to the atmosphere. Steam dump to the condenser is assumed not to be available. If the steam flow rate through the power-operated relief valves is not available, the steam generator safety valves may lift to dissipate the sensible heat of the fuel and coolant plus the residual decay heat produced in the reactor.

B. As the no-load temperature is approached, the steam generator power-operated relief valves (or safety valves if the power-operated relief valves are not available) are used to dissipate the residual decay heat and to maintain the plant at the hot shutdown condition.

The following provides the necessary protection against a loss of normal feedwater:

1. Reactor trip on low-low water level in any steam generator.

2. Two motor driven auxiliary feedwater pumps which are started on:

    a. Low-low level in any steam generator

b. Trip of both feedwater pumps

c. A safety injection signal

d. Loss of offsite power

e. Manual actuation

f. Loss of one main feedwater pump with turbine load greater than 77% (Unit 2) and 76.6% (Unit 1).

3. One turbine driven auxiliary feedwater pump which utilizes steam from the steam generators is started on:

a Low-low level in any two steam generators, or

b. Trip of both feedwater pumps

c. Loss of offsite power

d. Safety injection signal

e. Manual actuation

f. Loss of one main feedwater pump with turbine load greater than 77% (Unit 2) and 76.6% (Unit 1).

The motor driven auxiliary feedwater pumps are supplied with power by the diesel generators if a loss of offsite power occurs and the turbine-driven pump utilizes steam from the main steam system. Both type pumps are designed to supply at least, minimum required flow within one minute of the initiating signal even if a loss of all non-emergency AC power occurs simultaneously with loss of normal feedwater. The turbine exhausts the used steam to the atmosphere. The auxiliary pumps take suction from the condensate storage tank for delivery to the steam generators.

An analysis of the system transient is presented below to show that following a loss of normal feedwater, the auxiliary feedwater system is capable of removing the stored and residual heat, thus, preventing either overpressurization of the Reactor Coolant System or loss of water from the reactor core.

The analysis takes into account a maximum of 15 percent uniform tube plugging in the steam generators.

15.2.8.2 Analysis of Effects and Consequences

Method of Analysis

A detailed analysis using the RELAP5/MOD2 (Reference 12) is performed to obtain the plant parametric response due to a loss of normal feedwater. The digital computer simulation of RELAP5 includes plant nuclear kinetics, reactor coolant system (with pressurizer and steam generators), main

feedwater, auxiliary feedwater, and safety injection systems. The code computes the resultant system parameters including the steam generator level, pressurizer water level, and the reactor coolant average temperature.

Major assumptions are:

1. The plant is initially operating at 102% of 3423 MWt.

2. Core decay heat is conservatively calculated based upon 1.0 times ANS 5.1 of 1971 decay heat curve with B&W heavy actinides contribution to decay heat.

3. Only one motor driven auxiliary feedwater pump is available one minute after the low-low steam generator level signal is initiated in any steam generator.

4. Auxiliary feedwater flow rate of 410 gpm is split uniformly between two steam generators.

5. Secondary system steam relief is achieved through the self-actuated safety valves. Note that steam relief will, in fact, be through the power operated relief valves or condenser dump valves for most cases of loss of normal feedwater. However, for the sake of analysis these have been assumed unavailable.

6. The initial reactor coolant average temperature is 5.5°F higher than the nominal value since this results in a greater expansion of Reactor Coolant System water during the transient and, thus, in a higher water level in the pressurizer.

Results

Figures 15.2.8-1 through 15.2.8-4 show plant parameters following a loss of normal feedwater. Following the reactor and turbine trip from full load, the water level in the steam generators will fall due to the reduction of steam generator void fraction and because steam flow through the safety valves continues to dissipate the stored and generated heat. One minute following the initiation of the low-low level trip, at least one auxiliary feedwater pump is automatically started, reducing the rate of water level decrease in two steam generators.

The capacity of one motor driven auxiliary feedwater pump is such that the water level in two steam generators does not recede below the lowest level at which sufficient heat transfer area is available to dissipate core residual heat without water relief from the RCS relief or safety valves. Figure 15.2.8-2b shows that at no time is there water relief from the pressurizer.

The calculated sequence of events for this accident is listed in Table 15.2-1. As shown in Figures 15.2.8-1 through 15.2.8-4, the plant approaches a stabilized condition following reactor trip and auxiliary feedwater initiation.

15.2.8.3 Conclusions

Results of the analysis show that a loss of normal feedwater does not adversely affect the core, the RCS, or the steam system since the auxiliary feedwater capacity is such that the reactor coolant water is not relieved from the pressurizer relief or safety valves.

The Loss of Normal Feedwater event has been evaluated with respect to the CENP-Westinghouse steam generator replacement at Sequoyah Unit 1 and Unit 2. The evaluation concludes that the parameters important to the consequences of this event are not adversely affected by the RSG.

15.2.9 Loss of Off-Site Power to the Station Auxiliaries

15.2.9.1 Identification of Causes and Accident Description

In the event of a complete loss of offsite power and a turbine trip there will be a loss of power to the plant auxiliaries, i.e., the reactor coolant pumps, condensate pumps, etc.

The events following a loss of AC power with turbine and reactor trip are described in the sequence listed below:

1. Plant vital instruments are supplied by emergency power sources.

2. As the steam system pressure rises following the trip, the steam system power operated relief valves may be automatically opened to the atmosphere. Steam dump to the condenser is assumed not to be available. If the steam flow rate through the power relief valves is not available, the steam generator safety valves may lift to dissipate the sensible heat of the fuel and coolant plus the residual decay heat produced in the reactor.

3. As the no load temperature is approached, the steam generator power-operated relief valves (or safety valves, if the power-operated relief valves are not available) are used to dissipate the residual decay heat and to maintain the plant at the hot shutdown condition.

4. The Class 1E standby diesel generators, started on loss of voltage on the plant emergency busses, begin to supply plant vital loads.

The auxiliary feedwater system is started automatically as discussed in the loss of normal feedwater analysis. The turbine driven auxiliary feedwater pump utilizes steam from the main steam system and exhausts to the atmosphere. The motor driven auxiliary feedwater pumps are supplied by power from the diesel generators. The auxiliary feedwater pumps take suction from the condensate storage tank for delivery to the steam generators.

Following the RCP coastdown caused by the loss of AC power, the natural circulation capability of the RCS will remove residual and decay heat from the core, aided by auxiliary feedwater in the secondary system. An analysis is presented here to show that the natural circulation flow in the RCS following a loss of AC power event is sufficient to remove residual heat from the core.

The analysis presented takes into account a maximum of 15 percent uniform tube plugging in the steam generators.

15.2.9.2 Analysis of Effects and Consequences

Method of Analysis

A detailed analysis using RELAP5/MOD2 (Reference 12) is performed to obtain the plant parametric response due to a loss of offsite power. The digital computer simulation of RELAP5 includes plant

nuclear kinetics, reactor coolant system (with pressurizer and steam generators), main feedwater, auxiliary feedwater, and safety injection systems. The code computes the resultant system parameters including the steam generator level, pressurizer water level, and the reactor coolant average temperature.

Major assumptions are:

1. The plant is initially operating at 100.7% of 3455 MWt.

2. Core decay heat is conservatively calculated based upon 1.0 times ANS 5.1 of 1971 decay heat curve with B&W heavy antinides contribution to decay heat.

3. Only one motor-driven auxiliary feedwater pump is available one minute after the low-low steam generator level signal is initiated in any steam generator.

4. Auxiliary feedwater flow rate of 410 gpm is split uniformly between two SGs.

5. The initial reactor coolant average temperature is 7.0°F lower than the nominal value since this results in a greater expansion of Reactor Coolant System water during the transient and a higher water level in the pressurizer.

<u>Results</u>

The transient response of the RCS following a loss of AC power is shown in Figures 15.2.9.1 through 15.2.9.4. The calculated sequence of events for this event is listed in Table 15.2-1.

The first few seconds of the transient following receipt of a reactor trip signal will closely resemble a simulation of the complete loss of flow incident (see Subsection 15.3.4), i.e., core damage due to rapidly increasing core temperatures is prevented by promptly tripping the reactor. After the reactor trip, stored and residual decay heat must be removed to prevent damage to either the RCS or the core.

15.2.9.4 Conclusions

Results of the "Complete Loss of Forced Reactor Coolant Flow" analysis (Section 15.3) and the loss of non-emergency AC power to the station auxiliaries show that no adverse conditions occur in the reactor core. The DNBR is maintained above the safety limit. The Reactor Coolant System is not overpressurized and no water relief will occur through the pressurizer relief valves. The pressurizer safety valves do not lift. Thus there will be no cladding damage and no release of fission products to the RCS.

15.2.10 Excessive Heat Removal Due to Feedwater System Malfunctions

15.2.10.1 Identification of Causes and Accident Description

Reductions in feedwater temperature or additions of excessive feedwater are means of increasing core power above full power. Such transients are attenuated by the thermal capacity of the secondary plant and of the RCS. The overpower - overtemperature protection (high neutron flux, overtemperature and overpower ΔT trips) prevents any power increase which could lead to a DNBR less than the safety analysis limit.

Excessive feedwater flow could be caused by a full opening of one or more feedwater regulator valves due to a feedwater control system malfunction or an operator error. At power this excess flow causes a greater load demand on the RCS due to increased subcooling in the steam generators. With the plant at no-load conditions, the addition of cold feedwater may cause a decrease in RCS temperature and thus a reactivity insertion due to the effects of the negative moderator coefficient of reactivity. Continuous addition of excessive feedwater is prevented by the steam generator high-high level trip, which closes all feedwater regulator isolation valves, trips main feedwater pumps and trips the turbine.

15.2.10.2 Analysis of Effects and Consequences

Method of Analysis

The excessive heat removal due to a feedwater system malfunction transient is analyzed by using the detailed digital computer codes, RELAP5 and LYNXT (References 12 and 13). The codes are described in section 15.1.9.8 and section 15.1.9.11, respectively. The core limits as illustrated in Figure 15.1.3-1 are used as input to the RELAP5 and LYNXT codes to determine the minimum DNBR during the transient for the full power case. The RELAP5 model used incorporated a detailed representation of the condensate and feedwater system piping including the feedwater heaters, condensate booster pumps, and the main feedwater pumps.

Operation With Digital Feedwater Control

The system is analyzed to evaluate plant behavior in the event of a feedwater system malfunction. The multi-loop failure mode was eliminated in the digital control system. The single loop failure mode in the digital control system will cause the main feedwater pump speed demand signal to both pumps to increase to a maximum value. The digital control system analysis addresses this failure mode by modeling the maximum feed pump speed allowed by the pump overspeed protection equipment.

Excessive feedwater addition due to a control system malfunction or operator error which allows one or more feedwater control valves to open fully is considered. The most limited cases are discussed.:

1. Accidental opening of all feedwater regulating valves and feedwater regulating bypass valves to the full open position in a single loop with the reactor at zero load.

2. Accidental opening of all feedwater regulating valves and feedwater regulating bypass valves to the full open position in a single loop with the reactor at full power.

The plant response following a feedwater system malfunction is calculated with the following assumptions:

1. Reactor at zero load

   a. The reactor is assumed to be just critical in the hot shutdown condition.

   b. An increase in feedwater flow to one steam generator from zero flow to full flow assuming 2 condensate booster pumps are operating at maximum rpm and 1 main feed pump is operating at the maximum speed allowed by the pump overspeed trip with maximum uncertainty applied.

   c. The feedwater temperature is assumed at a conservatively low value of 58°F, corresponding to lowest condenser hotwell conditions.

2. Reactor at full power

   a. Initial operating conditions are assumed at extreme values consistent with the steady state full power operation allowing for calibration and instrument errors. This results in minimum margin to DNB at the start of the accident.

b. Both automatic and manual rod control was assumed for each of the full power cases. The results from the most limiting scenario are presented.

c. A step increase in feedwater flow to one steam generator from nominal flow to full flow assuming all 3 condensate booster pumps are operating at maximum rpm and 2 main feed pumps are operating at the maximum speed allowed by the pump overspeed trip with maximum uncertainty applied.

3. For cases 1 and 2,

a. The initial water level in all steam generators is at a conservatively low level for the initial conditions.

b. No credit is taken for the heat capacity of the Reactor Coolant System in attenuating the resulting plant cooldown.

c. The feedwater flow from a fully open regulator valve is terminated by the steam generator high-high level signal which closes all feedwater regulator valves and feedwater isolation valves and trips the main feedwater pumps.

d. A conservatively large moderator coefficient of reactivity characteristic of end of life core conditions is used.

Results

For the case of an accidental full opening of all feedwater regulating valves and feedwater regulating bypass valves in a single loop with the reactor at zero power and the above mentioned assumptions, the maximum reactivity insertion rate is less than the maximum reactivity insertion rate analyzed in Subsection 15.2.1, Uncontrolled Control Rod Assembly Withdrawal from a Subcritical Condition, and therefore, the results of the analyses are not presented. It should be noted that if the incident occurs with the unit just critical at no load, the reactor may be tripped by the power range high neutron flux trip (low setting) set at approximately 35 percent.

The full power cases give the largest reactivity feedback and result in the greatest power increases. Transient results for operation with the digital feedwater control (see Figures 15.2.10-1 thru 15.2.10-5) show the pressurizer pressure, T_{avg}, and DNBR, as well as the increase in nuclear power and ΔT_{avg}, associated with the increased thermal load on the reactor. A turbine trip is actuated when the steam generator level reaches the high-high level setpoint. The DNB ratio does not drop below the safety analysis limit.

For all excessive feedwater cases continuous addition of cold feedwater is prevented by closure of all feedwater control valves and a trip of the feedwater pumps on steam generator high-level.

The time sequence of events during this transient is shown in Table 15.2-1.

15.2.10.3 Conclusions

It has been shown that the reactivity insertion rate which occurs at no load following excessive feedwater addition is less than the maximum value considered in the analysis of the rod withdrawal from a subcritical condition. Also, the DNB ratios encountered for excessive feedwater addition at power are well above the safety analysis limit.

The Excessive Heat Removal due to Feedwater System Malfunctions event has been evaluated with respect to the CENP-Westinghouse steam generator replacement at Sequoyah Unit 1 and Unit 2. The evaluation concludes that the parameters important to the consequences of this event are not adversely affected by the RSG.

15.2.11 Excessive Load Increase

15.2.11.1 Identification of Causes and Accident Description

An excessive load increase incident is defined as a rapid increase in the steam flow that causes a power mismatch between the reactor core power and the steam generator load demand. The reactor control system is designed to accommodate a 10% step load increase or a 5% per minute ramp load increase in the range of 15 to 100% of full power. Any loading rate in excess of these values may cause a reactor trip actuated by the Reactor Protection System.

This accident could result from either an administrative violation such as excessive loading by the operator or an equipment malfunction in the steam dump control or turbine speed control.

During power operation, steam dump to the condenser is controlled by reactor coolant condition signals; i.e., high reactor coolant temperature indicates a need for steam dump. A single controller malfunction does not cause steam dump; an interlock is provided which blocks the opening of the valves unless a large turbine load decrease or a reactor trip has occurred.

Protection against an excessive load increase accident is provided by the following Reactor Protection System signals:

1. Overpower ΔT

2. Overtemperature ΔT

3. Power range high neutron flux

15.2.11.2 Analysis of Effects and Consequences

Method of Analysis

System and nuclear response is performed using the RELAP5/MOD2-B&W computer code (Reference 12). The RELAP5/MOD2-B&W code simulate the neutron kinetics, reactor coolant system and steam system thermal-hydraulics. The code is described in Section 15.1.9.8.

The LYNXT computer code (Reference 13) is utilized to predict core subchannel thermal-hydraulic effects and uses boundary conditions generated with RELAP5/MOD2-B&W. Margin to the occurrence of DNB in the hottest fuel pin is predicted via the application of LYNXT for the excessive load increase transient. LYNXT is described in Section 15.1.9.11.

Four cases are analyzed to demonstrate the plant behavior following a 10% step load increase from rated load. These cases are as follows:

1. Manually controlled reactor at beginning-of-life.

2. Manually controlled reactor at end-of-life.

3. Reactor in automatic control at beginning-of-life.

4. Reactor in automatic control at end-of-life.

At beginning of life the core has the least negative moderator temperature coefficient of reactivity and therefore the least inherent transient capability. At end of life the moderator temperature coefficient of reactivity has its highest absolute value. This results in the largest amount of reactivity feedback due to changes in coolant temperature.

A conservative limit on the turbine valve opening is assumed, and all cases are studied without credit being taken for pressurizer heaters. Initial operating conditions are assumed at extreme values consistent with the steady state full power operation allowing for calibration and instrument errors. This results in minimum margin to DNB at the start of the event.

Results

Figures 15.2.11-1 through 15.2.11-4 illustrate the transient with the reactor in the manual control mode. As expected, for the beginning of life case there is no significant power increase (zero moderator feedback), and the average core temperature shows a large decrease. This results in a DNBR which increases above its initial value. For the end of life manually controlled case there is a much larger increase in reactor power due to the moderator feedback. A reduction in DNBR is experienced but DNBR remains above the safety analysis limit.

Figures 15.2.11-5 through 15.2.11-8 illustrate the transient assuming the reactor is in the automatic control mode. Both the beginning of life and the end of life cases show that core power increases, thereby reducing the rate of decrease in coolant average temperature and pressurizer pressure. For both the beginning of life and end of life cases, the minimum DNBR remains above the safety analysis limit. The time sequence of events for this transient is shown in Table 15.2-1.

15.2.11.3 Conclusions

The Excessive Load Increase has been evaluated with respect to the CENP-Westinghouse steam generator replacement at Sequoyah Unit 1 and Unit 2. The evaluation concludes that the parameters important to the consequences of this event are not adversely affected by the RSG.

It has been demonstrated that for an excessive load increase the minimum DNBR during the transient will not be below the safety analysis limit.

15.2.12 Accidental Depressurization of the Reactor Coolant System

15.2.12.1 Identification of Causes and Accident Description

The most severe core conditions resulting from an accidental depressurization of the Reactor Coolant System (RCS) are associated with an inadvertent opening of a pressurizer safety valve. Initially the event results in a rapidly decreasing RCS pressure until this pressure reaches a value corresponding to the hot leg saturation pressure. At that time, the pressure decrease is slowed considerably. The pressure continues to decrease, however, throughout the transient. The effect of the pressure decrease would be to decrease the neutron flux via the moderator density feedback, but the reactor control system (if in the automatic mode) functions to maintain the power essentially constant throughout the initial stage of the transient. The average coolant temperature decreases slowly, but the pressurizer level increases until the reactor trip.

The reactor will be tripped by one of the following Reactor Protection System signals:

1. Pressurizer low pressure

2. Overtemperature ΔT

This transient represents the limiting analysis for the RCS accidental depressurization and imposes the worst temperature/pressure profile onto the reactor core for Condition II events. The inadvertent opening of a pressurizer safety valve event does not establish the design basis piping load condition to be adhered for RCS piping (Reference 11).

15.2.12.2 Analysis of Effects and Consequences

Methods of Analysis

The accidental depressurization transient is analyzed by employing the detailed digital computer code LOFTRAN (Reference 4). This code is described in section 15.1.9.3. The LOFTRAN results and core limits as illustrated in Figure 15.1.3-1 are used as input to LYNXT (Reference 13) to determine the minimum DNBR of the hot channel during the transient.

In calculating the DNBR the following conservative assumptions are made:

1. Initial conditions of maximum core power and reactor coolant temperatures and minimum reactor coolant pressure resulting in the minimum initial margin to DNB (See Section 15.1).

2. A zero moderator coefficient of reactivity conservative for beginning of life operation in order to provide a conservatively low amount of negative reactivity feedback due to changes in moderator density. The spatial effect of void due to local or subcooled boiling is not considered in the analysis with respect to reactivity feedback or core power shape.

3. A high (absolute value) Doppler coefficient of reactivity such that the resultant amount of positive feedback is conservatively high in order to retard any power decrease due to moderator reactivity feedback.

4. The pressurizer safety valve capacity is assumed to be 10% greater to increase the depressurization rate.

It should also be noted that in the analysis power peaking factors are kept constant at the design values while, in fact, the core feedback effects would result in considerable flattening of the power distribution. This would significantly increase the calculated DNBR; however, no credit is taken for this effect.

Results

Figure 15.2.12-1 illustrates the nuclear power transient following the event. Reactor trip on overtemperature ΔT occurs as shown in Figure 15.2.12-1. The pressure and vessel average coolant temperature transients during the accident, including a 10% increase in capacity, are given in Figure 15.2.12-2. The resulting DNBR never goes below the safety analysis limit as shown in Figure 15.2.12-3.

15.2.12.3 Conclusions

The pressurizer low pressure and the overtemperature ΔT Reactor Protection System signals provide adequate protection against this accident, and the minimum DNBR remains greater than the safety analysis limit.

The Accidental Depressurization of the RCS event has been evaluated with respect to the CENP-Westinghouse steam generator replacement at Sequoyah Unit 1 and Unit 2. The evaluation concludes that the parameters important to the consequences of this event are not adversely affected by the RSG.

15.2.13 Accidental Depressurization of the Main Steam System

15.2.13.1 Identification of Causes and Accident Description

The most severe core conditions resulting from an accidental depressurization of the main steam system are associated with an inadvertent opening of a single steam dump, relief or safety valve. The analyses performed assuming a rupture of a main steam pipe are given in Section 15.4.

The steam release as a consequence of this accident results in an initial increase in steam flow which decreases during the accident as the steam pressure falls. The energy removal from the Reactor Coolant System (RCS) causes a reduction of coolant temperature and pressure. In the presence of a negative moderator temperature coefficient, the cooldown results in a reduction of core shutdown margin.

The analysis is performed to demonstrate that the following criterion is satisfied: Assuming a stuck rod cluster control assembly and a single failure in the Engineered Safety Features the DNB design basis will be met after reactor trip for a steam release equivalent to the spurious opening, with failure to close, of the largest of any single steam dump, relief or safety valve.

The following systems provide the necessary protection against an accidental depressurization of the main steam system.

1. Safety Injection System actuation from any of the following:

    a. Two-out-of three low steam line pressure signals in any one loop.

    b. Two-out-of three low pressurizer pressure signals.

2. The overpower reactor trips (neutron flux and ΔT) and the reactor trip occurring in conjunction with receipt of the safety injection signal.

3. Redundant isolation of the main feedwater lines: Sustained high feedwater flow would cause additional cooldown. Therefore, in addition to the normal control action which will close the main feedwater isolation valves following a reactor trip, a safety injection signal will rapidly close all main and bypass feedwater regulating valves and trip the main feedwater pumps.

15.2.13.2 Analysis of Effects and Consequences

Method of Analysis

The following analyses of a secondary system steam release are performed for this section.

1. A full plant digital computer simulation, LOFTRAN (Reference 4) code, to determine RCS temperature and pressure during cooldown.

2. An evaluation to determine that the DNB design basis is met.

The following conditions are assumed to exist at the time of a secondary system depressurization.

1. End of life shutdown margin at no load, equilibrium xenon conditions, and with the most reactive assembly stuck in its fully withdrawn position. Operation of rod cluster control assembly banks during core burnup is restricted in such a way that addition of positive reactivity in a secondary system break accident will not lead to a more adverse condition than the case analyzed.

2. A negative moderator coefficient corresponding to the end of life rodded core with the most reactive rod cluster control assembly in the fully withdrawn position. The variation of the coefficient with temperature and pressure is included. The K_{eff} versus temperature at 1000 psi corresponding to the negative moderator temperature coefficient used plus the Doppler temperature effect, is shown in Figure 15.2.13-1.

3. Minimum capability for injection of high concentration boric acid solution corresponding to the most restrictive single failure in the Safety Injection System. The injection curve assumed is shown in Figure 15.2.13-2. This corresponds to the flow delivered by one charging pump delivering its full contents to the cold leg header. Subsequent to this analysis, the minimum charging pump performance requirements were reduced from those shown in Figure 15.2.13-2. However, the flow reduction was more than offset by the minimum flow available from one safety injection pump. While not specifically modeled in the analysis, the flow from one safety injection pump is also credited in Reference 19 to establish that the results of the analysis remain conservative and bounding for the current charging pump minimum performance requirements in Figure 6.3.2-7. The analysis conservatively assumes that the safety injection lines downstream of the RWST contain no borated water (0 ppm). This water must be swept from the safety injection lines prior to the delivery of boric acid (1950 ppm) from the RWST to the reactor coolant loops.

4. The case studied is an initial total steam flow of 228 lbs/second at 1015 psia from all steam generators with offsite power available. This is the maximum capacity of any single steam dump or safety valve. Initial hot shutdown conditions at time zero are assumed since this represents the most pessimistic initial condition.

   Should the reactor be just critical or operating at power at the time of a steam release, the reactor will be tripped by the normal overpower protection when power level reaches a trip point. Following a trip at power the RCS contains more stored energy than at no load, the average coolant temperature is higher than at no load and there is appreciable energy stored in the fuel.

   Thus, the additional stored energy is removed via the cooldown caused by the steam line break before the no load conditions of RCS are reached. After the additional stored energy is removed, cooldown proceeds in the same manner as in the analysis which assumes no load condition at time zero. However, since the initial steam generator water inventory is greatest at no load, the magnitude and duration of the RCS cooldown are less for steam line breaks occurring at power.

5. In computing the steam flow the Moody Curve for fL/D = 0 is used.

6. Perfect moisture separation in the steam generator is assumed.

7. The auxiliary feedwater system provides a flow rate of 588 GPM to each steam generator. This auxiliary feedwater is not required to mitigate the transient and is modeled to increase the severity of the core cooldown.

Results

The calculated time sequence of events for this accident is listed in Table 15.2-1. The results presented are a conservative indication of the events which would occur assuming a secondary system steam release since it is postulated that all of the conditions described above occur simultaneously.

Figure 15.2.13-3 shows the transients arising as a result of a steam release having an initial steam flow of 228 lb/second at 1015 psia with steam release from one safety valve. The assumed steam release is the maximum capacity of any single steam dump or safety valve. Safety injection is initiated automatically by low pressurizer pressure. Operation of only one train of ECCS pumps is assumed. Boron solution at 1950 ppm enters the RCS providing sufficient negative reactivity to assure that the DNB design basis is met.

The transient is quite conservative with respect to cooldown, since no credit is taken for the energy stored in the system metal other than that of the fuel elements or energy stored in the other steam generators. Since the transient occurs over a period of about 5 minutes, the neglected stored energy is likely to have a significant effect in slowing the cooldown.

15.2.13.3 Conclusions

The analysis has shown that the criteria stated earlier in this section is satisfied. Since the minimum DNBR remains above the limiting value, no consequential damage to the core or reactor system occurs.

The Accidental Depressurization of the Steamline event has been evaluated with respect to the CENP-Westinghouse steam generator replacement at Sequoyah Unit 1 and Unit 2. The evaluation concludes that the parameters important to the consequences of this event are not adversely affected by the RSG.

15.2.14 Spurious Operation of the Safety Injection System at Power

15.2.14.1 Identification of Causes and Accidents Descriptions

NOTE: The BIT terminology will be used here since this analysis of record includes the Boron Injection Tank (now the Centrifugal Charging Pump Injection Tank) and provides bounding results.

Spurious SIS operation at power could be caused by operator error or a false electrical actuating signal. A spurious signal in any of the following channels could cause this incident.

1. High containment pressure

2. Low pressurizer pressure

3. Low steam line pressure

Following the actuation signal, the suction of the centrifugal charging pumps is diverted from the volume control tank to the refueling water storage tank. The valves isolating the injection tank from the charging pumps and the injection header then automatically open. The charging pumps then provide RWST water through the header and injection line and into the cold legs of each loop. The safety injection pumps also start automatically but provide no flow when the RCS is at normal pressure. The passive injection system and the low head system also provide no flow at normal RCS pressure.

An SIS signal normally results in a reactor trip followed by a turbine trip. However, it cannot be assumed that any single fault that actuates the SIS will also produce a reactor trip. Therefore, two different courses of events are considered.

Case A Trip occurs at the same time spurious injection starts

Case B The reactor protection system produces a trip later in the transient.

For Case A the operator would stop safety injection and bring the plant to hot standby conditions. If the safety injection system must be disabled for repair, boration should continue through the normal boration mode and the plant brought to cold shutdown.

For Case B the reactor protection system does not produce an immediate trip and the reactor experiences a negative reactivity excursion causing a decrease in reactor power. The power unbalance causes a drop in T_{avg} and consequent coolant shrinkage. The pressurizer pressure and level drop. Load will decrease due to the effect of reduced steam pressure on load after the electro-hydraulic governor fully opens the turbine throttle valve. If automatic rod control is used, these effects will be lessened until the rods have moved out of the core. The transient is eventually terminated by the reactor protection system low pressure trip or by manual trip.

The time to trip is affected by initial operating conditions including core burnup history which affects initial boron concentration, rate of change of boron concentration, Doppler and moderator coefficients.

Recovery from this incident for case B is made in the same manner described for case A. The only difference is the lower T_{avg} and pressure associated with the power unbalance during the transient. The time at which reactor trip occurs is of no concern for this accident. At lower loads coolant contraction will be slower, resulting in a longer time to trip.

Reference 17 addresses a PWR transient condition where a spurious safety injection signal with an immediate reactor trip could challenge the non-escalation criteria. A spurious safety injection signal, a Condition II event, can become a Condition III event (Small Break LOCA), if the resulting safety injection flow fills the pressurizer and a pressurizer relief or safety valve opens, discharges water, and then fails to close. This condition can be precluded if operator actions to terminate safety injection flow can be completed before the pressurizer becomes water solid or the pressurizer relief and safety valves are fully qualified to close following a water discharge.

15.2.14.2 Analysis of Effects and Consequences

Method of Analysis

The spurious operation of the SIS system is analyzed by employing the detailed digital computer program LOFTRAN (Reference 4) and LYNXT (Reference 13). These codes are described in section 15.1.9.3 and 15.1.9.11, respectively.

Because of the power and temperature reduction during the transient, operating conditions do not approach the core limits. Analysis of several cases shows the results are relatively independent of time to trip.

A transient is presented representing conditions at beginning of core life. Results at end of life are similar except that moderator feedback effects result in a slower transient.

The assumptions are:

1. Initial Operating Conditions - the initial reactor power and Reactor Coolant System temperatures are assumed at their maximum values consistent with the steady state full power operation including allowances for calibration and instrument errors.

2. Moderator and Doppler Coefficients of Reactivity - A low beginning of life moderator temperature coefficient was used. A low absolute value Doppler power coefficient was assumed.

3. Reactor Control - The reactor was assumed to be in manual control.

4. Pressurizer Heaters - Pressurizer heaters were assumed to be nonoperable in order to increase the rate of pressure drop.

5. Injection - At time zero, two charging pumps inject 20,000 ppm borated water from the BIT and 1950 ppm of borated water from the RWST water into the cold legs of each loop. Even though the BIT is functionally removed, Westinghouse analysis conservatively assumes that the BIT is still intact. This assumption lends to a larger power mismatch with subsequent RCS cooling and inventory shrinkage.

6. Turbine Load - Turbine load was assumed constant until the electro- hydraulic governor drives the throttle valve wide open. Then turbine load drops as steam pressure drops.

7. Reactor Trip - Reactor Trip was initiated by low pressurizer pressure assumed at a conservatively low value of 1775 psia.

To address the pressurizer overfill transient in Reference 17, a calculation of the pressurizer fill time for the spurious safety injection transient was performed using a Sequoyah plant specific evaluation model developed with the RELAP5/MOD2-B&W computer code. The calculation was based on a number of best-estimates assumptions and input parameters to provide a realistic pressurizer fill time for the transient condition (see Reference 18).

Results

The transient response is shown in Figures 15.2.14-1 and 15.2.14- 2. Nuclear power starts decreasing immediately due to boron injection but steam flow does not decrease until 15 seconds into the transient when the turbine throttle valve goes wide open. The mismatch between load and nuclear power causes T_{avg}, pressurizer water level, and pressurizer pressure to drop. The low pressure trip set point is reached at 64 seconds and rods start moving into the core at 66 seconds.

After trip, pressures and temperatures slowly rise since the turbine is tripped and the reactor is producing some power due to delayed neutron fissions and decay heat. The time sequence of events during this transient is shown in Table 15.2-1.

The time required to fill the pressurizer was demonstrated to exceed the required operator action time of 15 minutes to terminate safety injection flow (see Reference 18).

15.2.14.3 Conclusions

Results of the analysis show that spurious safety injection with or without immediate reactor trip presents no hazard to the integrity of the Reactor Coolant System.

DNB ratio is never less than the initial value. Thus there will be no cladding damage and no release of fission products to the reactor coolant system.

If the reactor does not trip immediately, the low pressure reactor trip will be actuated. This trips the turbine and prevents excess cooldown thereby expediting recovery from the incident.

The degradation of a spurious safety injection event to a SBLOCA is precluded for Sequoyah since the time required to fill the pressurizer during the event is greater than the maximum 15 minute operator action time required to terminate the transient (see Reference 18).

The Spurious Operation of the Safety Injection at Power event has been evaluated with respect to the CENP-Westinghouse steam generator replacement at Sequoyah Unit 1and Unit 2. The evaluation concludes that the parameters important to the consequences of this event are not adversely affected by the RSG.

15.3 CONDITION III - INFREQUENT FAULTS

By definition Condition III occurrences are faults which may occur very infrequently during the life of the plant. They will be accommodated with the failure of only a small fraction of the fuel rods although sufficient fuel damage might occur to preclude resumption of the operation for a considerable outage time. The release of radioactivity will not be sufficient to interrupt or restrict public use of those areas beyond the exclusion radius. A Condition III fault will not, by itself, generate a Condition IV fault or result in a consequential loss of function of the Reactor Coolant System or containment barriers. For the purposes of this report the following faults have been grouped into this category:

1. Loss of Reactor Coolant, from Small Ruptured Pipes or from Cracks in Large Pipes, which actuates Emergency Core Cooling.

2. Minor Secondary System Pipe Break.

3. Inadvertent Loading of a Fuel Assembly into an Improper Position.

4. Complete Loss of Forced Reactor Coolant Flow.

5. Waste Gas Decay Tank Rupture.

6. Single Rod Cluster Control Assembly Withdrawal at Full Power.

7. Steam Line Break Coincident With Rod Withdrawal at Power.

The time sequence of events during applicable Condition III faults 1, 4, and 7 above is shown in Tables 15.3.1-1, 15.3.4-1, and 15.3.7-1.

15.3.1 Loss of Coolant from Small Ruptured Pipes or from Cracks in Large Pipes Which Actuate the Emergency Core Cooling System

15.3.1.1 Identification of Causes and Accident Description

A loss of coolant accident (LOCA) is defined as a rupture of the reactor coolant system (RCS) piping or of any line connected to the system. See Section 3.6 for a more detailed description of the loss of reactor coolant accident boundary limits. Ruptures of small cross section will cause a loss of coolant at a rate that can be accommodated by the charging pumps. Pumped flow would maintain an operational water level in the pressurizer and permit the operator to execute an orderly shutdown.

The maximum break size for which the normal makeup system can maintain the pressurizer level is obtained by comparing the calculated flow from the RCS through the postulated break against the charging pump makeup flow at normal RCS pressure. Makeup flow rate from one centrifugal charging pump is typically adequate to sustain pressurizer level at 2250 psia for a break through a 0.375-inch diameter hole. Should a larger break occur, inventory loss through the break results in a reduction in pressurizer level and pressure. These breaks are considered small breaks of consequence and are examined in the analysis of this section.

At the time of break initiation, the plant is assumed to be operating at 102% of full power. Heat produced in the reactor core is exactly balanced by the heat transferred to the secondary side of the steam generator. As the RCS depressurizes, safety injection is initiated and the reactor is tripped on low pressurizer pressure. After reactor trip, heat continues to be added to the reactor coolant system by core decay heat and the hot passive heat structures.

The reactor coolant pumps are assumed to trip coincident with reactor trip. The safety injection signal isolates the main feedwater. Secondary inventory is subsequently controlled by auxiliary feedwater. The turbine will trip on reactor trip.

An important phenomenon during the small break LOCA transient is the occurrence of loop seal clearing, which is accompanied by a momentary core level depression. The momentary core depression causes a brief heatup in the upper core region. After loop seal clearing, the break mass flow rate is reduced with a phase change (predominantly liquid to predominantly steam) at the break. As a result of loop seal clearing, the RCS depressurizes; the rate of depressurization is primarily a function of break size and the number of loop seals clearing. The occurrence of loop seal clearing also marks the initiation of the core boildown phase of the transient.

During the boildown phase of the transient, a prolonged core heatup may occur depending on the ECCS pump performance. The ECCS injection rate is dependent on the system depressurization rate. Smaller breaks result in lower depressurization rates and lower ECCS flow but the mass lost to the break is also low, reducing the possibility of core uncovery. Larger small breaks cause a rapid depressurization of the RCS and the ECCS flow is sufficiently high to maintain the core in a liquid-covered state.

Intermediate small breaks are typically the worst in terms of core heatup. The break is large enough to cause a significant RCS mass loss. The depressurization rate is slow enough for these breaks to minimize pumped injection and the core may become uncovered.

Ultimately, the small break transient is mitigated by the pumped ECCS injection and/or the passive (accumulator) injection. Reactor power is reduced rapidly by reactor trip and the injection of borated water by the ECCS. The ECCS injection also serves to make up for the mass lost to the break and floods the core, ensuring prolonged decay heat removal.

15.3.1.2 Small Break LOCA Evaluation Model

The AREVA S-RELAP5 SBLOCA evaluation model for event response of the primary and secondary systems and hot fuel rod used in this analysis (Reference 1) consists of two computer codes. The appropriate conservatisms, as prescribed by Appendix K of 10 CFR 50, are incorporated. This methodology has been reviewed and approved by the NRC to perform SBLOCA analyses. The two AREVA computer codes used in this analysis are:

(1) The RODEX2-2A code (Reference 2) was used to determine the burnup-dependent initial fuel rod conditions for the system calculations.

(2) The S-RELAP5 code (Reference 9) was used to predict the thermal-hydraulic response of the primary and secondary sides of the reactor system and the hot rod response.

The gap conditions used to initialize S-RELAP5 are taken at EOC, consistent with an EOC top-peaked axial power distribution. The use of EOC fuel rod conditions along with an EOC power shape is bounding of BOC because (1) the gap conductance is higher at EOC, and (2) the power shape is more top-skewed at EOC. The initial stored energy, although higher at BOC, has a negligible impact on SBLOCA results since the stored energy is dissipated long before core uncovery.

Unit 1 Exception

Technical Specification changes associated with the SBLOCA Evaluation Methodology update described above will be staggered for the two Sequoyah units. Unit 1 will lag Unit 2. In the interim, the methods used for SBLOCA licensing analyses supporting Unit 1 remain the predecessor methods, governed by References 15, 16, and 17 as described in the following paragraphs.

The RELAP5/MOD2-B&W code is used to predict the RCS thermal-hydraulic and core heatup responses to a small break LOCA. The code has been approved by the NRC for licensing application, and is documented in detail in Reference 15. Methods and models associated with the application of RELAP5/MOD2-B&W to small break LOCA analysis are described at length in Volume II of Reference 16.

The Sequoyah reactor core model is divided radially into two regions. One region representing the hot channel and the other representing the average channel (remainder of the core). The core is further segmented axially to allow detailed computation of hot assembly cladding and vapor temperatures and provides resolution of core mixture level to within approximately 0.5 feet. Fuel pin initial conditions parameters are calculated with the TACO3 computer code (Reference 17). The RCS model contains sufficient detail to represent the coolant void distribution that affects the system hydrostatic balance during a small break.

The steam generator tube region is divided into two radial regions. One region for the shortest half of the tubes and the other region for the remainder of the tubes. This provides sufficient modeling accuracy to simulate tube length-induced draining effects.

15.3.1.3 Small Break LOCA Spectrum Analysis

The break spectrum calculations were executed for breaks of 1.00, 2.00, 2.75, 3.00, 3.50, 4.00, 4.50, 4.75, 4.90, 4.95, 5.00, 5.05, 5.10, 5.12, 5.13, 5.14, 5.15, 5.20, 5.25, 5.50, 5.75, 6.00, 6.50, 7.00, 8.00, 8.50, 9.00, 9.75, 9.76, 9.77 and 9.78-inch diameter (the 9.76-inch diameter break corresponds to an area equal to 10% of the cold leg area). A 8.75-inch diameter accumulator line break, located at the check valve nearest to the cold leg and a 1.34-inch diameter centrifugal charging line break, located in the top of the pump discharge pipe, were also analyzed.

The axial peaking distribution assumed in all of the small breaks is shown in Figure 15.3.1-1. The power peaks at the 10.0-ft core elevation, maximizes local power in the upper region of the core, and is conservative for small break analysis because of the top-down core uncovering process. As the core uncovers, the cladding in the upper elevations of the core heats up and is sensitive to the local power at that elevation. The cladding temperature in the lower elevation of the core, below the two-phase mixture height, remains near the coolant temperature. The peak power used in the analysis is based on a total peaking factor, F_q, of 2.65.

The analysis of record was performed assuming a single failure in pumped ECCS injection that minimizes RCS liquid inventory during the small break transient. One train of charging, SI, and RHR pumps are assumed operable and aligned for injection. The total flow rates associated with these systems are provided in Figure 15.3.1-2. For the charging line break, the charging flow to the intact loops is conservatively neglected.

Table 15.3.1-1 presents a time sequence of events predicted in the small break LOCA spectrum studies and Table 15.3.1-2 summarizes the results of the hot rod heatup calculations. Principal parameters of interest resulting from the 9.76-inch break case are presented in Figures 15.3.1-3 through 15.3.1-7. These figures depict primary system pressure, leak flow rate, mixture level, loop seal levels, and hot spot cladding temperature.

15.3.1.4 Conclusions

This analysis supports implementation for the transition from AREVA Mark-BW fuel to AREVA M5-clad HTP fuel. The break spectrum included pump discharge cold leg piping breaks ranging from 1.0 inch diameter to 9.78 inch diameter breaks. The charging and accumulator line breaks and the reactor coolant pump trip sensitivity study were also included. The small break LOCA event model is configured to simulate RSGs in both Sequoyah Unit 1 and Unit 2.

The results of the small break LOCA spectrum studies performed with the S-RELAP5 evaluation model show that the small break LOCA is not limiting with respect to large break LOCA results. The predicted peak cladding temperature is 1470ºF for the pump discharge break with an area equivalent to 9.76-inch diameter pipe for the Analysis of Record. With the limited temperature excursion, the local and whole-core metal-water reaction percentages are negligible. The hot pin thermal transient is insufficient to cause significant fuel pin deformation and the core remains amenable to cooling. Further, recovery of the core is demonstrated and continued operation of the ECCS will guarantee long-term cooling. The analysis, therefore, demonstrates that a significant safety margin exists between the calculated results and the 10 CFR 50.46 limits and that compliance with regulatory acceptance criteria is met.

The RCP trip sensitivity study (reference 18) shows a 2 minute delay in the tripping of the RCPs from loss of subcooling or from a SI signal does not result in a PCT greater than the limiting case, which assumes a RCP trip at break initiation. A generic study (reference 19) performed in support of the EOPs shows at least 5 minutes is available to trip the RCPs before PCT will exceed its limit.

An ECCS flow interruption evaluation was performed to address a single failure to isolate an RHR pump from the RWST during switchover. This could result in stopping the ECCS pumps to manually realign them to the sump. The evaluation conservatively considered the flow interruption in addition to the AOR single failure of an entire ECCS train. The evaluation concluded that a 5 minute flow interruption could be tolerated without exceeding the PCT limit.

15.3.2 Minor Secondary System Pipe Breaks

15.3.2.1 Identification of Causes and Accident Description

Included in this grouping are ruptures of secondary system lines which would result in steam release rates equivalent to a 6 inch diameter break or smaller.

15.3.2.2 Analysis of Effects and Consequences

Minor secondary system pipe breaks must be accommodated with the failure of only a small fraction of the fuel elements in the reactor. Since the results of analysis presented in Subsection 15.4.2 for a major secondary system pipe rupture also meet this criteria, separate analysis for minor secondary system pipe breaks is not required.

The analysis of the more probable accidental opening of a secondary system steam dump, relief or safety valve is presented in Subsection 15.2.13. These analyses are illustrative of a pipe break equivalent in size to a single valve opening.

15.3.2.3 Conclusions

The analysis presented in Subsection 15.4.2 demonstrate that the consequences of a minor secondary system pipe break are acceptable since a DNBR of less than 1.3 does not occur even for a more critical major secondary system pipe break.

15.3.3 Inadvertent Loading of a Fuel Assembly into an Improper Position

15.3.3.1 Identification of Causes and Accident Description

Fuel and core loading errors such as can arise from the inadvertent loading of one or more fuel assemblies into improper positions, loading a fuel rod during manufacture with one or more pellets of the wrong enrichment or the loading of a full fuel assembly during manufacture with pellets of the wrong enrichment will lead to increased heat fluxes if the error results in placing fuel in core positions calling for fuel of lesser enrichment. Also included among possible core loading errors is the inadvertent loading of one or more fuel assemblies requiring burnable poison rods into a new core without burnable poison rods.

Any error in enrichment, beyond the normal manufacturing tolerances, can cause power shapes which are more peaked than those calculated with the correct enrichments. The incore system of moveable flux detectors which is used to verify power shapes at the start of life is capable of revealing any assembly enrichment error or loading error which causes power shapes to be peaked in excess of the design value.

To reduce the probability of core loading errors, each fuel assembly is marked with an identification number and loaded in accordance with a core loading diagram. During core loading the identification number will be checked before each assembly is moved into the core. Serial numbers read during fuel movement are subsequently recorded on the loading diagram as a further check on proper placing after the loading is completed.

The power distortion due to any combination of misplaced fuel assemblies would significantly raise peaking factors and would be readily observable with in-core flux monitors. In addition to the flux monitors, thermocouples are located at the outlet of about one third of the fuel assemblies in the core. There is a high probability that these thermocouples would also indicate any abnormally high coolant enthalpy rise. In-core flux measurements are taken during the startup subsequent to every refueling operation.

15.3.3.2 Analysis of Effects and Consequences

Method of Analysis

Steady state power distribution in the x-y plane of the core are calculated using the TURTLE (Reference 5) code based on macroscopic cross section calculated by the LEOPARD (Reference 6) code. A discrete representation is used wherein each individual fuel rod is described by a mesh interval. The power distributions in the x-y plane for a correctly loaded core assembly are also given in Chapter 4 based on enrichments given in that section.

For each core loading error case analyzed, the percent deviations from detector readings for a normally loaded core are shown at all-in-core detector locations (see Figures 15.3.3-1 to 15.3.3-5, inclusive).

Results

The following core loading error cases have been analyzed:

Case A:

Case in which a Region 1 assembly is interchanged with a Region 3 assembly. The particular case considered was the interchange of two adjacent assemblies near the periphery of the core (see Figure 15.3.3-1).

Case B:

Case in which a Region 1 assembly is interchanged with a neighboring Region 2 fuel assembly. Two analyses have been performed for this case (see Figures 15.3.3-2 and 15.3.3-3).

In Case B-1, the interchange is assumed to take place with the burnable poison rods transferred with the Region 2 assembly mistakenly loaded into Region 1.

In Case B-2, the interchange is assumed to take place closer to core center and with burnable poison rods located in the correct Region 2 position but in a Region 1 assembly mistakenly loaded into the Region 2 position.

Case C:

Enrichment error: Case in which a Region 2 fuel assembly is loaded in the core central position (see Figure 15.3.3-4).

Case D:

Case in which a Region 2 fuel assembly instead of a Region 1 assembly is loaded near the core periphery (see Figure 15.3.3-5).

15.3.3.3 Conclusions

Fuel assembly enrichment errors would be prevented by administrative procedures implemented in fabrication.

In the event that a single pin or pellet has a higher enrichment than the nominal value, the consequences in terms of reduced DNBR and increased fuel and clad temperatures will be limited to the incorrectly loaded pin or pins.

Fuel assembly loading errors are prevented by administrative procedures implemented during core loading. In the unlikely event that a loading error occurs, analyses in this section confirm that resulting power distribution effects will either be readily detected by the in-core moveable detector system or will cause a sufficiently small perturbation to be acceptable within the uncertainties allowed between nominal and design power shapes.

This event is characterized by the misplacement of a fuel assembly in the reactor core. The event is statically examined using various neutronics codes. No system interaction or effects are included in the event analyses. The results of the analyses are completely independent of steam generator design. Thus, results with OSGs are equally applicable to operation of Sequoyah Unit 1 and Unit 2 with the RSGs.

15.3.4 Complete Loss of Forced Reactor Coolant Flow

15.3.4.1 Identification of Causes and Accident Description

A complete loss of forced reactor coolant flow may result from a simultaneous loss of electrical supplies to all reactor coolant pumps. If the reactor is at power at the time of the accident, the immediate effect of loss of coolant flow is a rapid increase in the coolant temperature. This increase could result in DNB with subsequent fuel damage if the reactor were not tripped promptly. The following provide necessary protection against a loss of coolant flow accident:

1. Undervoltage or underfrequency on reactor coolant pump power supply busses.

2. Low reactor coolant loop flow.

The reactor trip on reactor coolant pump bus undervoltage is provided to protect against conditions which can cause a loss of voltage to all reactor coolant pumps, i.e., station blackout. This function is blocked below approximately 10 percent power (Permissive 7).

The reactor trip on reactor coolant pump underfrequency is provided to open the reactor coolant pump breakers and trip the reactor for an underfrequency condition, resulting from frequency disturbances on the major power grid. The trip disengages the reactor coolant pumps from the power grid so that the pumps' kinetic energy is available for full coastdown.

The reactor trip on low primary coolant loop flow is provided to protect against loss of flow conditions which affect only one reactor coolant loop. It also serves as a backup to the undervoltage and underfrequency trips. This function is generated by two out of three low flow signals per reactor coolant loop. Above approximately 35 percent power (Permissive 8), low flow in any loop will actuate a reactor trip. Between approximately 10 percent power and 35 percent power (Permissive 7 and Permissive 8), low flow in any two loops will actuate a reactor trip.

Normal power for the reactor coolant pumps is from the unit station service transformers. Each reactor coolant pump is attached to a separate unit board and its supplied power is not interrupted for a turbine or generator trip. These pumps will continuously supply coolant flow to the core.

Although the original analysis was performed under the assumptions of a Condition III event, for the Cycle 9 reload, this event is analyzed with Condition II acceptance criteria.

15.3.4.2 Analysis of Effects and Consequences

Method of Analysis

The complete loss of flow transient has been analyzed for a loss of four pumps with four loops in operation.

The transient is analyzed using two digital computer codes. First, the RELAP5/MOD2-B&W code (Reference 11) is used to calculate the loop and core flow during the transient, the time of reactor trip based on the calculated flows, the nuclear power transient, and the primary system pressure and temperature transients. The system and core power responses from RELAP5/MOD2-B&W are used to determine the DNBR using the LYNXT code (Reference 12) and a statistical core design methodology (Reference 11). The DNBR transients presented represent the thermal-hydraulic conditions of the average channel. The DNBR curve shown is the minimum value at the hot spot of the hot channel.

The method of analysis and the assumptions made regarding initial operating conditions and reactivity coefficients are identical to those discussed in Section 15.2, except that following the loss of supply to all pumps at power, a reactor trip is actuated by either bus undervoltage or bus underfrequency. To maximize the power response during the event, the least negative Doppler power coefficient and +7.0 pcm/°F moderator coefficient are assumed.

The calculated sequence of events is shown in Table 15.3.4-1 for the case analyzed. Figures 15.3.4-1 and 15.3.4-2 show the core flows, thermal and neutron power and DNB ratios as a function of time for the case. The reactor is assumed to trip on the undervoltage signal. The DNBR was greater than the safety analysis limit for the duration of the event.

15.3.4.3 Conclusions

The analysis demonstrates that for the complete loss of forced reactor coolant flow, the DNBR does not decrease below the safety analysis limit during the transient and thus there is no clad damage or release of fission products to the Reactor Coolant System.

Analysis has shown that for frequency decay rates less than 6.8 Hz/second, no reactor coolant pump trip is necessary. A grid analysis was provided for the Sequoyah Nuclear Plant which determined that, for the worst case, the grid decay rate is less than 5.0 Hz/second.

The Complete Loss of Forced Reactor Coolant Flow event has been evaluated with respect to the CENP-Westinghouse steam generator replacement at Sequoyah Unit 1 and Unit 2. The evaluation concludes that the parameters important to the consequences of this event are not adversely affected by the RSG.

15.3.5 Waste Gas Decay Tank Rupture

15.3.5.1 Identification of Causes and Accident Description

The Gaseous Waste Processing System is designed to remove fission product gases from the reactor coolant. The system consists of a closed loop with waste gas compressors, hydrogen analyzers, waste gas decay tanks for service at power and other waste gas decay tanks for service at shutdown and startup.

The maximum amount of waste gases stored occurs after a refueling shutdown at which time the gas decay tanks store the radioactive gases stripped from the reactor coolant.

The accident is defined as an unexpected and uncontrolled release of radioactive xenon and krypton fission product gases stored in a waste decay tank as a consequence of a failure of a single gas decay tank or associated piping.

15.3.5.2 Analysis of Effects and Consequences

For the analyses and consequences of the postulated waste gas decay tank rupture, please refer to Subsection 15.5.2.

15.3.6 Single Rod Cluster Control Assembly Withdrawal at Full Power

15.3.6.1 Identification of Causes and Accident Description

No single electrical or mechanical failure in the rod control system could cause the accidental withdrawal of a single rod cluster control assembly from the inserted bank at full power operation.

The operator could deliberately withdraw a single rod cluster control assembly in the control bank. This feature is necessary in order to retrieve an assembly should one be accidentally dropped. In the extremely unlikely event of simultaneous electrical failures which could result in single rod cluster control assembly withdrawal, rod deviation and rod control urgent failure would both be displayed on the plant annunciator, and the rod position indicators would indicate the relative positions of the assemblies in the bank. The urgent failure alarm also inhibits automatic rod motion in the group in which it occurs. Withdrawal of a single rod cluster control assembly by operator action, whether deliberate or by a combination of errors, would result in activation of the same alarm and the same visual indications.

Each bank of rod cluster control assemblies in the system is divided into two groups of 4 mechanisms each, except control bank A which is comprised of two groups of two mechanisms each and group 2 of control bank D which consists of 5* mechanisms. The rods comprising a group operate in parallel through multiplexing thyristors. The two groups in a bank move sequentially such that the first group is always within one step of the second group in the bank. A definite schedule of actuation and deactuation of the stationary gripper, movable gripper, and lift coils of a mechanism is required to withdraw the rod cluster control assembly attached to the mechanism. Since the four stationary gripper, movable gripper, and lift coils associated with the four rod cluster control assemblies of a rod group are driven in parallel, any single failure which would cause rod withdrawal would affect a minimum of one group, or 4 rod cluster control assemblies except for control banks A (groups 1 and 2) and D (group 2). Mechanical failures either are in the direction of insertion, or immobility.

In the unlikely event of multiple failures which result in continuous withdrawal of a single rod cluster control assembly, it is not possible, in all cases, to provide assurance of automatic reactor trip such that core safety limits are not violated. Withdrawal of a single rod cluster control assembly results in both positive reactivity insertion tending to increase core power, and an increase in local power density in the core area "covered" by the rod cluster control assembly.

15.3.6.2 Analysis of Effects and Consequences

Method of Analysis

Power distributions within the core are calculated by the TURTLE (Reference 5) code based on macroscopic cross section generated by LEOPARD (Reference 6). The peaking factors calculated by TURTLE are then used by THINC to calculate the minimum DNB for the event. The case analyzed was for the worst rod withdrawn from bank D inserted at the insertion limit, with the reactor initially at full power. FDH for this case was 1.71 including appropriate allowances for calculational uncertainties.

Results

Two cases have been considered as follows:

1. If the reactor is in the manual control mode, continuous withdrawal of a single rod cluster control assembly results in both an increase in core power and coolant temperature, and an increase in the local hot channel factor in the area of the failed rod cluster control assembly. In

---

*U1 is permitted to operate with location H-8 Control Rod Assembly removed during U1C24 and U1C25. Therefore Group 2 of Control Bank D will have 4 mechanisms.

*U2 is permitted to operate with location H-8 Control Rod Assembly removed during Unit 2 Cycle 24 (U2C24) and U2C25. Therefore, Group 2 of Control Bank D will have 4 mechanisms.

terms of the overall system response, this case is similar to those presented in Subsection 15.2.2; however, the increased local power peaking in the area of the withdrawn rod cluster control assembly results in lower minimum DNBRs than for the withdrawn bank cases. Depending on initial bank insertion and location of the withdrawn rod cluster control assembly, automatic reactor trip may not occur sufficiently fast to prevent the minimum core DNB ratio from falling below the safety analysis limit. Evaluation of this case at the power and coolant conditions at which the overtemperature ΔT trip would be expected to trip the plant shows that an upper limit for the number of rods with a DNBR less than the safety analysis limit is 5 percent.

2. If the reactor is in automatic control mode, withdrawal of a single rod cluster control assembly will result in the immobility of the other rod cluster control assemblies in the controlling bank. The transient will then proceed in the same manner as Case 1 described above. For such cases as above a trip will ultimately ensue, although not sufficiently fast in all cases to prevent a minimum DNB ratio in the core of less than the safety analysis limit.

15.3.6.3 Conclusions

For the case of one rod cluster control assembly fully withdrawn, with the reactor in the automatic or the manual control mode and initially operating at full power with Bank D at the insertion limit, an upper bound of the number of fuel rods experiencing a DNBR of less than 1.3 is 5 percent of the total fuel rods in the core.

For both cases discussed, the indicators and alarms mentioned would function to alert the operator to the malfunction before DNB could occur. For case 2 discussed above, the insertion limit alarms (low and low-low alarms) would also serve in this regard.

The Single Rod Cluster Control Assembly Withdrawal at Full Power event has been evaluated with respect to the CENP-Westinghouse steam generator replacement at Sequoyah Unit 1 and Unit 2. The evaluation concludes that the parameters important to the consequences of this event are not adversely affected by the RSG.

15.3.7 Steam Line Break Coincident with Rod Withdrawal at Power (SLB c/w RWAP)

15.3.7.1 Identification of Causes and Accident Description

In September of 1979, IE-79-22 entitled "Qualification of Control Systems" was issued by the United States Nuclear Regulatory Commission (USNRC) identifying a potential unreviewed safety question resulting from Control and Protection Systems interactions. One of the postulated scenarios that was identified was the operation of the non-safety grade automatic rod control system following a steam line break inside or outside of containment. The automatic rod control system derives signals from the Nuclear Instrumentation System (specifically the excore power range neutron detectors) and the turbine impulse pressure, among other inputs, to determine if control rod motion is required. Since a steam line break may occur inside containment in the vicinity of the excore detectors (which are classified as Category "C" equipment per NUREG-0588, Revision 1, Appendix E), or outside containment in the vicinity of the turbine impulse pressure transmitters, the automatic rod control

system may be exposed to an adverse environment. This equipment is not qualified to preclude the steam line break from causing a control rod (bank) withdrawal due to an adverse environment. In addition to the potential rod withdrawal, the Power Range High Neutron Flux and OTΔT reactor protection trip functions may not be available as a result of the harsh environmental conditions which may exist.

15.3.7.2 Method of Analysis

This transient is simulated using the RELAP5/MOD2 and LYNXT codes (Reference 1 and 12) by modeling a steam line break in coincidence with the withdrawal of control bank D at hot full power (HFP) conditions. A spectrum of steam line break sizes were analyzed to determine the limiting condition. The reactivity assumption associated with the rod withdrawal was 15 pcm per second, which is based on the maximum speed of the rod speed controller (45 inches per minute) and the maximum differential rod worth of control bank D at HFP conditions (20 pcm per inch). Reactivity assumptions are verified each fuel cycle as part of the reload safety evaluation.

In the RELAP5/MOD2 system analysis model, the Doppler Power Coefficient was allowed to vary with power and the Moderator Temperature Coefficient was allowed to vary with core average temperature. Conservative values of Doppler Coefficient vs. Power and Moderator Coefficient vs. Temperature were used.

The following reactor trip functions may actuate during this postulated transient:

- Overpower ΔT (OPΔT): typically actuated for the small-to-intermediate breaks
- Low Steamline Pressure - Safety Injection (LSP-SI): typically actuated for the large breaks

15.3.7.3 Results

With respect to the minimum Departure from Nucleate Boiling Ratio (DNBR), the limiting case was for ton OPΔT having two-out-of-four coincidence logic. Furthermore, the measured vessel ΔT lead/lag values associated with this trip function were 5 seconds and 3 seconds, respectively. The results demonstrate that the DNB design basis was not met. A set of peaking limits were developed which protect against DNB on a cycle-specific basis; these limits much be used to prove that no DNB will occur during this event in the given cycle or to conduct a census of the pins which may experience DNB to confirm that radiological release limits are obeyed for this event in the given cycle. The sequence of events for this case is presented in Table 15.3.7-1. Plots associated with this transient are presented in Figures 15.3.7-1a thru 15.3.7-3a for AREVA Mark-BW fuel and Figures 15.3.7-1b thru 15.3.7-3c for AREVA HTP fuel.

15.4 CONDITION IV - LIMITING FAULTS

Condition IV occurrences are faults which are not expected to take place, but are postulated because their consequences would include the potential for the release of significant amounts of radioactive material. These are the most drastic which must be designed against and thus represent limiting design cases. Condition IV faults are not to cause a fission product release to the environment resulting in an undue risk to public health and safety in excess of guideline values of 10 CFR Part 100. A single Condition IV fault is not to cause a consequential loss of required functions of systems needed to cope with the fault including those of the Emergency Core Cooling System (ECCS) and the containment. For the purposes of this report the following faults have been classified in this category:

1. Major rupture of pipes containing reactor coolant up to and including double ended rupture of the largest pipe in the Reactor Coolant System (loss of coolant accident).

2. Major secondary system pipe ruptures.

3. Steam generator tube rupture.

4. Single reactor coolant pump locked rotor.

5. Fuel handling accident.

6. Rupture of a control rod mechanism housing (rod cluster control assembly ejection).

The analysis of thyroid and whole body doses, resulting from events leading to fission product release, appears later in the Safety Analysis Report. The fission product inventories which form a basis for these calculations are presented in Chapter 11 and Section 15.1. The Safety Analysis Report also includes the discussion of systems interdependency contributing to limiting fission product leakages from the containment following a Condition IV occurrence.

15.4.1 Major Reactor Coolant System Pipe Ruptures (Loss of Coolant Accident)

The analysis specified by 10CFR50.46 "Acceptance Criteria for Emergency Core Cooling Systems for Light Water Nuclear Power Reactors", is presented in this section. The results of the loss of coolant accident analysis are shown in Table 15.4.1-3 and show compliance with the acceptance criteria.

A Large Break LOCA is initiated by a postulated rupture of the Reactor Coolant System (RCS) primary piping. Based on deterministic studies, the worst break location is in the cold leg piping between the reactor coolant pump and the reactor vessel for the RCS loop containing the pressurizer. The break initiates a rapid depressurization of the RCS. A reactor trip signal is initiated when the low pressurizer pressure trip setpoint is reached; however, reactor trip is conservatively neglected in the analysis. The reactor is shut down by coolant voiding in the core.

The plant is assumed to be operating normally at full power prior to the accident. The cold leg break is assumed to open instantaneously. For this break, a rapid depressurization occurs, along with a

core flow stagnation and reversal. This causes the fuel rods to experience departure from nucleate boiling (DNB). Subsequently, the limiting fuel rods are cooled by film convection to steam. The coolant voiding creates a strong negative reactivity effect and core fission ends. As heat transfer from the rods is reduced, the cladding temperature rises.

Coolant in all regions of the RCS begins to flash. At the break plane, the loss of subcooling in the coolant results in substantially reduced break flow. This reduces the depressurization rate, and leads to a period of positive core flow or reduced downflow as the reactor coolant pumps in the intact loops continue to supply water to the vessel. Cladding temperatures may be reduced and some portions of the core may rewet during this period. The positive core flow or reduced downflow period ends as two-phase conditions occur in the reactor coolant pumps, reducing their effectiveness. Once again, the core flow reverses as most of the vessel mass flows out through the broken cold leg.

Mitigation of the Large Break LOCA begins when the Safety Injection System signal is actuated. This signal is initiated by either high containment pressure or low pressurizer pressure. Regulations require that a worst single-failure be considered. This single-failure has been determined to be the loss of one diesel (one ECCS pumped injection train) with fully functional containment sprays. The Realistic Large Break LOCA methodology conservatively assumes an on-time start and normal lineups of the containment spray to conservatively reduce containment pressure and increase break flow. Hence, the analysis assumes that one charging pump, one Safety Injection pump, one RHR pump and two containment spray pumps are operating.

When the RCS pressure falls below the accumulator pressure, fluid from the accumulators is injected into the cold legs. In the early delivery of accumulator water, high pressure and high break flow will drive some of this fluid to bypass the core. During this bypass period, core heat transfer remains poor and fuel rod cladding temperatures increase. As RCS and containment pressures equilibrate, ECCS water begins to fill the lower plenum and eventually the lower portions of the core; thus, core heat transfer improves and cladding temperatures decrease. Eventually, the relatively large volume of accumulator water is exhausted and core recovery must rely on pumped ECCS coolant delivery alone. As the accumulators empty, the nitrogen gas used to pressurize the accumulators exits through the break. This gas release may result in a short period of improved core heat transfer as the nitrogen gas displaces water in the downcomer. After the nitrogen gas has been expelled, the ECCS temporarily may not be able to sustain full core cooling because of the core decay heat and the higher steam temperatures created by quenching in the lower portions of the core. Peak fuel rod cladding temperatures may increase for a short period until more energy is removed from the core by the charging, Safety Injection and RHR while the decay heat continues to fall. Steam generated from fuel rod rewet will entrain liquid and pass through the core, vessel upper plenum, the hot legs, the steam generator, and the reactor coolant pump before it is vented out the break. Some steam may flow to the upper head and pass through the spray nozzles which would provide a vent path to the break. The resistance of this flow path to the steam flow is balanced by the driving force of water filling the downcomer. This resistance may act to retard the progression of the core reflood and postpone core wide cooling. Eventually (within a few minutes of the accident), the core reflood will progress sufficiently to ensure core wide cooling. Full core quench occurs within a few minutes after core wide cooling. Long-term cooling is then sustained with the RHR system.

15.4.1.1 Performance Criteria for Emergency Core Cooling System

The reactor is designed to withstand thermal effects caused by a loss of coolant accident including the double ended severance of the largest Reactor Coolant System Pipe. The reactor core and internals, together with the ECCS are designed so that the reactor can be shutdown safely and the essential heat transfer geometry of the core can be preserved following the accident.
The ECCS even when operating during the injection mode with the most severe single active failure, is designed to meet the Acceptance Criteria, Reference 1.

15.4.1.2 Method of Thermal Analysis

The RLBLOCA methodology is documented in Reference 67. The methodology follows the Code Scaling, Applicability, and Uncertainty (CSAU) evaluation methodology (Reference 68). This method outlines an approach for defining and qualifying a best-estimate thermal-hydraulic code and quantifies the uncertainties in a LOCA analysis.

The RLBLOCA methodology consists of the following computer codes:

- RODEX3A for computation of the initial fuel stored energy, fission gas release, and fuel-cladding gap conductance.
- S-RELAP5 for the system thermal-hydraulic calculation.

The governing two-fluid (plus noncondensibles) model with conservation equations for mass, energy, and momentum transfer is used. The reactor core is modeled in S-RELAP5 with heat generation rates determined from reactor kinetics equations (point kinetics) with reactivity feedback, and with actinide and decay heating. The two-fluid formulation uses a separate set of conservation equations and constitutive relations for each phase. The effects of one phase on another are accounted for by interfacial friction, and heat and mass transfer interaction terms in the equations. The conservation equations have the same form for each phase; only the constitutive relations and physical properties differ.

The modeling of plant components accounts for physical dimensions and the dominant phenomenon expected during the LBLOCA event. The basic building blocks for modeling are the hydraulic volume for fluid paths and the heat structure for a heat transfer surface. In addition, special purpose components exist to represent specific components such as the pumps or the steam generator separators. All geometries are modeled at the resolution necessary to best resolve the flow field and the phenomena being modeled within practical computational limitations. The S-RELAP5 model explicitly describes the RCS, reactor vessel, pressurizer, and accumulator lines. The charging injection flows are connected to the RCS and the SI and RHR injection flows are connected to the accumulator lines, consistent with the plant layout. This model also describes the secondary-side steam generator that is instantaneously isolated (closed Main Steam Isolation Valves and feedwater trip) at the time of the break. A symmetric steam generator tube plugging level of 15% per steam generator was assumed. The break is modeled in the same loop as the pressurizer, as directed by the RLBLOCA methodology. The RLBLOCA transients are of sufficiently short duration that the switchover to sump cooling water (i.e. Recirculation) for CCS pumped injection need not be considered.

As described in the AREVA RLBLOCA methodology, many parameters associated with LBLOCA phenomenological uncertainties and plant operation ranges are sampled. The LBLOCA

phenomenological uncertainties are provided in Reference 67. Values for process or operational parameters, including ranges of sampled process parameters, and fuel design parameters used in the analysis are given in Table 15.4.1-1. Plant data are analyzed to develop uncertainties for the process parameters sampled in the analysis. Two parameters, Refueling Water Storage Tank (RWST) temperature for pumped ECCS flows and diesel start time, are set at conservative bounding values for all calculations. Where applicable, the sampled parameter ranges are based on technical specification limits or supporting plant calculations that provide more bounding values.

Following the establishment of an acceptable steady-state condition, the transient calculation is initiated by introducing a break into one of the loops (specifically, the loop with the pressurizer). The evolution of the transient through blowdown, refill and reflood is computed continuously using S-RELAP5. Containment pressure is also calculated by S-RELAP5 using containment models derived from ICECON (Reference 69) which is based on the CONTEMPT-LT code (Reference 70) and has been updated for modeling ice condenser containments.

The final step of the best-estimate methodology is to combine all the uncertainties related to the code and plant parameters and estimate the Peak Cladding Temperature (PCT) at a high probability level.

15.4.1.3 Containment Analysis

The concurrent containment transient pressure calculation is performed by the ICECON module within the S-RELAP5 code. For the Realistic Large Break LOCA analysis, dominant containment parameters, as well as NSSS parameters, were established via a Phenomena Identification and Ranking Table (PIRT) process. Other model inputs are generally taken as nominal or conservatively biased. The PIRT outcome yielded two important (relative to Peak Cladding Temperature) containment parameters-containment pressure and temperature. In many instances, the conservative guidance of Containment Systems Branch Technical Position 6-1 (Reference 71) was used in setting the remainder of the containment model input parameters. As indicated in Table 15.4.1-1, containment temperature is a sampled parameter. Containment pressure response is indirectly ranged by sampling the upper containment volume. The minimum value is carried over from use in the long-term containment integrity analysis of record for Sequoyah. The maximum value is a simplified value computed as the volume available within the upper dome of the containment and within the crane wall above the control rod drive missile shield with no accounting for internal structures and the volumes of the refueling canal and the annular region separating the ice compartments neglected. This volume is maximized by neglecting the volume of internal structures. The lower compartment volume is biased low in order to promote flow through the ice baskets. In accordance with Reference 67, the condensing heat transfer coefficient is intended to be closer to a best-estimate instead of a bounding high value. In the ice compartment, the water formed by melted ice and condensed steam flows to the lower ice compartment sump where it accumulates, if the ice bay drains are not large enough to accommodate the rate of water production. When the water level in the lower ice compartment sump rises above the bottom of the lower doors, water spillage through the lower doors occurs in addition to flow through the drain ports. The water drainage (spillage plus drainage) from the ice compartment falls through the lower compartment vapor. This condenses steam and reduces the containment pressure. The ice compartment drainage flow is treated as a 100 percent efficient spray during the post-blowdown period of the transient.

The initial conditions and boundary conditions are given in Table 15.4.1-4. The building spray is modeled at maximum heat removal capacity. While there is an option within the computer code model to deliver spray to the lower compartment, this option is not applicable to Sequoyah. All spray

flow is delivered to the upper compartment. Because the start time for the recirculation fan is 600 seconds, forced flow from the upper compartment to the lower compartment is not likely to occur during the time period analyzed. The flow of steam or air, from the lower compartment to the upper compartment, backwards through the back draft dampers, is not modeled (no reverse direction flow). This approach is conservative in that no bypass of the ice beds (from lower to upper compartments) is allowed, and all flow from the lower compartment is directed through the ice beds. The passive flow of air and steam, from the upper compartment to the lower compartment, is modeled however. This is a passive flow, which is only a function of the excess pressure of the upper compartment compared to the lower compartment, the flow area of the recirculation fan back draft dampers, and the loss coefficient of the dampers. The back draft dampers are designed such that reverse flow from the lower to the upper compartment is prevented. However, when the upper compartment pressure is at least 0.5 psi greater than the lower compartment, the dampers open and allow flow from the upper compartment to the lower compartment. Flow in this manner, from the upper to lower compartment, is modeled without this minimum pressure difference, i.e. any excess pressure is modeled as resulting in flow.

Passive heat sink parameters are listed in Table 15.4.1-5. Surface coatings, where they existed, were incorporated as an equivalent thickness of base material in order to eliminate any insulating effects on the exposed surfaces of the heat structures. Because the original basis for the size of each heat sink was biased low (for a different application), the values listed in Table15.4.1-5 reflect a 10 percent increase in heat transfer surface area as compensation. Passive heat sinks were added to the lower containment to represent the advanced design containment sump strainers recently installed over the sump intake (17 ft^3 of steel). Additionally, all heat structure exposed surfaces remain available for condensing steam, even when they may become covered by ice melt or condensate.

The mass and energy release rates used for the containment backpressure calculation as a function of time during blowdown are given in Figures 15.4.1-15 and 15.4.1.-21 for the limiting case.

15.4.1.4 <u>Results of Large Break Spectrum</u>

Two case sets of 93 transient calculations were performed, one with Loss of Offsite Power and another with offsite power continuing to be available. For each transient calculation, Peak Cladding Temperature (PCT) was calculated for a $U0_2$ rod and for Gadolinia bearing rods with concentrations of 2, 4, 6 and 8 w/o Gd_20_3. The limiting case set, that contained the PCT, was the set with offsite power available. The limiting PCT (1941°F) occurred in Case 86 for a $U0_2$ rod. As the results of random sampling within defined limits, a few of the characteristics defining the limiting case include a fuel assembly burnup of 11.6 GWd/MTU, a top skewed axial power shape, and a split break configuration with an area of 3.867 ft^2 per side (relative to an intact cold leg cross sectional flow area of 4.125 ft^2).

The time sequence of accident milestones for the limiting transient is characterized in Table 15.4.1- 2. Table 15.4.1-3 lists the results of the limiting case. The fraction of total hydrogen generated was not directly calculated; however, it is conservatively bounded by the calculated total percent oxidation, which is well below the 1 percent limit. A nominal best estimate PCT case was identified as Case 72, which corresponded to the median case out of the 93-case set with offsite power available. The nominal PCT was 1484°F. This result can be used to quantify the relative conservatism in the limiting case result. In this analysis, it was 457 °F.

Key parameters for the limiting PCT case are shown in Figures 15.4.1-1 through 15.4.1-11. Figure 15.4.1-14 is the plot of PCT independent of elevation; and this figure clearly indicates that the transient exhibits a sustained and stable quench.

15.4.1.5 Effect of Containment Purging

To assess the impact of purging on the calculated post-LOCA Sequoyah containment pressure, a calculation was first performed to obtain the amount of mass which exits through three available sets of purge lines during the initial portion of a postulated LOCA transient. Purge-line isolation closure time is assumed at 4.0 seconds after receipt of signal; during this interval, the full flow area is presumed to be available. In addition, the time to reach the SI signal setpoint and the delay necessary to generate the SI signal are conservatively assessed as 1.5 seconds total. Thus, flow through three pairs of fully open available purge lines was evaluated from 0.0 to 5.5 seconds for the postulated double-ended cold leg break.

The calculation employed the 50-node TMD computer code model which is described in Section 6.2.1.3.4. The 24-inch purge supply lines are connected to Volumes 34, 37, and 25; purge exhaust lines are connected to 36 and 25. Possible combinations of supply lines and exhaust lines open to the atmosphere were considered. Each of these purge lines is represented by a flow path of cross section area equal to 2.948 ft^2 and a total flow resistance factor equal to 3.98 (entrance and exit loss, three fully open butterfly valves and a debris screen). The most conservative two pairs of 24-inch purge and supply lines were assumed to be open in this calculation. In addition, two 12-inch lines connected to TMD node 29 were modeled as open.

In a computation for ECCS performance, the greatest impact on containment pressure occurs for the purge case of maximum air mass loss, which is based upon the two 12-inch lines being open and involves three open purge lines in the lower compartment (TMD elements 34, 36, and 37) and one purge line open in the upper compartment together with a cold leg break in TMD Volume 1. A total of 2620 pounds of air are calculated to be lost in this case. The maximum air loss case is the limiting case because any steam lost through purging in an ECCS backpressure elevation would otherwise be calculated to condense in the ice bed. Therefore, any steam lost through purging is ultimately of no consequence in the containment pressure determination, while any air loss directly reduces calculated pressure.

The impact of the reduced containment pressure on ECCS performance is accommodated in the calculated peak cladding temperature. While the containment backpressure calculation does not directly incorporate the loss of 2620 pounds of air at the beginning of the accident, the input data is sufficiently biased to produce an estimate of pressure that is lower than "best" estimate. Relative to the historical Westinghouse calculation of containment backpressure, the RLBLOCA analysis is based on a smaller value for the free volume of the Lower Compartment and a larger volume of the Upper Compartment. This produces the same result of blowing less air from the Lower Compartment into the Upper and also results in lower initial compression in the Upper Compartment. On this basis, the Realistic Large Break LOCA analysis permits purging of the Sequoyah containment during normal operation to be conducted through three sets of purge lines.

15.4.1.6 Additional Items Impacting Peak Clad Temperature

Variations in the PCT from the analysis of record as reported herein (due to model assessments, sensitivity analysis, and margin allocations) are reported to the NRC by means of 10CFR50.46.

A sensitivity study has been performed to characterize swelling rupture and relocation (SRR) of fuel fragments. The full case set in the base RLBLOCA analysis was reanalyzed. The SRR sensitivity study applies an 80% packing factor and takes no credit for the droplet shatter model (cooling effects). A comparison of the limiting cases for the base case and the SRR sensitivity study indicate an increase in peak cladding temperature (PCT) with a small increase in the transient maximum local oxidation and a small decrease in the core-wide oxidation. With the addition of SRR effects, the limiting case PCT increased +44ºF. It is widely recognized that, physically, there would be some cooling as a result of steam desuperheating via droplet shattering against the intruding rupture and a related heat transfer enhancement. This cooling mechanism is not credited in the SRR sensitivity

studies. It is also recognized that the packing factor of 80% is not anticipated to occur in the Sequoyah RLBLOCA cases due to the M5® cladding strains observed in the rupture cases. Table 15.4.1-3b reports the RLBLOCA PCT with the addition of SRR effects for Sequoyah plants.

15.4.1.7 Conclusions - Thermal Analysis

For cases considered, the ECCS will meet the Acceptance Criteria as presented in 10CFR50.46. That is:

1. The calculated peak fuel element clad temperature provides margin to the requirement of 2200°F, based on an Fq value of 2.65.

2. The amount of fuel element cladding that reacts chemically with water or steam does not exceed 1 percent of the total amount of zirconium alloy in the reactor.

3. The clad temperature transient is terminated at a time when the core geometry is still amenable to cooling. The clad oxidation limits of 17 percent are not exceeded during or after quenching.

4. The core temperature is reduced and decay heat is removed for an extended period of time, as required by the long-lived radioactivity remaining in the core.

15.4.2 Major Secondary System Pipe Rupture

15.4.2.1 Rupture of a Main Steam Line

15.4.2.1.1 Identification of Causes and Accident Description

The steam release arising from a rupture of a main steam line pipe would result in an initial increase in steam flow which decreases during the accident as the steam pressure falls. Subsequently, excess energy removal from the Reactor Coolant System (RCS) causes a reduction of coolant temperature and pressure. In the presence of a negative moderator temperature coefficient, the cooldown results in a reduction of core shutdown margin. If the most reactive rod cluster control assembly (RCCA) is assumed stuck in its fully withdrawn position after reactor trip, there is an increased possibility that the core will become critical and return to power. A return to power following a steam line rupture is a potential problem mainly because of the high power peaking factors which exist assuming the most reactive RCCA to be stuck in its fully withdrawn position. The core is ultimately shut down by the boric acid injection delivered by the Safety Injection System.

The analysis of a main steam line rupture is performed to demonstrate that the following criterion is satisfied:

> Assuming a stuck RCCA, with or without offsite power, and assuming a single failure in the engineered safeguards there is no consequential damage to the primary system and the core remains in place and intact.

Although DNB and possible clad perforation following a steam line rupture are not necessarily unacceptable, the following analysis, in fact, shows that no DNB occurs for any rupture assuming the most reactive RCCA stuck in its fully withdrawn position.

The following functions provide the necessary protection against the steam pipe rupture:

1. Safety injection system actuation from any of the following:

    a. Two-out-of-three low steam line pressure signals in any one loop
    b. Two-out-of-three low pressurizer pressure signals
    c. Two-out-of-three high containment pressure signals

2. The overpower reactor trips (neutron flux and ΔT) and the reactor trip occurring in conjunction with receipt of the safety injection signal.

3. Redundant isolation of the main feedwater lines. Sustained high feedwater flow would cause additional cooldown. Therefore, in addition to the normal control action which will close the main feedwater valves, a safety injection signal will rapidly close the main and bypass feedwater control valves and trip the main feedwater pumps.

4. Trip of the fast acting steam line stop valves on:

    a. Two-out-of-three low steam line pressure signals in any one loop.
    b. Two-out-of-four high-high containment pressure signals
    c. Two-out-of-three high steam line pressure rate signals in any one loop.

Fast-acting isolation valves are provided in each steam line that are assumed to fully close 8 seconds after a steam line isolation signal setpoint is reached. For breaks downstream of the isolation valves, closure of all valves would completely terminate the blowdown. For any break, in any location, no more than one steam generator would blowdown even if one of the isolation valves fails to close. A description of steam line isolation is included in Chapter 10.

Steam flow is measured by monitoring dynamic head in flow restrictors located in the steam generator nozzles (Unit 1 and Unit 2). The flow restrictors are of considerably smaller diameter than the steam generator nozzles and thereby also serve to limit the maximum steam flow for any downstream break.

15.4.2.1.2 Analysis of Effects and Consequences

Method of Analysis

The analysis of the steam pipe rupture has been performed to determine:

1. The core heat flux, RCS temperature, and pressure resulting from the cooldown following the steam line break. The RELAP5/MOD2-B&W code (Reference 56) is used to calculate system response and the NEMO code (Reference 59) is used to calculate limiting core power distributions.

2. The thermal and hydraulic behavior of the core following a steam line break. A detailed thermal-hydraulic digital-computer calculation (LYNXT code, Reference 60) has been used to determine whether DNB occurs for the core conditions computed in (1) above.

The following conditions were assumed to exist at the time of a main steam line break accident.

1. End-of-life shutdown margin at no-load, equilibrium xenon conditions, and the most reactive RCCA stuck in its fully withdrawn position. Operation of the control rod banks during core burnup is restricted in such a way that addition of positive reactivity in a steam line break accident will not lead to a more adverse condition than the case analyzed.

2. A negative moderator coefficient corresponding to the end-of-life rodded core with the most reactive RCCA in the fully withdrawn position. The variation of the coefficient with temperature and pressure has been included. The effect of power generation in the core on overall reactivity is shown in Figure 15.4.2-1.

   The core properties associated with the sector nearest the affected steam generator and those associated with the remaining sector were conservatively combined to obtain average core properties for reactivity feedback calculations in RELAP5. Further, it was conservatively assumed that the core power distribution was uniform in RELAP5. These two conditions cause under-prediction of the reactivity feedback in the high power region near the stuck rod. To verify the conservatism of this method, the reactivity as well as the power distribution was checked with NEMO for the limiting statepoints shown on Table 15.4.2-1. The NEMO core analysis considered the Doppler reactivity from the high fuel temperature near the stuck RCCA, moderator feedback from the high water enthalpy near the stuck RCCA, power redistribution and nonuniform core inlet temperature effects. For cases in which steam generation occurs in the high heat flux regions of the core, the effect of void formation was also included. A 3-D statepoint analysis with NEMO confirmed that the reactivity employed in the kinetics analysis was larger than the reactivity calculation including the above local effects for the statepoints in Table 15.4.2-1. These results verify conservatism, i.e., under-prediction of negative reactivity feedback from power generation.

3. Minimum capability for injection of boric acid (1950 ppm from the RWST) solution corresponding to the most restrictive single failure in the Safety Injection System. The Emergency Core Cooling System consist of three systems: 1) the passive accumulators, 2) the Residual Heat Removal System, and 3) the Safety Injection System. Only the Safety Injection System and the accumulators are modeled for the steam line break accident analysis.

   The injection curve used is shown in Figure 15.4.2-2. The flow corresponds to that delivered by one SI pump delivering its full flow to the cold leg header. Subsequent to this analysis, the minimum safety injection pump performance requirements were reduced from those shown in Figure 15.4.2-2. However, the flow reduction was more than off-set by the minimum flow available from one centrifugal charging pump. While not specifically modeled in the OSG analysis, the flow from one charging pump is also credited in Reference 72 to establish that the results of the analysis remain conservative and bounding for the current safety injection pump minimum performance requirements in Figure 6.3.2-6. The analysis conservatively assumes that the safety injection lines downstream of the second check valve removed from the cold leg, has a boron concentration of 0 ppm. Modeling an unborated purge volume accounts for possible dilution via the diffusion of RCS coolant back into the lines plus potential leakage of the first set of check valves. Once the unborated water is purged, boron is assumed to be injected into the RCS at a concentration of 1950 ppm via a single intermediate head pump. This is a reasonable method of modeling postacident boron injection in that it both is conservative and reflective of the actual plant configuration. Subsequent to the original Framatome analysis, sensitivity studies have been performed related to the assumption of boron delivery to the RCS for the main steam line break event. The sensitivity studies examine the extent that leakage/diffusion of RCS coolant can occur in the safety injection lines before the results of the limiting case are adversely affected. The studies show that coolant with a boron concentration equivalent to that of the End of Life RCS (0 ppm) can exist in the safety injection system piping back as far as three check valves removed from the cold leg up to the discharge of the safety injection pump. A boron concentration of 1950 ppm is assumed from the RWST to the discharge of the SI pumps with 0 ppm from the pump discharge to the RCS. Based on these conditions, the limiting break (a complete severance of the steam line upstream of the pipe flow reducer with offsite power available), remains valid and limiting. The sensitivity studies performed prove that the original Framatome analysis remains bounding and the return to power associated with the other nonlimiting steam line break cases will also remain less than the

return to power associated with the limiting case assuming 0 ppm boron back to the discharge of the SI pump. Based on the system design and the Technical Specification required venting surveillance (with a 31 day frequency) of the SI pump and piping, it is technically acceptable to allow the assumption of a 1950 ppm boron concentration in the SI pump and suction piping for the main steam line break event.

For the cases with offsite power assumed, the following alignment sequence takes place prior to coolant injection via the Safety Injection System. After the generation of the safety injection signal (with appropriate delays for instrumentation, logic, and signal transport included), the makeup tank is isolated and the SI pump suction is aligned with the refueling water storage tank. In 28 seconds the pump is aligned and considered to be at full speed. The volume of unborated water in the pump discharge piping is swept into the RCS before the 1950 ppm water from the RWST reaches the core. The "purge" delay, described above, is explicitly modeled.

In the cases where offsite power is not available, an additional 30 second delay is assumed to allow for starting and loading the necessary safety injection equipment on to the diesel generators.

4. Four combinations of break sizes and initial plant conditions have been considered in determining the core power RCS transients:

   A. Complete severance of a pipe outside the containment (downstream of the steam flow measuring nozzle) with the plant initially at no load conditions, full reactor coolant flow with offsite power available.

   B. Complete severance of a pipe inside the containment at the outlet of the steam generator (upstream of the steam flow measuring nozzle) with the plant initially at no load conditions, full reactor coolant flow with offsite power available. Note: The design of the replacement steam generators on Unit 1 and Unit 2 includes an integral flow limiter in the main steam nozzle, which eliminates the potential for a main steam line break upstream of the flow limiter.

   C. Case (A) above with loss of offsite power. Loss of offsite power results in coolant pump coastdown.

   D. Case (B) above with the loss of offsite power.

5. Power peaking factors corresponding to one stuck RCCA and nonuniform core inlet coolant temperatures are determined for end-of-life core conditions. The coldest core inlet temperatures are assumed to occur in the sector with the stuck rod. The power peaking factors account for the effect of the local fluid conditions in the region of the stuck control assembly during the return to power phase following the steam line break. These fluid conditions in conjunction with the large negative moderator coefficient partially offsets the effect of the stuck assembly. The power peaking factors depend upon the core power, temperature, pressure, and flow, and thus are different for each case studied.

   The limiting statepoint conditions of the four steam line break accidents analyzed are given in Table 15.4.2-1. The limiting case is selected on the basis of hot channel factors, core power, core inlet temperature, and reactor coolant pressure. The core parameters evaluated for each of the cases correspond to values determined from the respective transient analysis.

The reactor is protected in at-power conditions by the normal overpower protection system. All the cases assume initial hot zero power conditions, however, since this represents the most pessimistic initial condition. The lack of stored energy in the core, high initial steam generator liquid inventory, and high steam pressure associated with this operational mode all contribute to a conservative over-cooling event.

6. In computing the steam flow during a steam line break, the Moody Curve (Reference 22) for fL/D = 0 is used.

7. Non-homogeneous flow in the steam generator and high moisture separation in the moisture separator is assumed. The assumption leads to conservative results since, in fact, considerable water would be discharged. Water carryover would reduce the magnitude of the temperature decrease in the core and the pressure increase in the containment.

8. A conservatively high auxiliary feedwater flow rate (2350 gpm) is assumed to be delivered to the faulted steam generator. This auxiliary feedwater is not required to mitigate the transient and is modeled to increase the severity of the core cooldown.

Results

The results presented are a conservative indication of the events which would occur assuming a steam line rupture since it is postulated that all of the conditions described above occur simultaneously.

Core Power and Reactor Coolant System Transient

Figures 15.4.2-3 through 15.4.2-10 show the RCS transient following a main steam line rupture (complete severance of a pipe) outside the containment, downstream of the flow measuring nozzle at initial no load conditions (Case A). The break assumed is the largest break which can occur anywhere outside the containment either upstream or downstream of the isolation valves.

Offsite power is assumed available such that full reactor coolant flow exists. The transient shown assumes an uncontrolled steam release from only one steam generator. Should the core be critical at near zero power when the rupture occurs the initiation of safety injection signal by low steam line pressure will trip the reactor and isolate the steam lines. Even with the failure of one steam line valve, release is limited to no more than 10 seconds for the other steam generators while the one steam generator blows down. The steam line isolation valves are required to be closed within the time specified by the technical specifications.

As shown in the reactivity plot (Figure 15.4.2-7) the core attains criticality with the rod cluster control assemblies inserted (with the design shutdown of 1600 pcm assuming one stuck assembly) before a boron solution of approximately 1950 ppm enters the RCS from the Safety Injection System. The delay time associated with boron delivery consists of system alignments and discharge line purging described above. Core power peaks well below the nominal full power value.

The accumulators provide an additional source of borated water (1950 PPM) after the RCS pressure decreases to below 641.5 psig. The calculation assumes the 1950 ppm boric acid is mixed with, and diluted by the water flowing in the RCS prior to entering the reactor core. The concentration after

mixing depends upon the relative flow rates in the RCS and in the Safety Injection System. The variation of mass flow rate in the RCS due to water density changes is included in the calculation as is the variation of flow rate from the Safety Injection System and the accumulator due to changes in the RCS pressure. The core boron concentration vs. time for each of the four cases analyzed is shown in Figures 15.4.2-8, 15.4.2-16, 15.4.2-24, and 15.4.2-32.

Figures 15.4.2-11 through 15.4.2-18 show Case B, a steam line rupture at the exit of a steam generator (upstream of the flow measuring nozzles) at no load. The sequence of events is similar to those of Case A except that criticality is attained earlier due to more rapid cooldown and a higher peak core average power is attained.

Figures 15.4.2-19 through 15.4.2-26 and 15.4.2-27 through 15.4.2-34 show the responses of the salient parameters for Case C and Case D, respectively. These cases correspond to the cases discussed above with the added complication of a loss of offsite power at the time of break initiation; Case C assumes a break downstream from the flow measuring device and Case D assumes an upstream break. Safety injection begin 60 seconds after the break; delays associated with system alignment, diesel generator startup, and pump discharge line purging are accounted for. In both Case C and Case D, criticality is achieved later and the core power increase is slower than in the similar case with offsite power available. The ability of the emptying steam generator to extract heat from the RCS is reduced by the decreased flow in the RCS. For both these cases the peak core power remains well below the nominal full power value.

The sequence of events tables for the Main Steam Line Break analyses are included in Table 15.4.1-12, Sheets 1 and 2. It should be noted that following a steam line break only one steam generator blows down completely. Thus, the remaining steam generators are still available for long-term core cooling after the initial transient is over. Operators are instructed to maintain the intact steam generator levels within the narrow range level scale. In cases assuming a loss of offsite power core decay heat is removed to the atmosphere via the steam line safety valves which have been adequately sized for this purpose.

Generic thermal stress analyses and subsequent fracture mechanics analyses of reactor vessels have been performed for 4-Loop plants. These analyses were applied to a 4-Loop reactor vessel having material properties and end of life (40 years) accumulated fluence similar to the Sequoyah vessel. The fracture mechanics analysis utilized linear elastic fracture mechanics method in the evaluation of the reactor vessel integrity. The fracture mechanics analysis results show that the reactor vessel integrity under large steam line break conditions would be maintained over the design life of the vessel.

Steam pressure from the steam generators is relieved by the steam dump system, secondary system atmospheric safety valves, or secondary system relief valves. The operator is instructed to terminate auxiliary feedwater flow to the faulted steam generator as soon as he determines which steam generator is faulted. As soon as an indicated water level returns to the pressurizer the operator is instructed to turn off the safety injection pumps and restrict the charging pumps as required.

Following a steam line break incident, a steam line isolation signal will be generated almost immediately, causing the steam line isolation valves to close within a few seconds. If the break is downstream of the isolation valves, all of which subsequently close, the break will be isolated. If the

break is upstream of the isolation valves or one valve fails to close, the break will be isolated to three steam generators while the faulted one will continue to blow down. Only the case in which one steam generator continues to blow down is discussed here since the break followed by isolation of all steam generators will terminate the transient.

A safety injection signal (generated a few seconds after the break) will cause main feedwater isolation to occur. The only source of water available to the faulted steam generator is then the auxiliary feedwater system. Following steam line isolation, steam pressure in the steam line with the faulted steam generator will continue to fall rapidly, while the pressure stabilizes in the remaining three steam lines. The indication of the different steam pressures will be available to the operator within a few seconds of steam line isolation. This will provide the information necessary to identify the faulted steam generator so that auxiliary feedwater to it can be isolated. Manual controls are provided in the control room for start and stop of the auxiliary feedwater pumps and for the control valves associated with the auxiliary feedwater system. The means for detecting the faulted steam generator and isolation of auxiliary feedwater to it requires only the use of safety grade equipment available following the break. The removal of decay heat in the long term (following the initial cooldown) using the remaining steam generators requires only the Auxiliary Feedwater System as a water source and the secondary system safety valves and/or the power operated relief valve to relieve steam. Power to the motor driven auxiliary feedwater pumps is supplied by the onsite diesel generator units. The turbine driven AFW pump has redundant steam supplies. Flow (440 gpm) from one motor-driven auxiliary feedwater pump to one steam generator is sufficient for long term cooling.

The operator has available, in the control room, an indication of pressurizer water level from the instrumentation used in the reactor protection system. Indicated water level returns to the pressurizer in approximately five to seven minutes following the steam line break. The Operators have the procedures and equipment necessary to terminate the safety injection and gain control of the pressurizer level prior to pressurizer overfill. The pressurizer level instrumentation and manual controls for operation of the charging pumps meet the required standards for safety systems.

As indicated, the information for terminating auxiliary feedwater is available to the operator within one minute of the break while the information required for stopping the charging pumps and safety injection pump becomes available within five to seven minutes following the break. The requirements to terminate auxiliary feedwater flow to the faulted steam generator and stop the charging pumps and safety injection pumps can be met by simple switch actions by the operators, i.e., closing auxiliary feed discharge valves and stopping charging pumps and safety injection pumps. Thus, the required simple actions to limit the cooldown and depressurization can be easily recognized, planned, and performed within ten minutes. For the longer time requirements for decay heat removal and plant cooldown the operator has time on the order of hours to respond.

The worst case condition for long term cooling following a steam line break is loss of offsite power with failure of one emergency power train, since the condition requires the greatest amount of operator action and the longest time to achieve cold shutdown. However, since the plant can be maintained safely at hot standby conditions for extended periods of time, there is no safety requirement which dictates rapid achievement of cold shutdown conditions.

With only onsite power available, the plant can be maintained in a safe hot standby condition using the intact steam generators by supplying feedwater with the auxiliary feedwater system, and venting steam through the secondary side, power-operated relief valves. The relief valves will be controlled to gradually reduce pressure and temperature as the core residual heat decays. If the relief valves

are not available, the safety valves will be used for steam dump. In this case, the primary system pressure would be controlled such that adequate subcooling is maintained. Primary system temperature would be maintained at that value necessary to lift the steam generator safety valves as necessary to match the decay heat from the core. This temperature would be approximately 553 F which corresponds to the lowest steam generator safety valve setpoint of 1064 psig. For either means of steam relief, the steam generator water level will be maintained within the span of the narrow range indicators.

Margin to Critical Heat Flux

A complete set of statepoints are reviewed to determine the most limiting condition. Past experience in performing DNB analyses for steam line breaks for Westinghouse cores has shown that Case B (inside break with offsite power) is always worse than Case A. Cases A and B generally have very similar temperatures and pressures, but Case B returns to a power level of 1.5 to 2 percentage points greater than Case A. It is this higher power level that makes Case B the worse of the two.

A detailed nuclear and thermal-hydraulic analysis of this limiting steam line break, Case B, statepoint (see Table 15.4.2-1) is performed or dispositioned on a cycle-specific basis. This analysis ensures that the appropriate design limit requirements are met (indicating that DNB will not occur during this event) or conducts a census of pins which are expected to experience DNB. This is done on a cycle-specific basis because cycle-specific core peaking data is necessary for a detailed analysis. Historically, the DNBR has been very high compared to the safety limits and it has been shown that DNB will not occur.

15.4.2.1.3 AREVA Safety Evaluation with Replacement Steam Generators in Unit 1 and Unit 2

The thermal response characteristics of the transient discount a challenge to the RCS and main steam system pressure limit. RCS pressure is reduced throughout the transient in response to the excessive heat removal from the steam generators. Therefore, this event is analyzed for DNB concerns.

Sequoyah has replaced the steam generators in both Units 1 and 2. Compared to the original steam generators (OSG) and pertinent to the steam line break event, the replacement steam generators (RSG) has a flow restrictor at the steam generator outlet with an area of 1.42 ft^2, and an increased heat transfer surface area. Both the heat transfer area and break size are critical parameters that affect the system and core responses during a steam line break. The limiting steam line break event therefore was reanalyzed for the RSG utilizing identical methods described in Section 15.4.2.1.2. The limiting event (Case B) is a complete severance of a pipe inside containment downstream of the integral flow limiter in the main steam nozzle. The plant is initially at no load conditions, full reactor coolant flow, and with offsite power available. Further, the RSG analysis explicitly included a reduction in the minimum safety injection pump performance requirements to those illustrated in Figure 15.4.2-2 along with credit for one centrifugal charging pump as discussed in Reference 72.

Figure 15.4.2-35 through 15.4.2-38 show the calculated plant parameters following a limiting steam line break inside containment with offsite power. The calculated sequence of events is presented in Table 15.4.1-12, Sheet 3.

The RELAP5/MOD2 analysis results for the RSG are similar to the OSG analysis (Case B). With the RSG, the return to power is slightly smaller than that of the OSG. In addition, the RCS pressure remains higher at the time of peak power; however, the RCS average temperature is also slightly higher at the time of peak power. As a result, the LYNXT analysis showed a slightly higher margin

to DNB. Therefore, the analysis with OSGs remains bounding and applicable to Sequoyah Unit 1 and Unit 2 with RSGs. All acceptance criteria for this event continue to be met subsequent to the installation of the RSGs.

15.4.2.2 Major Rupture of a Main Feedwater Pipe

15.4.2.2.1 Identification of Causes and Accident Description

A major feedwater line rupture is defined as a break in a feedwater pipe large enough to prevent the addition of sufficient feedwater to the steam generators to maintain shellside fluid inventory in the steam generators. If the break is postulated in a feedline between the check valve and the steam generator, fluid from the steam generator may also be discharged through the break.

Further, a break in this location could preclude the subsequent addition of auxiliary feedwater to the affected steam generator. If the break is postulated in a feedline upstream of the check valve, it would affect the Nuclear Steam Supply System only as a loss of feedwater (see Subsection 15.2.8). If the break occurs upstream or downstream of the feedline check valve in the main steam valve vaults, the main feedwater isolation valves may become submerged due to flooding and fail to respond to automatic or manual control/isolation signals and/or may spuriously fully or partially close. However, since main feedwater isolation is not necessary to mitigate the consequences of a feedwater line break (see Subsection 15.4.2.2.2) or loss of feedwater event (see Subsection 15.2.8), the loss of operability of the main feedwater isolation valves is an acceptable consequence of a main feedwater line break in the main steam valve vaults (Reference 57). Similarly, the main steam isolation bypass valves and their operators would also be submerged, the MSIBVs are closed and their control circuits deenergized during power operation and so they remain closed following submergence. In addition, the MFIVs and MSIBVs are designated as containment isolation valves and have post-accident monitoring valve position indication in the MCR which would also be lost or be unreliable. However, since valve position indication is not utilized to mitigate a loss of MFW nor MFLB event, loss of position indication for these valves is an acceptable consequence of a main feedwater line break in the main steam valve vaults (again, see Reference 57).

Depending upon the size of the break and the plant operating conditions at the time of the break, the break could cause either a RCS cooldown (by excessive energy discharge through the break), or a RCS heatup. Potential RCS cooldown resulting from a secondary pipe rupture is evaluated in Paragraph 15.4.2.1, "Rupture of a Main Steam Line." Therefore, only the RCS heatup effects are evaluated for a feedline rupture.

A feedline rupture reduces the ability to remove heat generated by the core from the RCS because of the following reasons:

1. Feedwater to the steam generators is reduced. Since feedwater is subcooled, its loss may cause reactor coolant temperatures to increase prior to reactor trip;

2. Liquid in the steam generator may be discharged through the break, and would then not be available for decay heat removal after trip;

3. The break may be large enough to prevent the addition of any main feedwater after trip.

An Auxiliary Feedwater System is provided to assure that adequate feedwater will be available such that:

1. No substantial overpressurization of the RCS shall occur; and

2. Liquid in the RCS shall be sufficient to cover the reactor core at all times.

The severity of the feedwater line break transient depends on a number of system parameters including break size, initial reactor power, and credit taken for the functioning of various control and safety systems. Based on sensitivity studies, it has been shown that the most limiting feedwater line rupture is a double-ended rupture of the largest feedwater line, occurring at full power with and without loss of offsite power, with no credit taken for pressurizer spray. The method of analysis, results, and conclusions for these cases are discussed below. A number of analyses have also been performed based on the functioning of the EAM and TTD safety systems. These analyses are discussed in Reference 53.

The following provides the necessary protection against a main feedwater rupture;

1. A reactor trip on any of the following conditions:

    a. High pressurizer pressure,
    b. Overtemperature delta-T
    c. Low-low steam generator water level in one or more steam generator,
    d. Safety injection signals from either of the following:

        i. Low steam line pressure
        ii. High containment pressure

    (Refer to Chapter 7 for a description of the actuation system.)

2. An Auxiliary Feedwater System to provide an assured source of feedwater to the steam generators for decay heat removal. (Refer to Section 10.4.7.2 for description of the Auxiliary Feedwater System.)

15.4.2.2.2 Analysis of Effects and Consequences

Analysis of the effects and consequences following a main feedwater line break have been conducted by the licensee and by Framatome Technologies Inc. Both analyses determine the plant transient upon such an event. The licensee analysis examines the pressure response inside containment using the MONSTER code (Reference 55) and is documented in Reference 56. The licensee analysis focuses on a reactor trip initiated by a safety-injection signal upon receipt of High Containment pressure. The analysis conducted by Framatome as follows focuses on a reactor trip following a low-low steam generator water level in one or more steam generators. The steam generators are assumed to have 15% of the tubes plugged.

Method of Analysis

A detailed analysis using RELAP5/MOD2 (Reference 60) is performed to obtain the plant parametric response due to a feedline rupture. The digital computer simulator of RELAP5 includes plant nuclear kinetics, reactor coolant system (with pressurizer and steam generators), main feedwater, auxiliary feedwater, and safety injection systems. The code computes the resultant system parameters including the steam generator level, pressurizer water level, and the reactor coolant average temperature.

Major assumptions are:

1. The plant is initially operating at 102% of the engineered safeguards design rating.

2. Initial reactor coolant average temperature is 5.5°F above the nominal value, and the initial pressurizer pressure is 30 psi above its nominal value.

3. No credit is taken for the pressurizer spray.

4. No credit is taken for the high pressurizer pressure reactor trip.
   Note: This assumption is made for calculational convenience. Pressurizer power-operated relief valves and spray could act to delay the high pressure trip. Assumptions 3 and 4 permit evaluation of one hypothetical, limiting case rather than two possible cases: one with a high pressure trip and no pressure controls; and one with a pressure control but no high pressure trip.

5. Main feed water to all steam generators is assumed to stop at the time the break occurs.

6. Discharge through the break in the affected steam generator is not restricted to liquid only. Two-phase discharge is modeled at the break.

7. No credit is taken for the low-low water level trip on the affected steam generator until the steam generator level reaches 0% of the narrow range span and after the expiration of any applicable delays imposed by the TTD System.

8. The worst possible break area is assumed; i.e., one that ensures that the initial reactor coolant system depressurization is maximized. This assumption minimizes subcooling margin during the post trip reactor coolant heatup period.

9. No credit is taken for heat energy deposited in reactor coolant system metal during the Reactor Coolant System heatup.

10. No credit is taken for charging or letdown.

11. Loss of offsite electrical power is assumed after the reactor trip, and reactor coolant flow decreases to natural circulation.

12. The RELAP5 code realistically calculates the appropriate heat transfer based upon the prevailing physical conditions in the generator.

13. Conservative core residual heat generation is assumed based upon long term operation at the initial power level preceding the trip.

14. The auxiliary feedwater is actuated by the low-low steam generator water level signal. The auxiliary feedwater system is assumed to supply a total of 410 gpm to two unaffected steam generators as follows:

    a. The turbine-driven pump is assumed to fail.

    b. The motor-driven pump supplying the faulted steam generator is assumed to conservatively spill all its flow out the break. The intact steam generator aligned to that pump is therefore assumed to receive no flow.

    c. The remaining motor-driven pump supplies flow to two intact steam generators.

    A 60 second delay was assumed following the low-low level signal to allow time for startup of the emergency diesel generators and the auxiliary feedwater pumps.

Note: An auxiliary feedwater system failure scenario involving a motor-driven pump was also analyzed by Westinghouse with 5% of the tubes plugged in the steam generators. See discussion under the "Results" section for a description of the scenario, assumptions, and results. Framatome has confirmed that the discussion is also applicable to the 15% steam generator tube plugging condition.

Results

Comparing the analyses conducted by the licensee and Framatome, the Framatome analysis bounds the licensee analysis, with regard to RCS heatup. Results from the Framatome analysis are presented herein.

Figures 15.4.2-39 and -40 show the calculated plant parameters following a feedline rupture for the case with offsite power. Figures 15.4.2-41 and -42 show similar results from the case with loss of offsite power. The calculated sequence of events for both cases analyzed are presented in Table 15.4.1-9.

The system response following the feedwater line rupture is similar for both cases analyzed. The results show that the pressures in the RCS and main steam system remain below 110 percent of the respective design pressures. Pressurizer pressure remains at or slightly below the steady-state pressure before the reactor trip on low-low steam generator level. When the turbine trips on reactor trip, the primary pressure shows a rapid increase due to the mismatch between the heat generated and the heat removed by the steam generators. This is followed by reduction in heat generation in the core due to rod drop and the event becomes an overcooling event. The primary pressure drops rapidly due to cooldown and the pressurizer level drops. When the low steamline pressure SI signal actuates isolation of the steam generators from the affected generator, the primary system heats up. The primary safety valves do not open in this event. Safety injection is actuated by the low steamline pressure signal and the reactor vessel and the pressurizer start to refill to original levels. When the intact steam generators fill back up to normal levels, the steam produced in the steam generators is relieved through the MSSVs and a viable heat removal mechanism is maintained via the auxiliary feedwater.

In both of the cases, the core remains fully covered with water throughout the transient. The auxiliary feedwater is capable of removing the decay heat and cooling the primary system. Bulk boiling does not occur in the RCS at any time in the transient.

An evaluation of the full power feedline rupture and the part-power feedline rupture cases analyzed for the TTD system was performed by Westinghouse (for the 5 percent plugged tubes) considering an auxiliary feedwater system failure scenario involving a motor-driven pump. This evaluation is valid for the 15 percent tube plugging levels since the conclusions are not dependent upon the tube plugging levels. Under this scenario, the auxiliary feedwater system is assumed to provide 1070 gal/min to 3 unaffected steam generators 10 minutes after the low-low steam generator water level signal. Assuming a feedline rupture to loop 4, the following assumptions were made:

1. Steam Generators 1 and 2 receive no auxiliary feedwater from the Train A motor-driven auxiliary feedwater pump (single failure).

2. Steam Generators 3 and 4 receive no auxiliary feedwater from the Train B motor-driven auxiliary feedwater pump (all flow out of the break).

3. The turbine-driven auxiliary feedwater pump flow spills out of the break (Steam Generator 4) and thereby starves the remaining unfaulted steam generators (1, 2, and 3).

4. Operator action isolates the auxiliary feedwater line from the turbine-driven auxiliary feedwater pump and the Train B motor-driven auxiliary feedwater pump. Ten minute operator action is taken credit for isolating the auxiliary feedwater system from the faulted steam generator.

The turbine-driven auxiliary feedwater pump provides flow to Steam Generators 1, 2, and 3, and the motor-driven auxiliary feedwater pump provides flow to Steam Generator 3. A total of 1070 gal/min auxiliary feedwater is available after the 10 minute operator action time to the three unfaulted steam generators. The secondary side steam pressure in the unfaulted steam generators, which drives the turbine-driven AFW pump, reaches and remains at or near the Main Steam safety valve (MSSV) set point pressure during the critical transient time (AFW initiation to event turnaround) and after event turnaround. After event turnaround, less AFW is required to continue plant cooldown.

The single failure of the turbine-driven pump proved more limiting for the full power feedline break cases. The single failure case of the motor-driven auxiliary feedwater pump does not invalidate the TTD analysis presented in Reference 53.

15.4.2.2.3 Conclusion

Results of the analysis show that for the postulated feedline rupture, the assumed Auxiliary Feedwater System capacity is adequate to remove decay heat, to prevent overpressurizing the RCS, and to prevent uncovering the reactor core.

The Rupture of a Main Feedwater Pipe event has been evaluated with respect to the CENP-Westinghouse steam generator replacement at Sequoyah Unit 1 and Unit 2. The evaluation concludes that the parameters important to the consequences of this event are not adversely affected by the RSG.

15.4.3 Steam Generator Tube Rupture

15.4.3.1 Identification of Causes and Accident Description

The accident examined is the complete severance of a single steam generator tube. The accident is assumed to take place at power with the reactor coolant contaminated with fission products corresponding to continuous operation with a limited amount of defective fuel rods. The accident leads to an increase in contamination of the secondary system due to leakage of radioactive coolant from the RCS. In the event of a coincident loss of offsite power, or failure of the condenser dump system, discharge of activity to the atmosphere takes place via the steam generator safety and/or power operated relief valves.

In view of the fact that the steam generator tube material is Inconel 600 and is highly ductile material, it is considered that the assumption of a complete severance is somewhat conservative. The more probable mode of tube failure would be one or more minor leaks of undetermined origin. Activity in the steam and power conversion system is subject to continual surveillance and an accumulation of minor leaks which exceed the limits established in the Technical Specifications is not permitted during the unit operation.

The operator is expected to determine that a steam generator tube rupture has occurred, and to identify and isolate the faulty steam generator on a restricted time scale in order to minimize

contamination of the secondary system and ensure termination of radioactive release to the atmosphere from the faulty unit. The recovery procedure can be carried out on a time scale which ensures that break flow to the secondary system is terminated before water level in the affected steam generator rises into the main steam pipe. Sufficient indications and controls are provided to enable the operator to carry out these functions satisfactorily.

Consideration of the indications provided at the control board, together with the magnitude of the break flow, leads to the conclusion that the isolation procedure can be completed within 30 minutes of accident initiation.

Assuming normal operation of the various plant control systems, the following sequence of events is initiated by a tube rupture:

a. Pressurizer low pressure and low level alarms are actuated and charging pump flow increases in an attempt to maintain pressurizer level. On the secondary side there is a steam flow/feedwater flow.

   Mismatch before trip as feedwater flow to the affected steam generator is reduced due to the additional break flow which is now being supplied to that steam generator.

b. Continued loss of reactor coolant inventory leads to a reactor trip signal generated by low pressurizer pressure. Resultant plant cooldown following reactor trip leads to a rapid change of pressurizer level, and the safety injection signal, initiated by low pressurizer pressure, and follows soon after the reactor trip. The safety injection signal automatically terminates normal feedwater supply and initiates auxiliary feedwater addition.

c. The steam generator blowdown liquid monitor, main steamline monitor, and the condenser off gas radiation monitor will alarm, indicating a sharp increase in radioactivity in the secondary system. The steam generator blowdown liquid monitor will automatically terminate steam generator blowdown.

d. The reactor trip automatically trips the turbine and if offsite power is available the steam dump valves open permitting steam dump to the condenser. In the event of a coincident station blackout, the steam dump valves would automatically close to protect the condenser. In this case, the steam generator pressure would rapidly increase resulting in steam discharge to the atmosphere through the steam generator safety and/or power operated relief valves.

e. Following reactor trip, the continued action of auxiliary feedwater supply and borated safety injection flow (supplied from the refueling water storage tank) provide a heat sink which absorbs some of the decay heat. Thus, steam bypass to the condenser, or in the case of loss of offsite power, steam relief to atmosphere, is attenuated during the 30 minutes in which the recovery procedure leading to isolation is being carried out.

f. Safety injection flow results in increasing pressurizer water level. The time after trip at which the operator can clearly see returning level in the pressurizer is dependent upon the amount of operating auxiliary equipment.

15.4.3.2 Analysis of Effects and Consequences

Method of Analysis

In estimating the mass transfer from the RCS through the broken tube the following conservative assumptions are made:

a. Reactor trip occurs automatically as a result of low pressurizer pressure.

b. Following the initiation of the safety injection signal, all centrifugal charging SI pumps are actuated and continue to deliver flow for 30 minutes.

c. After reactor trip the break flow reaches equilibrium at the point where incoming safety injection flow is balanced by outgoing break flow. The resultant break flow persists for 30 minutes beyond initiation of the accident.

d. The steam generators are controlled at the safety valve setting rather than the power operated relief valve setting. Auxiliary feedwater flowrate equivalent to approximately 2% of the nominal main feedwater flowrate (660 gal/min) is assumed to be available to all steam generators.

e. The operator identifies the accident type and terminates break flow to the faulty steam generator within 30 minutes of accident initiation. Included in this 30 minute time period would be an allowance of 5 minutes to trip the reactor and actuate the safety injection system, 10 minutes to identify the accident as a steam generator tube rupture and 15 minutes to isolate the faulty steam generator.

Mass and energy balance calculations are performed to determine primary to secondary mass release and to determine amount of steam vented from each of the steam generators.

Recovery Procedure

Immediately apparent symptoms of a tube rupture accident such as falling pressurizer pressure and level and increased charging pump flow are also symptoms of small steam line breaks and loss of coolant accident. It is therefore important for the operator to determine that the accident is a rupture of a steam generator tube in order that he may carry out the correct recovery procedure. The accident under discussion is uniquely identified by a main steam line radiation alarm, condenser air ejector radiation alarm and/or a steam generator blowdown radiation alarm and the operator will proceed with the following recovery procedures if one of these alarms is received. In the event of a relatively large rupture, it will be clear soon after trip that the level in one steam generator is rising more rapidly than in the other. This too is a unique indication of a tube rupture accident.

The operator carries out the following procedures subsequent to reactor trip which lead to isolation of the ruptured steam generator and to unit cooldown.

With Offsite Power Available:

a. Identify ruptured steam generator by rising water level or high radiation indication in shell side fluid.

b. Isolate flow from ruptured steam generator by closing the main steam isolation valve and bypass valve, steam generator blowdown valves, and turbine-driven auxiliary feedwater pump steam supply from ruptured steam generator.

c. When water level in ruptured steam generator is above a minimum level, then isolate auxiliary feedwater flow to ruptured steam generator.

d. Initiate RCS cooldown by dumping steam from intact steam generators to condenser. This action is required to establish adequate subcooling to permit reducing RCS pressure.

e. When adequate subcooling is established, then reduce RCS pressure using pressurizer sprays or a power-operated relief valve to terminate break flow and restore pressurizer level.

f. Verify SI termination criteria is met and then terminate ECCS flow.

g. Resume RCS cooldown using intact steam generators until RHR system is placed in service.

Without Offsite Power:

a. Identify ruptured steam generator by rising water level or high radiation indication in shell side fluid.

b. Isolate flow from ruptured steam generator by closing the main steam isolation valve and bypass valve, steam generator blowdown valves, and turbine-driven auxiliary feedwater pump steam supply from ruptured steam generator.

c. When water level in ruptured steam generator is above a minimum level, then isolate auxiliary feedwater flow to ruptured steam generator.

d. Initiate RCS cooldown using atmospheric relief valves on intact steam generators. This action is required to establish adequate subcooling to permit reducing RCS pressure.

e. When adequate subcooling is established, then reduce RCS pressure using a pressurizer power-operated relief valve to terminate break flow and restore pressurizer level.

f. Verify SI termination criteria is met and then terminate ECCS flow.

g. Resume RCS cooldown using intact steam generators until RHR system is placed in service.

After the Residual Heat Removal System is placed in operation, the condensate accumulated in the secondary system can be examined and processed as required.

Section 15.4.3.1 describes the accident sequence as analyzed. The flow from a broken tube is assumed to reach an equilibrium at the point where safety injection flow is balanced by break flow. This break flow is conservatively assumed to persist until 30 minutes following accident initiation at which time the operator will have terminated the break flow through the faulty steam generator. Section 15.4.3.2 outlines operations which the operator could perform to terminate flow through the faulty steam generator.

Following isolation of the faulty steam generator, the primary pressure is reduced by either pressurizer spray or operation of the pressurizer power operated relief valve. It should be noted that the reduction in primary pressure will result in a decrease in break flow. When the primary pressure has been reduced to ruptured steam generator pressure, excess makeup flow is stopped and break flow is terminated.

The core will remain completely covered by liquid throughout the accident, thus clad temperatures will remain very near the saturation temperature of the coolant, even if DNB was postulated to occur.

There is ample time available to carry out the above recovery procedures such that isolation of the affected steam generator is established before water level rises into the main steam pipes. This analysis used 30 minutes as the time that operators stop flow from the primary to the secondary side of the faulted steam generator; however, at least 40 minutes is available for operators to stop this flow before the water level rises into the main steam pipes.

Results

The previous assumptions lead to a conservative estimate for the total amount of reactor coolant transferred to the secondary side of the ruptured steam generator as a result of a tube rupture accident. Approximately 172,700 lbs. of reactor coolant is discharged to the secondary side of the ruptured steam generator before break flow is isolated at 30 minutes (8400 lbs. before reactor trip and at 164,300 lbs. after reactor trip). Reactor trip occurs at 65 seconds into the accident. A fraction of the break flow flashes directly to steam while the remainder mixes with the secondary coolant in the steam generator. This flashing fraction is conservatively determined based on hot leg temperature to be 18.0% prior to reactor trip and 4.74% after reactor trip.

Also, approximately 138,900 lbs. of steam are released from the ruptured steam generator to the atmosphere during the 30-minute period (76,588 lbs. before reactor trip and 62,312 lbs. after reactor trip). The steam releases from the intact steam generators were conservatively calculated to be:

0 - 65 sec.	232,000 lbs.
65 - 1800 sec.	170,000 lbs.
0.5 - 2.0 hr.	360,000 lbs.
2 - 8 hr.	1,237,000 lbs.

The accident radiological consequences are reported in Section 15.5.5 based on the above values for break flows, flashing fractions, and steam releases.

15.4.3.3 Conclusions

A steam generator tube rupture will cause no subsequent damage to the Reactor Coolant System or the reactor core. An orderly recovery from the accident can be completed even assuming simultaneous loss of offsite power.

The Steam Generator Tube Rupture event has been evaluated with respect to the CENP-Westinghouse steam generator replacement at Sequoyah Unit 1 and Unit 2. The evaluation concludes that the parameters important to the consequences of this event are not adversely affected by the RSG.

15.4.4 Single Reactor Coolant Pump Locked Rotor

15.4.4.1 Identification of Causes and Accident Description

The accident postulated is an instantaneous seizure of a reactor coolant pump rotor. Flow through the affected reactor coolant loop is rapidly reduced, leading to an initiation of a reactor trip on a low flow signal.

Following initiation of the reactor trip, heat stored in the fuel rods continues to be transferred to the coolant causing the coolant to expand. At the same time, heat transfer to the shell side of the steam generators is reduced, first because the reduced flow results in a decreased tube side film coefficient and then because the reactor coolant in the tubes cools down while the shell side temperature increases (turbine steam flow is reduced to zero upon plant trip). The rapid expansion of the coolant in the reactor core, combined with reduced heat transfer in the steam generators causes an insurge into the pressurizer and a pressure increase throughout the Reactor Coolant System. The insurge into the pressurizer compresses the steam volume, and may open the pressurizer safety valves in the analysis. For conservatism in peak pressures, the power-operated relief valves are not included in the analysis.

15.4.4.2 Analysis of Effects and Consequences

Method of Analysis

Two digital computer codes are used to analyze this transient. The RELAP5/MOD2-B&W code (Reference 60) is used to calculate the resulting loop and core flow transients following the pump seizure, the time of reactor trip based on the loop flow transient, the nuclear power following reactor trip, and to determine the peak pressure. The thermal behavior of the fuel located at the core hot spot is investigated by using the LYNXT code (Reference 64) and the statistical core design methodology of BAW-10170 (Reference 57a).

At the beginning of the postulated locked rotor accident, i.e., at the time the shaft in one of the reactor coolant pumps is assumed to seize, the plant is assumed to be in operation under the nominal steady-state conditions, i.e., 102% steady state power level, steady state pressure and steady state coolant average temperature. The DNB calculations are performed according to a statistical core design methodology that incorporates calibration and measurement uncertainties. Consequently, nominal conditions are adequate for transient analysis. Only the primary safety valves are allowed to maintain the primary pressure in the transient, thus maximizing the peak primary pressures. The pressure response is shown in Figure 15.4.4-4. For the DNB calculations, the pressure is assumed constant at the initial value. To maximize the power response during the event, the least negative Doppler power coefficient and +7.0 pcm/F moderator coefficient are assumed.

Evaluation of the Pressure Transient

After pump seizure, reactor coolant system flow is reduced and the system heats up and pressurizes. A reactor trip occurs as a consequence of low flow. The neutron flux is rapidly reduced by control rod insertion. Loss of off-site power is assumed to occur simultaneously with the reactor trip.

No credit is taken for the pressure reducing effect of pressurizer relief valves, pressurizer spray, steam dump or controlled feedwater flow after the plant trip. Although these operations are expected to occur and would result in a lower peak pressure, an additional degree of conservatism is provided by ignoring their effect. The pressurizer safety valves are actuated at 2500 psia and their capacity for relief is as stated in Section 5.2.2.

Evaluation of the Effects of DNB in the Core During the Accident

The minimum DNBR calculated in the hot channel for this event is less than the DNBR limit of 1.5. Consequently, a clad temperature excursion of short duration is predicted. Less than 10% of the fuel pins could experience DNB during the accident.

Locked Rotor Results

Table 15.4.4-1 gives a summary of the results for the transient analysis of the reactor coolant pump locked rotor event. Transient values of pressurizer pressure, reactor vessel flow coastdown, nuclear power and thermal power are shown in Figures 15.4.4-1 through 15.4.4-5.

15.4.4.3 Conclusions

1. Since the peak RCS pressure reached during any of the transients is less than that which would cause stresses to exceed the faulted condition stress limits, the integrity of the primary coolant system is not endangered.

2. Since the peak fuel temperature is well below the 5080°F fuel temperature limit and the peak cladding temperature is well below the 1800°F cladding temperature limit, the core will remain intact with no consequential loss of core cooling capability. Typically, for the purpose of dose calculations, all pins that experience DNB are assumed to fail. The evaluation of DNB effects for this accident showed that less than 10% of the fuel pins experience DNB. This is bounded by the conclusions presented in Section 15.5.3.

The Single Reactor Coolant Pump Locked Rotor event has been evaluated with respect to the CENP-Westinghouse steam generator replacement at Sequoyah Unit 1 and Unit 2. The evaluation concludes that the parameters important to the consequences of this event are not adversely affected by the RSG.

15.4.5 Fuel Handling Accident

15.4.5.1 Identification of Causes and Accident Description

Refer to Subsection 15.5.6.

15.4.5.2 Analysis of Effects and Consequences

For the analysis and consequences of the postulated fuel handling accident, refer to Subsection 15.5.6.

15.4.6 Rupture Of a Control Rod Drive Mechanism Housing (Rod Cluster Control Assembly Ejection)

15.4.6.1 Identification of Causes and Accident Description

This accident is defined as the mechanical failure of a control rod mechanism pressure housing resulting in the ejection of a rod cluster control assembly and drive shaft. The consequence of this mechanical failure is a rapid reactivity insertion together with an adverse core power distribution, possibly leading to localized fuel rod damage.

Design Precautions and Protection

Certain features in the Sequoyah Nuclear Plant pressurized water reactor are intended to preclude the possibility of a rod ejection accident, or to limit the consequences if the accident were to occur. These include a sound, conservative mechanical design of the rod housings, together with a thorough quality control (testing) program during assembly, and a nuclear design which lessens the potential ejection worth of rod cluster control assemblies and minimizes the number of assemblies inserted at power.

Mechanical Design

The mechanical design is discussed in Section 4.2. Mechanical design and quality control procedures intended to preclude the possibility of rod cluster control assembly drive mechanism housing failure sufficient to allow a rod cluster control assembly to be rapidly ejected from core are listed below:

1. Each full length control rod drive mechanism housing is completely assembled and shop tested at 4100 psi.

2. The mechanism housings are individually hydrotested as they are attached to the head adapters in the reactor vessel head, and checked during the hydrotest of the completed RCS.

3. Stress levels in the mechanism are not affected by anticipated system transients at power, or by the thermal movement of the coolant loops. Moments induced by the design earthquake can be accepted within the allowable primary working stress range specified by the ASME Code, Section III, for Class 1 components.

4. The latch mechanism housing and rod travel housing are each a single length of forged Type-304 stainless steel. This material exhibits excellent notch toughness at all temperatures which will be encountered.

A significant margin of strength in the elastic range together with the large energy absorption capability in the plastic range gives additional assurance that gross failure of the housing will not occur. The joints between the latch mechanism housing and head adapter, and between the latch mechanism housing and rod travel housing, are threaded joints reinforced by canopy seal welds. These welds are inspected in accordance with the plant’s Inservice Inspection Program (Section 5.2.8) and a discussion on non-welding repair is provided in FSAR Section 4.2.3.2.2.

Nuclear Design

Even if a rupture of a rod cluster control assembly drive mechanism housing is postulated, the operation of a plant utilizing chemical shim is such that the severity of an ejected rod cluster control assembly is inherently limited. In general, the reactor is operated with the rod cluster control changes caused by core depletion and xenon transients are compensated by boron changes.

Further, the location and grouping of control rod banks are selected during the nuclear design to lessen the severity of a rod cluster control assembly ejection accident. Therefore, should a rod cluster control assembly be ejected from its normal position during high power operation, only a minor reactivity excursion, at worst, could be expected to occur.

However, it may be occasionally desirable to operate with larger than normal insertions. For this reason, a rod insertion limit is defined as a function of power level. Operation with the rod cluster control assemblies above this limit guarantees shutdown capability and acceptable power distribution. The position of all rod cluster control assemblies is continuously indicated in the control room. An alarm will occur if a bank of rod cluster control assemblies approaches its insertion limit or if one assembly deviates from its bank. There are low and low-low control bank rod insertion alarms with visual and audio signals. The control bank rod insertion alarms alert operators to take action to restore margin.

Reactor Protection

The reactor protection in the event of a rod ejection accident has been described in Reference 26. The protection for this accident is provided by the power range high neutron flux trip (high and low setting) and high rate of neutron flux increase trip. These protection functions are described in detail in Section 7.2.

Effects on Adjacent Housings

Disregarding the remote possibility of the occurrence of a rod cluster control assembly mechanism housing failure, investigations have shown that failure of a housing due to either longitudinal or circumferential cracking is not expected to cause damage to adjacent housings leading to increased severity of the initial accident.

Limiting Criteria

Due to the extremely low probability of a rod cluster control assembly ejection accident, limited fuel damage is considered an acceptable consequence.

Comprehensive studies of the threshold of fuel failure and of the threshold of significant conversion of the fuel thermal energy to mechanical energy, have been carried out as part of the SPERT project by the Idaho Nuclear Corporation (Reference 27). Extensive tests of UO_2 zirconium clad fuel rods representative of those in Pressurized Water Reactor type cores have demonstrated failure thresholds in the range of 240 to 257 cal/gm. However, other rods of a slightly different design have exhibited failures as low as 225 cal/gm. These results differ significantly from the TREAT (Reference 28) results, which indicted that this threshold decreases by about 10% with fuel burnup. The clad failure mechanism appears to be melting for zero burnup rods and brittle fracture for irradiated rods. Also important is the conversion ratio of thermal to mechanical energy. This ratio becomes marginally detectable above 300 cal/gm for unirradiated rods and 200 cal/gm for irradiated rods; catastrophic failure, (large fuel dispersal, large pressure rise) even for irradiated rods, did not occur below 300 cal/gm.

In view of the above experimental results, conservative criteria are applied to ensure that there is little or no possibility of fuel dispersal in the coolant, gross lattice distortion, or severe shock waves. These criteria are:

1. Average fuel pellet enthalpy at the hot spot below 225 cal/gm for uniradiated fuel and 200 cal/gm for irradiated fuel.

2. Peak reactor coolant pressure less than that which would cause stresses to exceed the faulted condition stress limits.

3. Fuel melting will be limited to less than 10% of the fuel volume at the hot spot even if the average fuel pellet enthalpy is below the limits of criterion (1) above.

15.4.6.2 Analysis of Effects and Consequences

Method of Analysis

The analysis of the RCCA ejection accident is performed in two stages, first an average core nuclear power transient calculation and then a hot spot heat transfer calculation. The average core calculation is performed using spatial neutron kinetics methods to determine the average power generation with time including the various total core feedback effects, i.e., Doppler reactivity and moderator reactivity. Enthalpy and temperature transients in the hot spot are then determined by multiplying the average core energy generation by the hot channel factor and performing a fuel rod transient heat transfer calculation. The power distribution calculated without feedback is pessimistically assumed to persist throughout the transient.

A detailed discussion of the method of analysis can be found in Reference 29.

Average Core Analysis

The spatial kinetics computer code, TWINKLE (Reference 30), is used for the average core transient analysis. This code uses cross sections generated by LEOPARD (Reference 31) to solve the two group neutron diffusion theory kinetic equations in one, two or three spatial dimensions (rectangular coordinates) for six delayed neutron groups and up to 2000 spatial points. The computer code includes a detailed multiregion, transient fuel-clad-coolant heat transfer model for calculation pointwise Doppler and moderator feedback effects. In this analysis, the code is used as a one dimensional axial kinetics code since it allows a more realistic representation of the special effects of axial moderator feedback and rod cluster control assembly movement and the elimination of axial feedback weighting factors. However, since the radial dimension is missing, it is still necessary to employ very conservative methods (described below) of calculating the ejected rod worth and hot channel factor. Further description of TWINKLE appears in Subsection 15.1.9.

Hot Spot Analysis

The average core energy addition, calculated as described above, is multiplied by the appropriate hot channel factors, and the hot spot analysis is performed using the detailed fuel and clad transient heat transfer computer code, FACTRAN (Reference 25). This computer code calculates the transient temperature distribution in a cross section of a metal clad UO_2 fuel rod, and the heat flux at the surface of the rod, using as input the nuclear power versus time and the local coolant conditions. The zirconium-water reaction is explicitly represented, and all material properties are represented as functions of temperature. A parabolic radial power generation is used within the fuel rod.

FACTRAN uses the Dittus-Boelter or Jens-Lottes correlation to determine the film heat transfer before DNB, and the Bishop-Sandburg-Tong correlation (Reference 32) to determine the film boiling coefficient after DNB. The DNB heat flux is not calculated, instead the code is forced into DNB by

specifying a conservative DNB heat flux. The gap heat transfer coefficient can be calculated by the code; however, it is adjusted in order to force the full power steady state temperature distribution to agree with that predicted by design fuel heat transfer codes presently used by Westinghouse.

For full power cases, the design initial hot channel factor ($F_Q T$) is input to the code. The hot channel factor during the transient is assumed to increase from the steady state design value to the maximum transient value in 0.1 seconds, and remain at the maximum for the duration of the transient. This is conservative, since detailed spatial kinetics models show that the hot channel factor decreases shortly after the nuclear power peak due to power flattening caused by preferential feedback in the hot channel (Reference 29). Further description of FACTRAN appears in Subsection 15.1.9.

<u>System Overpressure Analysis</u>

Because safety limits for fuel damage specified earlier are not exceeded, there is little likelihood of fuel dispersal into the coolant. The pressure surge may therefore be calculated on the basis of conventional heat transfer from the fuel and prompt heat generation in the coolant.

The pressure surge is calculated by first performing the fuel heat transfer calculation to determine the average and hot spot heat flux versus time. Using this heat flux data, a THINC calculation is conducted to determine the volume surge. Finally, the volume surge is simulated in a plant transient computer code. This code calculates the pressure transient taking into account fluid transport in the system, and heat transfer to the steam generators. No credit is taken for the possible pressure reduction caused by the assumed failure of the control rod pressure housing.

<u>Calculation of Basic Parameters</u>

Input parameters for the analysis are conservatively selected on the basis of calculated values for this type of core. The more important parameters are discussed below. Table 15.4.6-1 presents the parameters used in this analysis.

<u>Ejected Rod Worths and Hot Channel Factors</u>

The values for ejected rod worths and hot channel factors are calculated using a synthesis of one dimensional and two dimensional calculations. Standard nuclear design codes are used in the analysis. No credit is taken for the flux flattening effects of reactivity feedback. The calculation is performed for the maximum allowed bank insertion at a given power level, as determined by the rod insertion limits. Adverse Xenon distributions and part length rod positions are considered in the calculations.

The total transient hot channel factors $F_q T$, is then obtained by combining the axial and radial factors.

Appropriate margins are added to the results to allow for calculational uncertainties, including an allowance for nuclear power peaking due to fuel densification.

<u>Reactivity Feedback Weighting Factors</u>

The largest temperature rises, and hence the largest reactivity feedbacks occur in channels where the power is higher than average. Since the weight of a region is dependent on flux, these regions have high weights. This means that the reactivity feedback is larger than that indicated by a simple

single channel analysis. Physics calculations were carried out for temperature changes with a flat temperature distribution, and with a large number of axial and radial temperature distributions. Reactivity changes were compared and effective weighting factors determined. These weighting factors take the form of multipliers which when applied to single channel feedbacks correct them to effective whole core feedbacks for the appropriate flux shape. In this analysis, since a one dimensional (axial) spatial kinetics method is employed, axial weighting is not used. In addition, no weighting is applied to the moderator feedback. A conservative radial weighting factor is applied to the transient fuel temperature to obtain an effective fuel temperature as a function of time accounting for the missing spatial dimension. These weighting factors were shown to be conservative compared to three dimensional analysis (Reference 29).

Moderator and Doppler Coefficient

The critical boron concentrations at the beginning of life and end of life were adjusted in the nuclear code in order to obtain moderator density coefficient curves which are conservative compared to actual design conditions for the plant. As discussed above, no weighting factor is applied to these results.

The Doppler reactivity defect is determined as a function of power level using the one dimensional steady state computer code with a Doppler weighting factor of 1.0. The resulting curve is conservative compared to design predictions for this plant. The Doppler weighting factor should be larger than 1.0 (approximately 1.3), just to make the present calculation agree with design predictions before ejection. This weighting factor will increase under accident conditions, as discussed above. The transient weighting factor used in the analysis is presented in Table 15.4.6-1.

Delayed Neutron Fraction, β

Calculations of the effective delayed neutron fraction (β_{eff}) typically yield values of 0.70% at beginning of life and 0.50% at end of life for the first cycle. The accident is sensitive to the ejected rod when its worth is nearly equal to or greater than β_{eff} as in zero power transients. In order to allow for future fuel cycles, pessimistic estimates were used in the analysis (0.55% at beginning of cycle and 0.45% β_{eff} at end of cycle).

Trip Reactivity Insertion

The trip reactivity insertion is assumed to be 4% from hot full power and 2% from hot zero power including the effect of one stuck rod. These values are reduced by the ejected rod reactivity. The shutdown reactivity was simulated by dropping a rod of the required worth into the core. The start of rod motion occurred 0.5 seconds after the high neutron flux trip point is reached. This delay is assumed to consist of 0.2 seconds for the instrument channel to produce a signal, 0.15 seconds for the trip breaker to open and 0.15 seconds for the coil to release the rods. The curve of rod insertion versus time which was used is shown in Figure 15.1.5-1. The time to full insertion assumed together with the 0.5 second delay overestimates the time for significant insertion of shutdown reactivity into the core. This is particularly important conservatism for hot full power accidents.

Results

The values of the parameters used in the analysis, as well as the results of the analysis, are presented in Table 15.4.6-1 and discussed below.

Beginning of Cycle, Full Power

Control bank D was assumed to be inserted to its insertion limit. The worst ejected rod worth and hot channel factor were 0.20% ΔK/K and 7.11 respectively. The peak hot spot fuel center temperature reached the beginning of life melt temperature of 4900°F. However, melting was restricted to less than 10% of the pellet.

Beginning of Cycle, Zero Power

For this condition, control bank D was assumed to be fully inserted and C was at its insertion limit. The worst ejected rod is located in control bank D and has a worth of 0.75% Δk/k and a hot channel factor of 14.05.

End of Cycle, Full Power

Control bank D was assumed to be inserted to its insertion limit. The ejected rod worth and hot channel factors were 0.21% Δk/k and 7.88 respectively. The peak hot spot fuel temperature exceeded the end of life melt temperature of 4800°F. However, melting was restricted to less than 10% of the pellet. The variation in melt temperature with burnup is discussed in Paragraph 4.4.1.2.

End of Cycle, Zero Power

Original analysis - The ejected rod worth and hot channel factor for this case were obtained assuming control bank D to be fully inserted and bank C at its insertion limit. The results were 1.01% Δk and 22.2, respectively. The peak fuel center temperature was 4203°F.

Reanalysis - This transient was reanalyzed in Reference 65 to address an increase in the Cycle 8 ejected rod hot channel factor. The reanalysis was performed consistent with the original analysis except that the bounding Cycle 8 values of 0.91%Δk for ejected rod worth and 24.8 for the hot channel factor were assumed. The results of the reanalysis were bounded by the original analysis.

A summary of the cases presented above is given in Table 15.4.6-1. The nuclear power and fuel clad temperature transients for the worst case in terms of fuel melt (EOL full power) are presented in Figures 15.4.6-1 and 15.4.6-2. The same transients for the worst case in terms of clad temperature (EOL zero power) are presented in Figures 15.4.6-3 and 15.4.6-4.

Fission Product Release

It is assumed that fission products are released from the gaps of all rods having a DNBR of less than the safety analysis limit. In all cases considered, less than 10% of the rods entered DNB based on a detailed 3 dimensional THINC analysis. Although limited fuel melting at the hot spot was predicted for the full power cases, in practice melting is not expected since the analysis conservatively assumed that the hot spots before and after ejection were coincident.

Pressure Surge

A detailed calculation of the pressure surge for an ejection worth 1 dollar at BOL, hot full power, indicates that the peak pressure does not exceed that which would cause stress to exceed the faulted condition stress limits (Reference 29). Since the severity of the present analysis does not exceed this "worst case" analysis, the accident for this plant will not result in an excessive pressure rise or further damage to the RCS.

Lattice Deformations

A large temperature gradient will exist in the region of the hot spot. Since the fuel rods are free to move in the vertical direction, differential expansion between separate rods cannot produce distortion. However, the temperature gradients across individual rods may produce a force tending to bow the midpoint of the rods toward the hot spot. Physics calculations indicate that the net result of this would be a negative reactivity insertion. In practice, no significant bowing is anticipated, since the structural rigidity of the core is more than sufficient to withstand the forces produced. Boiling in the hot spot region would produce a net flow away from that region. However, the heat from the fuel is released to the water relatively slowly, and it is considered inconceivable that cross flow will be sufficient to produce significant lattice forces. Even if massive and rapid boiling, sufficient to distort the lattice, is hypothetically postulated, the large void fraction in the hot spot region would produce a reduction in the total core moderator to fuel ration, and a large reduction in this ratio at the hot spot. The net effect would therefore be a negative feedback. it can be concluded that no conceivable mechanism exists for a net positive feedback resulting from lattice deformation. In fact, a small negative feedback may result. The effect conservatively ignored in the analyses.

15.4.6.3 Conclusions

Even on a pessimistic basis, the analyses indicate that the described fuel and clad limits are not exceeded. It is concluded that there is no danger of sudden fuel dispersal into the coolant. Since the peak pressure does not exceed that which would cause stresses to exceed the faulted condition stress limits, it is concluded that there is no danger of further consequential damage to the primary system. The analyses have demonstrated that upper limit in fission product release as a result of a number of fuel rods entering DNB amounts to 10%.

The rupture of a Control Rod Drive Mechanism Housing event has been evaluated with respect to the CENP-Westinghouse steam generator replacement at Sequoyah Unit 1 and Unit 2. The evaluation concludes that the parameters important to the consequences of this event are not adversely affected by the RSG.

15.5 ENVIRONMENTAL CONSEQUENCES OF ACCIDENTS

Each unit specific cycle nuclear fuel reload analysis will verify the consequences of an accident previously evaluated in the FSAR have not increased. The reload core design does not have a direct role in mitigating the consequences of any design basis accident and does not affect any of the conclusions for the current 10CFR50 Appendix A, GDC-19 or 100CFR100 analyses described in this section. The reload core design ensures that all applicable design criteria and licensing basis acceptance criteria are met. Adherence to applicable standards and criteria ensures that the fission product barriers maintain an adequate design margin relative to the applicable safety margins.

15.5.1 Environmental Consequences of a Postulated Loss of A.C. Power to the Plant Auxiliaries

The postulated accidents involving release of steam from the secondary system will not result in a release of radioactivity unless there is leakage from the Reactor Coolant System to the secondary system in the steam generator. A conservative analysis of the potential offsite doses resulting from this accident is presented assuming steam generator leakage prior to the postulated accident for a time sufficient to establish equilibrium specific activity levels in the secondary system. Parameters used in the conservative analysis are listed in Table 15.5.1-1.

The following conservative assumptions and parameters are used to calculate the activity releases and offsite doses for the postulated loss of offsite power to the plant auxiliaries:

1. Offsite power is lost and the main steam condensers are not available for steam dump.

2. Eight hours after the accident the residual-heat removal system starts operation to cool down the plant.

3. After eight hours following the accident, no steam and activity are released to the environment.

4. No air ejector release and no steam generator blowdown during the accident.

5. The primary to secondary leakage is evenly distributed in steam generators.

6. Initial primary coolant activity (iodine and noble gas) is consistent with the model discussed in Appendix 15D. This model is consistent with Technical Specification limits on primary coolant activity limits.

7. The analysis assumes an iodine spike with two separate cases considered. For one case there is assumed to be a pre-existing iodine spike. For the second case the initial primary coolant iodine concentration is at the limit set in the Technical Specifications for equilibrium operation and an iodine spike is assumed to be initiated by the reactor trip associated with the event. The iodine spiking models are described in Appendix 15D.

8. Initial secondary coolant activity (iodine) is consistent with the model discussed in Appendix 15D. This model is consistent with Technical Specification limits on primary coolant activity limits. There is no noble gas activity in the secondary coolant.

9. The iodine partition factor is $\frac{\text{amount of iodine/unit mass steam}}{\text{amount of iodine/unit mass liquid}}$ = 0.01 in steam generators.

10. During the postulated accident, iodine transferred to the secondary side in the three good steam generators is uniformly mixed with the water in the steam generators.

11. The steam release for cooling down the plant is equally contributed by all steam generators.

12. The 0-2 and 2-8 hour atmospheric diffusion factors given in Appendix 15A and the 0-8 hour breathing rate of 3.47×10^{-4} m^3/sec are applicable.

The resulting doses for the case with the accident-initiated iodine spike are:

	Thyroid	Whole Body	Skin
Exclusion Area Boundary	0.69 rem	0.085 rem	0.18 rem
Low Population Zone	0.21 rem	0.013 rem	0.026 rem

These doses are well within the limits of 25 rem whole body and 300 rem thyroid defined in 10 CFR 100.

[For information only, the TEDE doses are 0.11 rem at the EAB and 0.02 at the LPZ.]

For the case with the pre-existing iodine spike the doses are:

	Thyroid	Whole Body	Skin
Exclusion Area Boundary	0.73 rem	0.078 rem	0.17 rem
Low Population Zone	0.18 rem	0.012 rem	0.024 rem

These doses are well within the limits of 25 rem whole body and 300 rem thyroid defined in 10 CFR 100.

[For information only, the TEDE doses are 0.10 rem at the EAB and 0.017 at the LPZ.]

Framatome ANP Safety Evaluation With Replacement Steam Generators

The primary-to-secondary leak rate primary coolant activity, iodine activity in the secondary side liquid, and iodine partition factor are set by Technical Specification limits and are not affected by SG design.

The steam release to cool the plant to the RHR cut-in temperature is approximately 5600 lbm less with the RSDs than with the OSGs. Also, the secondary mass at full power and at RHR cut-in is less with the RSGs. Therefore, the mass of secondary steam released to the atmosphere to cool the plant to the RHR cut-in temperature is bounded by the calculation with the OSG.

Since all parameters affecting the Loss of A.C. Power to the Plant Auxiliaries for environmental consequences are not adversely affected by the RSG, the results of the existing analysis are applicable and all acceptance criteria continue to be met with the steam generator replacement.

15.5.2 Environmental Consequences of a Postulated Waste Gas Decay Tank Rupture

The analysis of the postulated waste gas decay tank rupture is performed based on Regulatory Guide 1.24, 1972 (Reference 2).

The parameters used for waste gas decay tank rupture analysis are listed in Table 15.5.2-1. The bases for the analysis are:

1. The reactor has been operating at full power with one percent defective fuel and a shutdown to cold condition has been conducted near the end of an equilibrium core cycle. As soon as possible after shutdown, all noble gases have been removed from the Reactor Coolant System and transferred to the gas decay tank that is assumed to fail.

   The iodine inventory of the tank is based on plant operating procedures (degassing of volume control tank every 3 hours for 21 hours after shutdown). At 21 hours after shutdown the summation of the product of the iodine isotopic inventories in the tank and their respective dose conversion factors is a maximum.

2. The maximum content of the decay tank assumed to fail is used for the purpose of computing the noble gas inventory in the tank. Radiological decay is taken into account in the computation only for the minimum time period required to transfer the gases from the Reactor Coolant System to the decay tank. The noble gas and iodine inventories of the tank are given in Table 15.5.2-2.

3. The tank rupture is assumed to occur immediately upon completion of the waste gas transfer, releasing the entire contents of the tank at ground level to the outside atmosphere. The assumption of the release of the noble gas inventory from only a single tank is based on the fact that all gas decay tanks will be isolated from each other whenever they are in use.

4. The short-term, i.e., 0-2 hour, diffusion factor at the site boundary given in Appendix 15A is used to evaluate the doses from the released activity.

The resulting doses are:

	Thyroid	Whole Body	Skin
Exclusion Area Boundary	0.039 rem	1.8 rem	4.7 rem
Low Population Zone	0.005 rem	0.22 rem	0.56 rem

These doses are well within the limits of 25 rem whole body and 300 rem thyroid defined in 10 CFR 100.

[For information only, the TEDE doses are 1.8 rem at the EAB and 0.22 at the LPZ.]

Framatome ANP Safety Evaluation With Replacement Steam Generators

The tank activity assumed at the event initiation are conservatively determined based on the reactor coolant system volume. The RCS volume is unaffected by SG replacement and the assumed tank activity, based on OSGs, is unchanged.

15.5.3 Environmental Consequences of a Postulated Loss of Coolant Accident

The results of the analysis presented in this section demonstrate that the amounts of radioactivity released to the environment in the event of a Loss-of-Coolant Accident (LOCA) do not result in doses which exceed the guideline values specified in a 10 CFR 100.

An analysis based on Regulatory Guide 1.4, 1973, (Reference 3) was performed. Two cases were considered. The first case with a postulated single failure of one train of EGTS concurrent with the LOCA is applicable to Unit 1 & 2. The second with an alternate single failure of a pressure control operator (PCO) that causes the exhaust damper to remain in the full open position while both trains of EGTS remain in operation is applicable to Unit 2 only. The parameters used for the analysis are listed in Table 15.5.3-1. In addition, an evaluation of the dose to control room operators and an evaluation of the offsite dose resulting from the operation of the Post-Accident Sampling Facility are presented.

Fission Product Release to the Containment

Following a postulated double-ended rupture of a reactor coolant pipe with subsequent blowdown, the Emergency Core Cooling System keeps cladding temperatures well below melting, and limits zirconium-water reactions to an insignificant level, ensuring that the core remains intact and in place.

As a result of the increase in cladding temperature and rapid depressurization of the core, however, some cladding failure may occur in the hottest regions of the core. Thus, a fraction of the fission products accumulated in the pellet-cladding gap may be released to the Reactor Coolant System and thereby to the primary containment.

In order to conservatively evaluate the radiological consequences of a fission product release, the offsite doses were calculated for a core inventory fission product release case.

Core Activity Release (Regulatory Guide 1.4 Analysis)

The offsite doses resulting from a hypothetical accident such as a large LOCA assuming core activity releases have been analyzed. Activity releases of these magnitudes have a considerably lower probability than those associated with a gap release. For the analysis of this hypothetical case, it is assumed that of the entire core-fission product inventory, 100 percent of the noble gases, 50 percent of the halogens, and 1% of the solids in the fission product inventory are released to the containment. Of the fission product iodine released to the containment, 50 percent is considered to be available for leakage, while the remaining 50 percent is assumed to condense on the various structural surfaces in the containment.

Thus, a total of 100 percent of the noble gas core inventory and 25 percent of the core iodine inventory are assumed to be immediately available for leakage from the primary containment. Of the halogen activity available for release, it is further assumed that 91 percent is in elemental form, 4 percent in methyl form, and 5 percent in particulate form.

The fission product inventories used for the core activity release cases are listed in Table 15.5.3-5. Post LOCA radiation doses at the site boundary and low population zone are provided in Table 15.5.3-4.

Modeling of Removal Process

For fission products other than iodine, the only removal process considered is radioactive decay.

The fission product iodine is assumed to be present in the containment atmosphere in elemental, organic, and particulate form. It is assumed that 91 percent of the iodine available for leakage from the containment is in elemental (i.e., iodine vapor) form, 4 percent is assumed to be in the form of organic iodine compounds (e.g., methyl iodine), and 5 percent is assumed to be adsorbed on airborne particulate matter. In this analysis it was conservatively assumed that the organic form of iodine is not subject to any removal processes other than radioactive decay and leakage from the containment.

The effectiveness of the ice condenser for elemental iodine removal is described in Section 6.2.3.3.4. For the calculation of doses, the ice condenser was treated as a removal process proportional to the amount of elemental and particulate iodine airborne in the containment, with time dependent removal constants. The time dependent ice condenser iodine removal efficiencies for the conservative Regulatory Guide 1.4 (1973) analysis are given in Table 15.5.3-2.

Ice Condenser

The ice condenser is designed to limit the leakage of airborne activity from the containment in the event of a LOCA. This is accomplished by the removal of heat released to the containment during the accident to the extent necessary to initially maintain that structure below design pressure and then reduce the pressure to near atmospheric. The addition of an alkaline solution such as sodium tetraborate enhances the iodine removal qualities of the melting ice to a point where credit can be assumed in the radiological analyses.

The operation of the containment deck fans is delayed for 10 minutes following the LOCA. This delay in fan operation yields an initial inlet steam-air mixture into the ice condenser of greater than 90 percent steam by volume which results in more efficient iodine removal by the ice condenser.

As a result of experimental and analytical efforts, the ice condenser system has been proven to be an effective passive system for removing iodine from the containment atmosphere following a LOCA. (Reference 4)

With respect to iodine removal by the ice condenser, the following assumptions were made:

1. The ice condenser is only effective in removing airborne elemental and particulate iodine from the containment atmosphere.

2. The ice condenser is modeled as a time dependent removal process.

3. The effectiveness of the ice condenser in removing iodine is lost after all of the ice has melted using the most conservative assumptions.

Primary Containment Leak Rate

The primary containment leak rate used in the conservative Regulatory Guide 1.4 (1973) analysis is the design basis leak rate guaranteed in the technical specifications regarding containment leakage. For the first 24 hours following the accident, the leak rate was assumed to be 0.25 percent per day and the leak rate was assumed to be 0.125 percent per day for the remainder of the 30-day period.

The leakage from the primary containment can follow either of two paths: (1) leakage into the annulus volume, or (2) through-line leakage to rooms in the Auxiliary Building (see Figure 15.5.3-1). The environmental effects of the core-release source event have been analyzed on the basis that 25 percent of the total primary containment leakage goes to the Auxiliary Building.

Auxiliary Building Release Path

The Auxiliary Building allows holdup and is normally ventilated by the Auxiliary Building ventilation system. However, upon initiation of the SIS signal following a LOCA, the normal ventilation systems to all areas of the Auxiliary Building are shutdown and isolated. Upon Auxiliary Building isolation, the Auxiliary Building Gas Treatment System (ABGTS) is activated to provide ventilation of the area and filtration of the exhaust to the atmosphere. This system is described in Subsection 6.2.3.

Fission products which leak from the primary containment to areas of the Auxiliary Building will be diluted in the room atmosphere and will travel via ducts and other rooms to the fuel handling area or the waste packaging area where the suctions for the (ABGTS) are located. The mean holdup time for airborne activity in the Auxiliary Building areas other than the fuel handling area is greater than one hour with the Auxiliary Building isolated and both trains of the ABGTS operating. For the reference case, it has been conservatively assumed in the estimation of activity releases that activity leaking to the Auxiliary Building is immediately released without filtration to the environment for the first 5 minutes after which it is held up for 0.3 hours and then released through the ABGTS filter system. This assumption is based on an initial delay of 4 minutes to establish the ABSCE and 1 minute to draw down the ABSCE to a negative 1/4-inch water gauge. In the Regulatory Guide 1.4 analysis, the ABGTS filter system is assumed to have a removal efficiency of 99 percent for all forms of iodine.

The Auxiliary Building internal pressure will be maintained at less than atmospheric during normal operation (See Subsection 9.4.2), thereby preventing release to the environment without filtration following a LOCA. The annulus pressure will be maintained less than the Auxiliary Building internal pressure during normal operation, therefore, any leakage between the two volumes following a LOCA will be into the annulus. It has been assumed conservatively that there is no leakage via this route.

Shield Building Releases

The presence of the annulus between the containment vessel and the shield building reduces the probability of direct leakage from the containment vessel to the atmosphere and allows holdup, dilution, mixing, and plate- out of fission products in the shield building. Seventy five percent of the primary containment leakage is assumed to go into the annulus volume in the reference case.

The initial pressure in the annulus is less than atmospheric. After blowdown, the annulus pressure will increase rapidly due to expansion of the containment vessel as a result of primary containment

atmosphere temperature and pressure increases. The annulus pressure will continue to rise due to heating of the annulus atmosphere by conduction through the containment vessel. For the single train EGTS case following a LOCA, the annulus pressure will rise above negative ¼ inch water gauge starting at 46 seconds for approximately 8 seconds. For the PCO failure case, the annulus pressure will rise above negative ¼ inch water gauge starting at 47 seconds for approximately 2 seconds. After a delay of 38 seconds from the start of the accident, the Emergency Gas Treatment System (EGTS) will be operating at full flow to return the annulus pressure to negative 1/2 inch water gauge. See Reference 21.

The EGTS is essentially an annulus recirculation system with pressure activated valves which allow part of the system flow to be exhausted to atmosphere to maintain a "negative" annulus pressure. The system includes absolute and impregnated charcoal filters for removal of halogens. After the initial delay of the ABGTS, the EGTS combined with ABGTS ensures that all primary containment leakage is filtered before release to the atmosphere.

The EGTS suction points in the annulus are located at the top of the containment dome, while nearly all penetrations are located near the bottom of the containment (see Subsection 6.2.3.2.2), thereby minimizing the probability of leakage directly from the primary containment into the EGTS. However, it has been conservatively assumed for the reference case that, after the initial 30 second period, 100 percent of the primary containment leakage to the annulus volume goes directly to the EGTS suction.

The holdup time is a function of the EGTS flow and exhaust rates as well as the annulus volume. The mean holdup time (t_H) before release to the atmosphere is defined as:

$$t_H = \frac{\text{0.5 x Volume of the Annulus}}{\text{Exhaust Flow from the EGTS to Atmosphere}}$$

It is conservatively assumed that only 50 percent of the annulus free volume is available for mixing of activity.

Nearly all of the leakage is expected to occur in the area of the penetrations near the base of the annulus where it would be diluted by the EGTS flow and slowly travel to the EGTS suction.

Table 15.5.3-3 shows the variation of EGTS exhaust and recirculation flow rates with a single train of the EGTS air cleanup subsystem in operation. Table 15.5.3-3A shows the variation of EGTS exhaust and recirculation flow rates for the PCO failure case. Table 15.5.3-3 and Table 15.5.3-3A show flow rates, with time after the LOCA, which are used for calculation of activity releases for the conservative Regulatory Guide 1.4 analysis. The flow path of fission products which are drawn into the air handling systems is shown schematically in Figure 15.5.3-1.

Effectiveness of Double Containment Design

The analysis has demonstrated clearly the benefits of the double containment concept. As would be expected for a double barrier arrangement, the second barrier acts as an effective holdup tank, resulting in substantial reduction in the two-hour inhalation and whole body immersion doses. The expected offsite doses for the 30-day period at the low population zone are also substantially reduced, since the holdup process is effective for the duration of the accident.

The EGTS exhaust flow rate is dependent on the rate of air inleakage to the annulus. Studies (Reference 5) made of leak rates from typical concrete buildings of this type have resulted in leak

rates from 4 percent to 8 percent per day at a pressure differential of 14 inches of water. Although the pressure differential in this case will be much lower than this value, it has been assumed that a shield building inleakage flow of 500 SCFM for the single failure scenario of one EGTS train and 1637 SCFM for the PCO failure case exists throughout the 30-day period. The inleakage flow for the PCO failure case which results in one pressure control train in full exhaust to the shield building exhaust stack (while the other train remains functional) was conservatively assumed to be greater since the resulting annulus pressure is more negative than the original single failure scenario of one EGTS train. This inleakage flow includes leakage past ventilation system primary containment isolation valves assuming that a single isolation valve fails in the open position.

Emergency Gas Treatment System Filter Efficiencies

The EGTS takes suction from the annulus, and the exhaust gases are drawn through two banks of impregnated charcoal filters in series. Sufficient filter capacity is provided to contain all iodines, inorganic, organic, and particulate available for leakage. Since the air in the annulus is dry, filter efficiencies of greater than 99 percent are attainable. Tests reported in ORNL-NSIC-4 (Reference 6) have demonstrated that inorganic halogen removal efficiencies greater than 99.99 percent can be expected with low relative humidity.

For this analysis, the overall filter system efficiency for the two filter banks of 99 percent was assumed for all forms of iodine. In addition, the analysis assumes a 30 cfm leakage through the decay heat cooldown valves which results in a combined effective filter efficiency of 98.2% for all forms of iodine.

Discussion of Results

The gamma, beta, and thyroid doses for the LOCA at the exclusion area boundary and the low population zone are given in Table 15.5.3-4 for the analyses presented in this section. The dose limits for this accident are defined in 10 CFR 100 (25 rem whole body dose and 300 rem thyroid). Even for this conservative analysis, the doses are well within the 10 CFR 100 guidelines.

The major factor in the effectiveness of the secondary containment is its inherent capability to collect the containment leakage for filtration of the radioactive iodine prior to release to the environment. This effect is greatly enhanced by the recirculation feature of the air handling systems, which forces repeated filtration passes for the major fraction of the primary containment leakage before release to the environment.

Loss of Coolant Accident - Control Room Operator Doses

In accordance with General Design Criterion 19, the control room ventilation system and shielding have been designed to limit whole body dose during an accident period to 5 rem. Thyroid dose is limited to 30 rem and beta skin dose should not exceed 30 rem.

The doses to personnel during a postaccident period originate from several different sources. Exposure within the control room may result from airborne radioactive nuclides entering the control room via the ventilation system. In addition, personnel are exposed to direct gamma radiation penetrating the control room walls, floor, and roof from:

1. Radioactivity within the primary containment atmosphere.

2. Radioactivity released from containment which may have entered adjacent structures.

3. Radioactivity released from containment which passes above the control room roof.

Further exposure of control room personnel to radiation may occur during ingress to the control room from exclusion area boundary and during egress from the control room to site boundary.

In the event of a radioactive release incident, the control room will be isolated automatically by a safety injection system signal and/or by radiation signal from beta detectors located in the air intake stream common to the air intake ports at either end of the Control Building. These redundant signals are routed to redundant controls which actuate air-operated isolation dampers. Operation of the emergency pressurizing fans with inline HEPA filters and charcoal adsorbers is also initiated by these signals. Simultaneously, 4000 cfm of recirculation and makeup air is rerouted automatically through the HEPA filters and charcoal adsorbers. Approximately 200 to 1000 cfm of outside air bypasses the intake isolation dampers through a flow controlled duct routed to the emergency recirculation system upstream of the HEPA filters and charcoal adsorbers. This flow of outside air provides the control room with a slight positive pressure relative to the atmosphere outside and to surrounding structures. Isolation dampers located in each intake line may be selectively closed by control room personnel. The selection between the two would be based on the objective of admitting a minimum of airborne activity to the control room via the makeup airflow. The control room ventilation flow system is shown in Figure 9.4.1-1. The equivalent of 51 cfm of unfiltered outside air enters through the main control room doors as a result of personnel entering or leaving and through leakage from ducts and dampers. To evaluate the ability of the control room to meet the requirements of General Design Criterion 19, a time dependent model of the control room was developed. In this model, the outside air concentration enters the control room via the isolation damper bypass line and the HEPA filters and charcoal adsorbers. The concentration in the room is reduced by decay, leakage out, and by recirculation through the HEPA filters and charcoal adsorbers. Credit for filtration is taken during two passes through the charcoal adsorbers. Using these assumptions the following equations for the rate or change of the control room concentrations are obtained:

$$\frac{dM}{dt} = C_o(1 - K_1)\, L/V - L/V\, M - \frac{R_c}{V} M - \lambda M \qquad (1)$$

$$\frac{dN}{dt} = \frac{R_c}{V}(1 - K_2)\, M - L/V\, N - \lambda N \qquad (2)$$

$$C(t) = M(t) + N(t) \qquad (3)$$

Where

M(t) = Once filtered time dependent concentration

N(t) = Twice filtered time dependent concentration

C(t) = Total time dependent concentration in control room

C_o = Concentration of isotope entering air intake

K_1 = Effective filter efficiency for a particular isotope during first pass (corrected for bypass leakage)

K_2 = Filter efficiency for a particular isotope during second pass

L = Flow rate of outside air into control room and leakage out of control room

R_c = Recirculated air flow rate through filters

λ = Decay constant

V = Control room free volume

These equations are readily solvable if C_o is constant or a simple function of time during a time interval. Since C_o consists of a number of terms involving exponentials, it was assumed to be constant during particular time intervals corresponding to the average concentration during each interval as described below. Solving equations (1), (2), and (3) yields:

$$C(t) = \left[\frac{(1-K_1)\,(1-K_2)C_o}{W_m V}\right]\left[\frac{L}{(1-K_2)\,(1-e^{-W_m t})} + \frac{R_c L}{W_n V}\,(1-e^{-W_n t}) - L\,(1-e\ -\ e^{-W_m t})\right] \quad (4)$$

Where

$$W_m = \frac{(L + R_c + \lambda V)}{V}$$

$$W_n = \frac{(L + \lambda V)}{V}$$

The value of C_o used in equation (4) is determined as follows:

$$C_{oi} = \frac{(X/Q)_i}{t_{(i+1)} - t_i}\int_{t_i}^{t_{(i+1)}} R\,dt \quad (5)$$

Where

C_{oi} = Average concentration of activity outside control room during <u>ith</u> time period (Ci/m^3)

$(X/Q)_i$ = Atmospheric dilution factor (sec/m^3) during the <u>ith</u> time period

R = Time dependent release rate of activity from containment (Ci/sec)

The atmospheric dilution factors were determined using the accumulated meteorological data on wind speed, direction, and duration of occurrence obtained from the Sequoyah plant site applied to a building wake dilution model. The dilution factors are calculated by the ARCON96 methodology (Reference 11). The values used are given in Table 15.5.3-6.

Equation (4) is used to determine the concentration at any time within a time period and upon integrating and dividing by the time interval gives the average concentration during the time interval due to inflow of radioactivity with outside air as shown:

$$\overline{C_i} = \frac{\int_O^T C_i(t)dt}{T - O}$$

Where

T	= t- t_{i-1}
t	= Time after accident
t_{i-1}	= Time at end of previous time period

Further contributions to the concentration during time period are due to the concentrations remaining from prior time periods. These contributions are obtained from the following equations:

$$C_{R(i + j)} = M_{R(i + j)} + N_{R(i + j)} \quad (7)$$

$$\frac{dM_{R(i+j)}}{dt} = -(L/V + R_c/V + \lambda)\, M_{R(i+j)} \quad (8)$$

$$\frac{dN_{R(i+j)}}{dt} = R_c/V\,(1-K_2)\, M_{R(i+j)} -(L/V + \lambda)\, N_{R(i+j)} \quad (9)$$

With initial conditions:

$M_{R(i-j)}$ (O) = $M_{R0(i)}$ = (Once filtered concentration at the end of the ith time period.)

$N_{R(i+j)}$ (O)= $N_{R0(i)}$ = (Twice filtered concentration at end of the ith time period.)

Solving equations (8) and (9) and substituting certain initial condition relations equation (7) becomes:

$$C_{R(i + j)} = C_{Ro(i)} e^{-W_n(t - \tau)} - M_{RO(i)}\, K_2 \;\; e^{-W_n(t - \tau_i)} - e^{-W_m(t - \tau_i)} \quad (10)$$

Integrating equation (10) for each of the prior time periods gives the contribution from these time periods to the present time period. The average concentration is determined for these contributions using the method of equation (6).

Filter efficiencies of 95 percent for elemental and particulate iodine and 95 percent for organic iodine were deemed appropriate for the first filter pass. Since the concentration of iodine in the Main Control Room is much reduced as a result of this filtration, the efficiencies were reduced for the second pass to 70 percent for elemental and particulate iodine, and 70 percent for organic iodine.

To account for the unfiltered inleakage, 51 cfm were added to the make-up flow (L in equation 1) of 200 cfm, and the filter factor for the first pass was decreased to an equivalent value of 75.7 percent for elemental and particulate iodine, and 75.7 percent for organic iodine. For a 1000 cfm makeup flow, the filter-factor for the first pass was decreased to equivalent values of 90.4 percent for both species. In both cases, the filter efficiencies for the second pass are not affected by the unfiltered inleakage.

The filter efficiency for noble gases was taken as zero for all cases.

The above equations were incorporated into a computer program together with appropriate equations for computing gamma dose, beta dose, and thyroid dose using these average nuclide concentrations and time periods. The whole body gamma dose calculation consists of an incremental volume summation of a point kernel over the control room volume. The principal gammas of each isotope are used to compute the dose from each isotope. The dose computations for beta activity were based on a semi-infinite cloud model. Doses to thyroid were based on activity to dose conversion factors and the breathing rates presented in Table 15A-1. (The equations and various data are given below.) The doses from these calculations are presented in Table 15.5.3-7. Gamma dose contributions from shine through the control room roof due to the external cloud and from shine through the control room walls from adjacent structures and from containment are computed using an incremental volume summation of a point kernel which includes buildup factors for the concrete shielding. For the calculation of shine through the control room roof, an atmospheric, rectangular volume several thousand feet in height and several control room widths was used. The control room roof is a 2-foot, 3-inch-thick concrete slab and is the only shielding considered in this calculation. The average isotope concentrations at the control bay for each time period were used as the source concentrations. For the shine from adjacent structures the shielding consists of the 3-foot-thick (5-foot in certain areas) control room walls. The doses are calculated similarly to the shine dose through the roof. The average isotope concentrations at the control bay intake for each time period are also used for these calculations.

The shine from the spreading room below the control room is also computed in the same manner as adjacent structures. The shielding for this computation consists of the 8 inch thick concrete floor. The summation of the incremental elements is performed over the volume of each room or structure of interest.

In addition to the dose due to shine from surrounding structures and from the passing cloud, the shine from the Reactor Containment Building also contributes to the deep dose equivalent to personnel. This contribution is computed in the same manner as the methods used above. Due to the location of the Auxiliary Building between the Reactor Buildings and the control room and the thicker control room Auxiliary Building wall near the roof, the minimum ray path through concrete from the containment into the control room below 10 feet above the control floor, is 8 feet. All nuclides released to containment are assumed uniformly distributed and their time dependent concentrations were used to compute dose. The dose computed from this source is negligible and is not included in Table 15.5.3-7.

Several doors penetrate the control room walls, and the dose at these areas would be larger than the doses calculated as described above. The potential shine at these doors and at other penetrations has been evaluated. As a result, hollow steel doors filled with No. 12 lead shot have been incorporated into the design of the shield wall between the control room and the turbine building. These doors will provide shielding comparable to the concrete walls. Shine through other penetrations was found to be negligible.

Another contribution to the total dose of control room personnel is the exposure incurred during ingress from and egress to the exclusion area boundary. The doses to the Control Room personnel were computed based on the following assumptions:

1. Ten minutes are required to leave the control room and arrive at car or vice versa.

2. Five minutes are required to drive along the access road.

3. The radioisotope concentrations at the control room arrival or departure point are those computed for the control bay air intakes.

4. The concentration as a function of distance along the access road was determined from the atmospheric diffusion model.

5. One one-way trip first day, one round-trip/day 2nd through 30th day.

6. Other parameters used in the calculation were taken from Murphy and Campe[10]. They are:

1)	Occupancy Adjustment Factors:	100 percent occupancy 0-24 hours 60 percent occupancy 1-4 days 40 percent occupancy 4-30 days
2)	Wind Speed Factors:	5th percentile wind speed 0-8 hours 10th percentile wind speed 8-24 hours 20th percentile wind speed 1-4 days 40th percentile wind speed 4-30 days

It was also assumed that initially the make-up air intake would be through the vent admitting the highest radioisotope concentration, but that the Main Control Room personnel could switch intake vents 8 hours after the accident in order to admit a minimum of Airborne Activity to the Main Control Room via the make-up airflow.

The whole body and thyroid doses from the radiation sources discussed above are presented in Table 15.5.3-7. The dose to whole body is below the General Design Criterion 19 limit of 5 rem for control room personnel, and the thyroid dose is below the limit of 300 rem. The total calculated doses are within acceptable limits.

Dose Equations, Data, and Assumptions

The dose from gamma radiation originating within the control room is given by:

$$D\gamma = 1.696 \text{ X } 10^4 \sum_{j=1}^{\alpha} \left[\sum_{i=1}^{\beta} Q_{ij} \left(\sum_{k=1}^{\gamma} \left\{E_{ik}\, f_{ik} \frac{\mu_e}{(p)_{ki}} \sum_{m=1}^{\varepsilon} \sum_{n=1}^{\omega} \sum_{q=1}^{\sigma} \right.\right.\right.$$

$$\left.\left.\left.\frac{e^{-\mu ak \sqrt{x_m^2 + y_n^2 + z_q^2}}}{(x_m^2 + y_n^2 + z_q^2)} \bullet \Delta x \Delta y \Delta z\right\}\right)\right] \; (t_j - t_{j-1}) \qquad (11)$$

Where

- D_γ = Absorbed dose in flesh in mrads
- Q_{ij} = Concentration of isotope i during time period j in curies/m^3
- E_{ik} = Energy of gamma k isotope i in MeV
- f_{ik} = Number of the k gammas of isotope i given off per disintegration
- $\frac{\mu_e}{(p)_{ki}}$ = Mass attenuation coefficient for flesh determined at the energy of the kth gamma of isotope i in cm^2/gram.
- $\_\mu ak$ = Linear attenuation coefficient for air determined at the energy of the kth gamma of isotope i in inverse meters.
- x,y,z = Coordinate distances from the dose point to the source volume element (m,n,q) in meters.
- t_{j-l}, t_j = Times at the beginning and end of time period j in hours.

This equation may also be used for shine through concrete shields by the inclusion of two additional factors within the innermost summation.
These factors are:

1. $\exp(-\mu_{ck}\, t_c \sec \Theta)$
2. $B_c\,(\mu_{ck}\, t_c \sec \Theta)$

Where

μ_{ck} = The linear attenuation coefficient of concrete determined at the energy of the kth gamma of isotope i in inverse meters

t_c = Concrete shield thickness

B_c = Buildup factor for concrete

Θ = Angle between a vector normal to the shield and a vector from the dose point to the source point

Terms (1) and (2) are the linear attenuation exponential and the buildup factors for concrete respectively.

The dose from beta radiation is given by the semi-infinite cloud immersion dose:

$$D_B = (0.230)\ (X/Q)\left[\sum_{i=1}^{a} Q_i \left(\sum_{k=1}^{\gamma} E_{ik}\, f_{ik}\right)\right] \qquad (12)$$

Where

D_B = Dose due to beta in rem

X/Q = Atmospheric dispersion factor during time period in sec/m^3

Q_i = Accumulated activity release of isotope i during time period

E_{ik} = Average energy of beta k of isotope i

f_{ik} = Number of k betas of isotope i per disintegration

For beta dose in the control room equation (12) becomes:

$$D_B = (0.230) \sum_{j=1}^{\delta} \sum_{i=1}^{\alpha} \overline{C_{ij}} \sum_{k=1}^{\beta} E_{ik}\, f_{ik}\ (t_j - t_{j-1})$$

Where

$\overline{C}_{ij}$ = Average concentration of isotope i during time period j.

Inhalation Dose (Thyroid)

The inhalation dose for a given period of time has the general form:

$$D_i = (X/Q)\,(B)\left[\sum_{i=1}^{n} (Q_{ij})\,(DCF_i)\right](t_j - t_{(j-i)}) \qquad (13)$$

Where

D_i	= Thyroid inhalation dose, rem
X/Q	= Site dispersion factor during time period, sec/m^3
B	= Breathing rate during time period, m^3/hr
Q_{ij}	= Average activity release rate during time period j of iodine isotope i
DCF_i	= Dose conversion factor for iodine isotope i, rem/microcurie inhaled
t_j	= Total time at end of period j, hours

For inhalation dose within the control room equation (13) becomes:

$$D_i = (B)\left[\sum_{i=1}^{n} \overline{C}_{ij}\,(DCF_i)\right](t_j - t_{(j-i)}) \qquad (14)$$

In this expression $\overline{C}_{ij}$, the average concentration of isotope i during time period j, has replaced the following factor:

$(X/Q)\ Q_{ij}$

The C_{ij}'s are those determined by equations (4) and (6).

The assumed breathing rates, B, are shown on Table 15A-1.

Environmental Consequences Due to the Operation of the Postaccident Sampling Facility

Section 9.5.10 discusses the Postaccident Sampling Facility (PASF) at Sequoyah Nuclear Plant (SQN). The "worst case" offsite doses resulting from the operation of the PASF are calculated in this section. NUREG-0737 recommends the assumption of a postaccident release of radioactivity equivalent to that described in Regulatory Guide 1.4 (i.e., 50 percent of the core radioiodine, 100 percent of the core noble gas inventory, and 1 percent of the core solids are contained in the primary coolant). For this "worst case" analysis, the primary system remains intact and pressurized; consequently, the noble gases will stay in the reactor coolant and, in addition, there is no dilution by the Emergency Core Cooling System (ECCS) which would occur during a LOCA.

The assumptions used in determining the offsite doses are listed below:

1. The initial reactor coolant sample is drawn one hour postaccident, followed by daily samples for the next seven days. After the first week, one sample a week is taken. The offsite doses are based on the samples taken during the first 30 days after the accident.

2. A core release of 100 percent of the noble gases and 50 percent of the iodines is assumed to be mixed with the reactor coolant (94,350 gallons).

3. The postaccident sample collector drain tank is assumed to accumulate 60 gallons of water during each sampling mission. Twenty of the 60 gallons are reactor coolant and the rest are demineralized flush water.

4. All of the noble gases contained in the reactor coolant that are held in the sample collector drain tank are liberated to the tank's air space and exhausted to the atmosphere.

5. The vapor-water partition coefficients of the iodines in the sample collector drain tank are based on Reference 12.

6. All of the iodine liberated to the tank's air space are exhausted to the atmosphere through charcoal filters.

7. A charcoal filter iodine removal efficiency of 95 percent is used for both the organic and inorganic iodines.

8. Two-hour atmospheric dilution factors from FSAR Table 15A-2 are used for each release since each release occurs over short periods of time.

9. Radioactivity decay of the noble gases and iodines is taken into account for the reactor coolant only; there is no holdup in the sample collector drain tank assumed.

Discussion of Results

The offsite doses at the exclusion area boundary resulting from the operation of PASF for this "worst-case" evaluation are 15 rem deep dose equivalent, 9.4 rem beta, and 16.6 rem thyroid; at the low population zone, they are 1.8 rem deep dose equivalent, 1.2 rem beta, and 2.2 rem thyroid. It should

be noted that doses this large cannot occur simultaneously with the doses calculated for a Regulatory Guide 1.4 LOCA. The post-LOCA operation of the PASF would result in much lower offsite doses since most of the noble gases and other volatile nuclides would be released in the primary containment before they could get into the sample collector drain tank, FSAR 15.5.8, Reference 18. The doses resulting from the operation of the PASF are within the limits prescribed in 10 CFR 100.

Plant Accessibility Post LOCA

The Sequoyah Nuclear Plant was designed so that access is generally not required outside the main control room for 30 days after an accident. Access to areas within the auxiliary building and structures away from the main complex for the performance of specified tasks are examined individually. Approval of such missions is based on control room personnel performing the required task and not exceeding the limit of 10CFR50, Appendix A, General Design Criterion 19. SQN-DC-V-21.0 (Reference 17) addresses the design basis post accident mission regulatory requirements, provides the basis for determining which design basis accidents would require a post accident mission following a design basis event, and establishes the criteria used to determine when a post accident mission dose evaluation is required outside the main control room.

A study was performed to evaluate the Auxiliary Building shielding design to determine accessibility after an accident and to be used to calculate doses to equipment in the Auxiliary Building subsequent to an accident.

The study assumed the design LOCA with subsequent recirculation of contaminated water from the containment sump through the residual heat removal (RHR), containment spray, and safety injection systems. The source terms used for this accident are the Regulatory Guide 1.4 sources diluted by the full volume of injection water available plus the melted ice.

The dose rates through the Reactor Shield Building from activity released into the containment atmosphere were also calculated.

The sources of available water are:

Refueling Water Storage Tank	340,000 gallons
4 SIS Accumulators	27,676 gallons (negligible)
Ice Condenser	357,314 gallons

The reactor coolant volume is 12,612 cubic feet or 94,249 gallons; therefore, the total volume of water is 829,064 gallons.

For source volumes containing contaminated liquid, the activity in the liquid was assumed to consist of:

1. 100 percent of the noble gases.
2. 50 percent of the halogens with noble gas daughter products.
3. One percent of the solid fission products.

Dose rates were calculated using these sets separately as the source term. The results of this analysis are reported as the sum of these separate dose rates. Source terms used in this analysis are provided in FSAR Table 15.5.3-8. For source volume containing gaseous activity, source terms were calculated for 100 percent of the noble gases and 25 percent of the halogens. Post LOCA radiation doses in the Reactor Building are addressed in FSAR 15.5.8., Reference 17.

Flow diagrams, equipment, and field-routed piping layouts were reviewed to determine the flow paths which might be used after an accident and to determine the volume and physical locations of contaminated fluids in the Auxiliary Building. The layout of the shield walls and equipment within the rooms were conservatively modeled and source terms were calculated at various times after an accident. Dose rates were then calculated at several positions in the Auxiliary Building with respect to the contained sources and at various times after an accident. The locations where dose rates were calculated were chosen to conservatively calculate the dose rates in corridors outside equipment cubicles, in adjacent rooms, and within the equipment cubicles. The source volume in each pump room was modeled as a volume of water in a rectangular box equivalent to the volume of water contained in the pump and piping in that room. The smallest wall thickness of the pipes carrying significant volumes of contaminated liquid was used as an iron cladding around the source. Heat exchangers were modeled as equivalent volume rectangular boxes with a square cross-section and with an iron cladding equal to the shell thickness. Tanks are modeled similarly to heat exchangers. All of the piping in a pipe chase or pipe shaft was modeled as a single equivalent volume of water in a rectangular box extending the length of the pipe chase or shaft with the minimum pipe wall thickness as an iron cladding around the source. Post LOCA radiation doses for the Auxiliary Building are addressed in FSAR 15.5.8., Reference 17.

Of the vital areas, none is near an area containing postaccident sources. The discussion of the exposure of control room operators is therefore still valid without modification. The Technical Support Center (TSC) is located in the Control Building on the same floor as the control room, hence within the habitability zone. The exposure in the TSC should therefore be the same as in the control room. Table 15.5.3-7 provides the integrated 30-day operator dose. The continuous occupancy exposure rate in those two areas is less than the 15 mrem per hour limit suggested in NUREG 0578. Note that the calculated dose in the Control Building habitability zone is due almost entirely to airborne contamination of the zone and neighboring spaces due to the introduction of filtered outside air for maintaining a pressurized condition in the habitability zone. The contribution to the operator whole-body dose from the plume released at the containment vent is negligible.

The shutdown board room may require occupancy briefly to accomplish a single control function. Access restriction would be due only to airborne activity. Analyses shows that required access can be obtained with dose consequences within the limits of GDC19. TVA has also determined that it may be necessary to perform certain actions in the auxiliary building following a LOCA. Analyses have shown that required access can be obtained for all missions currently examined with dose consequences within the limits of GDC 19. Future missions will be analyzed as the need to perform such missions are identified. In no event will a mission be approved which exceeds the limits of GDC 19. FSAR Section 15.5.8, Reference 17, addresses the GDC 19 analyses and plant procedures associated with these analyses.

The RSGs have no effect on the assumptions and inputs used in the LOCA environmental consequences analyses. Therefore, the conclusions of the existing analyses are equally applicable to Sequoyah Unit 1 and Unit 2 with the RSGs.

15.5.4 Environmental Consequences of a Postulated Steam Line Break

The postulated accidents involving release of steam from the secondary system will not result in a release of radioactivity unless there is leakage from the Reactor Coolant System to the secondary system in the steam generator. A conservative analysis of the potential offsite doses resulting from this accident is presented assuming steam generator leakage prior to the postulated accident for a time sufficient to establish equilibrium specific activity levels in the secondary system. Parameters used in the analysis are listed in Table 15.5.4-1.

The following conservative assumptions and parameters are used to calculate the activity releases and offsite doses for the postulated steam line break.

1. Prior to the accident, an equilibrium activity of fission products exists in the primary and the secondary systems due to a primary to secondary leakage in steam generators.

2. Offsite power is lost, main steam condensers are not available for steam dump.

3. Eight hours after the accident, the residual heat removal system starts operation to cool down the plant.

4. The primary to secondary leakage is evenly distributed in steam generators.

5. After eight hours following the accident, no steam and activity are released to the environment.

6. No air ejector release and no steam generator blowdown during the accident.

7. Initial primary coolant activity (iodine and noble gas) is consistent with the model discussed in Appendix 15D. This model is consistent with Technical Specification limits on primary coolant activity limits.

8. The analysis assumes an iodine spike with two separate cases considered. For one case there is assumed to be a pre-existing iodine spike. For the second case the initial primary coolant iodine concentration is at the limit set in the Technical Specifications for equilibrium operation and an iodine spike is assumed to be initiated by the reactor trip associated with the event. The iodine spiking models are described in Appendix 15D.

9. Initial secondary coolant activity (iodine) is consistent with the model discussed in Appendix 15D. This model is consistent with Technical Specification limits on primary coolant activity limits. There is no noble gas activity in the secondary coolant.

10. The iodine partition factor is $\frac{\text{amount of iodine/unit mass steam}}{\text{amount of iodine/unit mass liquid}} = 0.01$ in the good steam generators

11. During the postulated accident, iodine transferred to the secondary side in the three good steam generators is uniformly mixed with the water in the steam generators.

12. In the affected steam generator, all the water boils off and releases through the break immediately after the accident. The partition factor for the iodine released is assumed to be 1.0. After this initial release, further iodine is released due to the primary to secondary leakage in the affected steam generator. A partition factor of 1.0 is also assumed for this iodine release.

13. The primary pressure remains constant at 2235 psig for 0-2 hours and decreases linearly to atmospheric from 2235 psig during the period of 2-8 hours.

14. The 0-2 and 2-8 hour atmospheric diffusion factors given in Appendix 15A and the 0-8 hour breathing rate of 3.47×10^{-4} m^3/sec are applicable.

The resulting doses for the case with the accident-initiated iodine spike are:

	Thyroid	Whole Body	Skin
Exclusion Area Boundary	5.4 rem	0.073 rem	0.11 rem
Low Population Zone	0.69 rem	0.01 rem	0.014 rem
Control Room	0.22 rem	.046 rem	0.009 rem

These doses are well within the limits of 25 rem whole body and 300 rem thyroid defined in 10 CFR 100 and the control room dose limits of 5 rem whole body, 30 rem thyroid, and 30 rem skin defined in Section 6.4 of the Standard Review Plan.

[For information only, the TEDE doses are 0.25 rem at the EAB, 0.032 at the LPZ and 0.053 rem in the control room.]

For the case with the pre-existing iodine spike the doses are:

	Thyroid	Whole Body	Skin
Exclusion Area Boundary	5.3 rem	0.061 rem	0.09 rem
Low Population Zone	0.67 rem	0.008 rem	0.011 rem
Control Room	0.20 rem	0.037 rem	0.008 rem

These doses are well within the limits of 25 rem whole body and 300 rem thyroid defined in 10 CFR 100 and the control room dose limits of 5 rem whole body, 30 rem thyroid, and 30 rem skin defined in Section 6.4 of the Standard Review Plan.

[For information only, the TEDE doses are 0.24 rem at the EAB, 0.03 at the LPZ and 0.043 rem in the control room.]

The parameters that effect the environmental consequences of a steam line break are not adversely affected by the steam generator. Therefore, all acceptance criteria continue to be met on Sequoyah Unit 1 and Unit 2 with the RSGs.

15.5.5 Environmental Consequences of a Postulated Steam Generator Tube Rupture

The postulated accidents involving release of steam from the secondary system will not result in a release of radioactivity unless there is leakage from the Reactor Coolant System to the secondary system in the steam generators. A conservative analysis of the postulated steam generator tube rupture assumes the loss of offsite power and hence involves the release of steam from the secondary system. A conservative analysis of the potential offsite doses resulting from this accident is presented assuming steam generator leakage prior to the postulated accident for a time sufficient to establish equilibrium specific activity levels in the secondary system. Parameters used in the analysis are listed in Table 15.5.5-1.

The following conservative assumptions and parameters are used to calculate the activity releases and offsite doses for the postulated steam generator tube rupture:

1. Prior to the accident, an equilibrium activity of fission products exists in the primary and the secondary systems due to primary to secondary leakage in steam generators.

2. Offsite power is lost, main steam condensers are not available for steam dump.

3. Eight hours after the accident, the residual heat removal system starts operation to cool down the plant.

4. The primary to secondary leakage is evenly distributed in the steam generators.

5. After eight hours following the accident, no steam and activity are released to the environment.

6. No air ejector release and no steam generator blowdown during the accident.

7. Initial primary coolant activity (iodine and noble gas) is consistent with the model discussed in Appendix 15D. This model is consistent with Technical Specification limits on primary coolant activity limits.

8. The analysis assumes an iodine spike with two separate cases considered. For one case there is assumed to be a pre-existing iodine spike. For the second case the initial primary coolant iodine concentration is at the limit set in the Technical Specifications for equilibrium operation and an iodine spike is assumed to be initiated by the reactor trip associated with the event. The iodine spiking models are described in Appendix 15D.

9. Initial secondary coolant activity (iodine) is consistent with the model discussed in Appendix 15D. This model is consistent with Technical Specification limits on primary coolant activity limits. There is no noble gas activity in the secondary coolant.

10. The iodine in the flashed portion of the break flow entering the ruptured steam generator is assumed to be released directly to the environment.

11. With the exception of the iodine in the flashed portion of the break flow entering the ruptured steam generator, the iodine entering the secondary side is assumed to uniformly mix in the steam generator water.

12. The iodine partition factor is $\frac{\text{amount of iodine/unit mass steam}}{\text{amount of iodine/unit mass liquid}} = 0.01$ in the steam generators.

13. Steam release to atmosphere and the associated activity release from the nondefective steam generators is terminated at eight hours after the accident when the residual heat removal system takes over in cooling down the plant.

14. Thirty minutes after the accident, the pressure between the defective steam generator and the primary system is equalized. The defective unit is isolated. No steam and fission product activities are released from the defective steam generator thereafter.

15. The 0-2 and 2-8 hour atmospheric diffusion factors given in Appendix 15A and the 0-8 hour breathing rate of 3.47×10^{-4} m^3/sec are applicable.

The resulting doses for the case with the accident-initiated iodine spike are:

	Thyroid	Whole Body	Skin
Exclusion Area Boundary	18.5 rem	1.6 rem	2.8 rem
Low Population Zone	2.3 rem	0.19 rem	0.4 rem

These doses are well within the limits of 25 rem whole body and 300 rem thyroid defined in 10 CFR 100.

[For information only, the TEDE doses are 2.2 rem at the EAB, 0.26 at the LPZ.]

For the case with the pre-existing iodine spike the doses are:

	Thyroid	Whole Body	Skin
Exclusion Area Boundary	41.1 rem	1.4 rem	2.6 rem
Low Population Zone	5.0 rem	0.16 rem	0.4 rem

These doses are well within the limits of 25 rem whole body and 300 rem thyroid defined in 10 CFR 100.

[For information only, the TEDE doses are 2.7 rem at the EAB, 0.32 at the LPZ.]

The safety evaluation for the replacement steam generators concludes that parameters important to the consequences of this event are not adversely affected by the RSG.

The doses given above are based on operators stopping the steam release from the ruptured steam generator by 30 minutes. Should operators take 45 minutes to stop the steam release from the ruptured steam generator, then the maximum offsite doses will be 62 rem to the thyroid and 2.4 rem whole body.

15.5.6 Environmental Consequences of a Postulated Fuel Handling Accident

Two analyses of a postulated fuel handling accident are performed: 1) an event occurring in the Auxiliary Building and 2) an event occurring inside the primary containment. The analyses use methodology from Regulatory Guide 1.183 (Reference 13) associated with the use of alternative source term modeling and do not use the dose calculation methodology presented in Appendix 15A. The parameters used for each of these analyses are listed in Table 15.5.6-1.

The basic analysis assumptions for the fuel handling accident in the Auxiliary Building are:

1. The accident occurs 100 hours after plant shutdown. Radioactive decay of the fission product inventory during the interval between shutdown and placement of the first spent fuel assembly into the spent fuel pool is taken into account.

2. All rods in one assembly rupture.

3. The assembly damaged is the highest powered assembly in the core region to be discharged. The values for individual fission product inventories in the damaged assembly are calculated assuming full power operation at the end of core life immediately preceding shutdown. A radial peaking factor of 1.70 is used.

4. The maximum fuel rod pressurization is 1200 psi.

5. The minimum water depth between the top of the damaged fuel rods and the spent fuel pool surface is 23 feet.

6. All of the gap activity in the damaged rods is released to the spent fuel pool and consists of 5 percent of the total noble gases other than Kr-85, 10 percent of the Kr-85, 5 percent of the total radioactive iodine other than I-131, and 8 percent of the I-131, in the rods at the time of the accident.

7. Noble gases released to the spent fuel pool do not experience retention in the water pool.

8. The iodine gap inventory is composed of inorganic species (99.85 percent) and organic species (0.15 percent).

9. The spent fuel pool decontamination factor for iodine is 200.

10. No credit is taken for natural decay either due to holdup in the Auxiliary Building or after the activity has been released to the atmosphere.

11. The activity released from the pool (iodine and noble gas) is all assumed to be released to the environment over a two-hour period.

If a fuel handling accident should occur inside the primary containment, there are several configurations the plant could be in. The Reactor Building Purge Ventilation System (RBPVS) could be operating, which discharges through the shield building vent. Any number of penetrations and hatches could be open, which could result in a number of different release points. A higher atmospheric dispersion factor will result in a higher dose. The Auxiliary Building vent has the highest atmospheric dispersion factor of all other potential release points. This is the same release point assumed in the fuel handling accident outside containment. Therefore the model for the fuel handling accident inside containment does not differ from that given above.

Doses were determined at the exclusion area boundary (EAB) and at the low population zone boundary (LZP) for the two-hour interval over which releases are assumed to take place and in the control room for an extended period of time after termination of releases in order to address the continued presence of activity in the control room atmosphere.

The accident doses were calculated using the dose model consistent with the use of the alternate source term methodology (Regulatory Guide 1.183) and are reported as Total Effective Dose Equivalent (TEDE).

The TEDE dose is the sum of the Committed Effective Dose Equivalent (CEDE) and the Effective Dose Equivalent (EDE) which are calculated using the following equations:

$$D_{CEDE} = (A)(X/Q)(BR)(DCF_{CEDE})$$

$$D_{EDE} = (A)(X/Q)(DCF_{EDE})$$

where: A = Activity of the nuclide released (Ci)
X/Q = atmospheric dispersion factor (sec/m^3)
BR = breathing rate (m^3/sec)
DCF_{CEDE} = CEDE dose conversion factor (rem/Ci inhaled)
DCF_{EDE} = dose conversion factor (rem-m^3/Ci-s)

	FHA in Auxiliary Building	FHA inside Primary Containment
Exclusion Area Boundary	2.8 rem TEDE	2.8 rem TEDE
Low Population Zone Outer Boundary	0.5 rem TEDE	0.5 rem TEDE
Control Room	0.6 rem TEDE	0.6 rem TEDE

These doses are within the dose acceptance limits of 6.3 rem TEDE for offsite doses (Regulatory Guide 1.183) and 5.0 rem TEDE for the control room dose (GDC 19) associated with the use of alternate source term methodology.

15.5.7 Environmental Consequences of a Postulated Rod Ejection Accident

The consequences of a postulated rod ejection accident are bounded by the results of the loss-of-coolant accident analysis evaluated in Section 15.5.3.

TABLE 15.5.1-1

PARAMETERS USED IN LOSS OF A.C. POWER ANALYSIS

Steam generator tube leak rate during accident	150 gpd per SG
Offsite power	Lost
Reactor Coolant Activity	
Noble Gas Activity Prior to Accident	See Appendix 15D
Iodine Activity Prior to Accident (without spike)	See Appendix 15D
Iodine Activity (pre-existing spike)	21 μCi/g D.E. I-131 (see Appendix 15D)
Equilibrium Iodine Appearance Rates	See Appendix 15D
Increase in Iodine Appearance Rate Increase Due to the Accident-Initiated Spike	500 times equilibrium rates
Duration of Accident-Initiated Spike	1 hour
Secondary Coolant Activity	
Iodine Activity Prior to Accident	0.1 μCi/g D.E. I-131 (see Appendix 15D)
Noble Gas Activity	None
Iodine Chemical Form	Elemental
Iodine partition factor in steam generator during accident	0.01
Duration of plant cooldown by Secondary System after accident	8 hr
Steam release from 4 steam generators	487,000 lb (0-2 hr) 1,090,000 lb (2-8 hr)
Meteorology	Accident (see Appendix 15A)

(1) Based on operating experience of Westinghouse PWR's.

TABLE 15.5.2-1

PARAMETERS USED IN WASTE GAS DECAY TANK RUPTURE ANALYSIS

Plant load factor	1.0
Fuel defects	1 percent
Activity released from GWPS	Noble gas inventory of one Reactor Coolant System volume[(1)]
Stripping fraction in volume control tank	1.0
Iodine partition factor in volume control tank	0.01
Time of accident	Immediately after shutdown at end of equilibrium core cycle
Meteorology	Accident (see Appendix 15A)

(1) Iodine releases are based on plant operating procedures (degassing of volume control tank every 3 hours for 21 hours after shutdown). At 21 hours after shutdown the summation of the product of the iodine isotopic inventories times their respective dose conversion factor is a maximum.

TABLE 15.5.2-2

WASTE GAS DECAY TANK INVENTORY (one unit)

(Regulatory Guide 1.24 (1972) Analysis)

Isotope	Activity (Curies)
Xe-133	8.46×10^{4}
Xe-133m	9.35×10^{2}
Xe-135	2.13×10^{3}
Xe-135m	4.80×10^{1}
Xe-138	1.70×10^{2}
Kr-85	4.30×10^{3}
Kr-85m	5.83×10^{2}
Kr-87	3.25×10^{2}
Kr-88	1.02×10^{3}
I-131	5.49×10^{-2}
I-132	4.00×10^{-5}
I-133	4.73×10^{-2}
I-134	- -
I-135	7.09×10^{-3}

TABLE 15.5.3-1 (Sheet 1)

PARAMETERS USED IN LOCA ANALYSES

	Regulatory Guide 1.4 Analysis
Core thermal power	3582 MWt
Primary containment free volume	1.241×10^6 ft^3
Upper primary containment free volume	7.16×10^5 ft^3
Lower primary containment free volume	4.0×10^5 ft^3
Ice condenser free volume	1.25×10^5 ft^3
Annulus free volume	3.75×10^5 ft^3
Primary containment deck fan flow rate	40,000 cfm
Number of deck fans assumed operating	1 of 2
Activity released to primary containment and available for release	
noble gases	100 percent of core inventory
iodines	25 percent of core inventory
Plateout of iodine activity released to primary containment	50 percent
Form of iodine activity in primary containment available for release	
elemental iodine	91 percent
methyl iodine	4 percent
particulate iodine	5 percent
Ice condenser removal efficiency for elemental iodine	See Table 15.5.3-2
Primary containment leak rate	0.25 percent per day (0-24 hours)
	0.125 percent per day (1-30 days)

TABLE 15.5.3-1 (Sheet 2)

PARAMETERS USED IN LOCA ANALYSES

	Regulatory Guide 1.4 Analysis
Percent of primary containment leakage to Auxiliary Building	25 percent
ABGTS filter efficiencies	
elemental iodine	99 percent
methyl iodine	99 percent
particulate iodine	99 percent
Delay time of activity in Auxiliary Building	0.3 hour
Time ABGTS filters are bypassed following LOCA	5 minutes
EGTS total intake flow	3600 cfm, Single Train 7200 cfm, PCO Failure Case*
Percent of annulus free volume available for mixing of activity	50 percent
EGTS exhaust flow rate	See Table 15.5.3-3, Table 15.5.3-3A
EGTS filter efficiencies	
elemental iodine	99 percent**
methyl iodine	99 percent**
particulate iodine	99 percent**
Percent of primary containment leakage to the annulus to EGTS air cleanup units suction	100 percent
Meteorology	Accident (see Appendix 15A)

* 2 of 2 EGTS air cleanup units operate resulting in maximum flow in the event of a failed EGTS exhaust controller.

** Modeled as 98.2% efficiency for elemental, methyl and particulate iodine to account for up to 30 cfm of leakage through the EGTS decay heat cooldown valves.

TABLE 15.5.3-2

ICE CONDENSER IODINE REMOVAL EFFICIENCY[(1)]

Time Interval Post LOCA (Hours)	Fractional Iodine Removal Efficiency
0.0 to 0.106	0.96
0.106 to 0.133	0.84
0.133 to 0.244	0.71
0.244 to 0.383	0.67
0.383 to 0.522	0.64
0.522 to 0.578	0.62
0.578 to 0.606	0.30
0.606 to 720	0.0

(1) The ice condenser removal efficiencies given in the above table are used for the conservative Regulatory Guide 1.4 analyses. The inlet steam-air mixture coming into the ice condenser is greater than 90 percent steam by volume initially due to the delaying of the operation of the deck fans. Without the delay of operation of the deck fans the amount of steam by volume in the inlet mixture initially would be much lower and the ice condenser iodine removal efficiencies would be reduced. The zero value after 0.606 hours results from all of the ice being melted.

TABLE 15.5.3-3

EMERGENCY GAS TREATMENT SYSTEM FLOW RATES: LARGE BREAK LOCA

Time Interval Post LOCA (Hours)	Recirculation Flow Rate (cfm)	Exhaust Flow Rate (cfm)
0 to 0.00833	0	0
0.00833 to 0.0128	3600	0

TABLE 15.5.4-1

PARAMETERS USED IN STEAM LINE BREAK ANALYSIS

Reactor Coolant Activity	
Noble Gas Activity Prior to Accident	See Appendix 15D
Iodine Activity Prior to Accident (without spike)	See Appendix 15D
Iodine Activity (pre-existing spike)	21 μCi/g D.E. I-131 (see Appendix 15D)
Equilibrium Iodine Appearance Rates	See Appendix 15D
Increase in Iodine Appearance Rate Increase Due to the Accident-Initiated Spike	500 times equilibrium rates
Duration of Accident-Initiated Spike	1 hour
Secondary Coolant Activity	
Iodine Activity Prior to Accident	0.1 μCi/g D.E. I-131 (see Appendix 15D)
Noble Gas Activity	None
Iodine Chemical Form	Elemental
Primary to Secondary Leak Rate (per steam generator)	150 gpd
Steam Release from Intact Steam Generators	
0-2 hours	4.79E5 lb
2-8 hours	1.03E6 lb
>8 hours	none
Blowdown of Faulted Steam Generator to Release the Initial Inventory of Activity	1.48E5 lb over 10 minutes
Intact Steam Generator Iodine Partition Factor	0.01
Faulted Steam Generator Iodine Partition Factor	1.0
Offsite Power	Lost
Atmospheric Dispersion Factor	Accident (see Appendix 15A)
Breathing Rate	3.74E-4m^3/sec
Control Room Parameters	
Volume	2.6E5 cubic feet
Filtered intake flow	1000 cfm
Filtered recirculation flow	2600 cfm
Filter efficiency for iodine	95%
Unfiltered inleakage	51 cfm
Atmospheric dispersion factor (X/Q)	
0-2 hours	1.93E-3 sec/m^3
2-8 hours	7.02E-4 sec/m^3
Occupancy factor	1.0
Breathing rate	3.47E-4m^3/sec

TABLE 15.5.5-1 (Sheet 1)

PARAMETERS USED IN STEAM GENERATOR TUBE RUPTURE ANALYSIS

Reactor Coolant Activity	
Noble Gas Activity Prior to Accident	See Appendix 15D
Iodine Activity Prior to Accident (without spike)	See Appendix 15D
Iodine Activity (pre-existing spike)	21 μCi/g D.E. I-131 (see Appendix 15D)
Equilibrium Iodine Appearance Rates	See Appendix 15D
Increase in Iodine Appearance Rate due to the Accident-Initiated Spike	500 times equilibrium rates
Duration of Accident-Initiated Spike	1 hour
Secondary Coolant Activity	
Iodine Activity Prior to Accident	0.1 μCi/g D.E. I-131 (see Appendix 15D)
Noble Gas Activity	None
Iodine Chemical Form	Elemental
Steam generator tube leak rate	150 gpd per SG
Off-site power	Lost on reactor trip
Time of reactor trip	65 sec
Iodine partition factor in non-defective steam generators prior to and during accident	0.01
Iodine partition factor in defective steam generator prior to accident	0.01
Iodine partition factor in condenser prior to reactor trip	0.01
Time to isolate ruptured steam generator (generic assumption for dose analysis)	30 min
Duration of plant cooldown by Secondary System after accident	8 hour
Tube Rupture Break Flow	
0 - 65 seconds	8400 lb
65 - 1800 seconds	164,300 lb
Percentage of Break Flow that Flashes (average over time interval)	
0 - 65 seconds	18.0%
65 - 1800 seconds	4.74%

TABLE 15.5.5-1 (Sheet 2)

PARAMETERS USED IN STEAM GENERATOR TUBE RUPTURE ANALYSIS

Steam Release from Ruptured Steam Generator (not including contribution from flashed break flow)	
0 - 65 seconds	76,588 lb
65 - 1800 seconds	62.312 lb
Steam Release from Intact Steam Generators	
0 - 65 seconds	232,000 lb
65 - 1800 seconds	170,000 lb
0.5 - 2 Hours	360,000 lb

DOSE MODELS USED TO EVALUATE THE ENVIRONMENTAL CONSEQUENCES OF ACCIDENTS

TABLE OF CONTENTS

LIST OF TABLES

APPENDIX 15A

DOSE MODELS USED TO EVALUATE THE ENVIRONMENTAL CONSEQUENCES OF ACCIDENTS

15A.1 Introduction

This Appendix identifies the models used to calculate the offsite radiological doses that would result from releases of radioactivity due to various postulated accidents. The postulated accidents are:

1. Waste Gas Decay Tank Rupture
2. Steam Generator Tube Rupture
3. Steam Line Break
4. Loss of A.C. Power
5. Rod Ejection Accident
6. Loss-of-Coolant Accident

The radiological consequences analysis for the Fuel Handling Accident does not use the modeling described here but instead uses the modeling associated with the use of alternate source term methodology as discussed in Section 15.5.6.

15A.2 Assumptions

The following assumptions are basic to both the model for the whole body and skin doses due to immersion in a cloud of radioactivity and the model for the thyroid dose due to inhalation of radioactivity.

1. Direct radiation from the source point is negligible compared to gamma and beta radiation due to submersion in the radioactivity leakage cloud.

2. All radioactivity releases are treated as ground level releases regardless of the point of discharge.

3. The dose receptor is a standard man as defined by the International Commission on Radiological Protection (ICRP II) (Reference 1).

4. Radioactive decay from the point of release to the dose receptor is neglected.

5. Isotopic data such as decay constants and dose conversion factors are as provided in Table 15A-1.

15A.3 Whole Body Dose and Skin Dose

The whole body and skin doses delivered to a dose receptor are obtained by considering the dose receptor to be immersed in a radioactive cloud which is infinite in all directions above the ground plane, i.e., an "infinite semispherical cloud." The concentration of radioactive material within this cloud is taken to be uniform and equal to the maximum centerline ground level concentration that would exist in the cloud at the appropriate distance from the point of release. Equations describing an infinite semispherical cloud were used to calculate the doses for a given time period as follows: (Reference 3).

Skin Dose (Rem) = $\left(\frac{X}{Q}\right)_t \sum_i A_i (DCF_{SDE})_i$

and

Gamma Dose (Rem) = $\left(\frac{X}{Q}\right)_t \sum_i A_i (DCF_{EDE})_i$

Where:.

A_i is the activity of isotope i released during a given time period t, curies

$\left(\frac{X}{Q}\right)_t$ is the atmospheric dilution factor for a given time period t, sec/m^3

$(DCF_{SDE})_i$ is the shallow dose equivalent Dose Conversion Factor for isotope i, rem-m^3/Ci-sec (Table 15A-1)

$DCF_{EDE})_i$ is the effective dose equivalent Dose Conversion Factor for isotope i, rem-m^3/Ci-sec (Table 15A-1)

15A.4 Thyroid Dose

The thyroid dose for a given time period t, is obtained from the following expression:

$$D = (X/Q)_t B_t \sum_i A_i (DCF_{thy})_i$$

where:

D	= thyroid dose, rem
$(X/Q)_t$	= atmospheric dispersion factor for time interval t, sec/m^3
B_t	= breathing rate for time interval t, m^3/sec (Table 15A-1)
A_i	= total activity of iodine isotope i released in time period t, curies
$(DCF_{thy})_i$	= dose conversion factor for iodine isotope, i, rem/curie inhaled (Table 15A-1)

The breathing rates are consistent with the guidance of Regulatory Guide 1.4 (Reference 2):

0 – 8 hours	3.47E-4 m^3/sec
8 – 24 hours	1.75E-4 m^3/sec
>24 hours	2.32E-4 m^3/sec

15A.5 Total Effective Dose Equivalent

The accident radiological consequences are also calculated in the form of Total Effective Dose Equivalent (TEDE) for information only. The TEDE dose is defined as being the sum of the whole body dose plus the Committed Effective Dose Equivalent (CEDE) dose. The CEDE dose is obtained from the following expression:

$$D_{CEDE} = (X/Q)_t \, B_t \, \Sigma_i \, A_i \, (DCF_{CEDE})_i$$

Where:

$(X/Q)_t$	= atmospheric dispersion factor for time interval t, sec/m^3
B_t	= breathing rate for time interval t, m^3/sec
A_i	= activity of isotope i released during time interval t, Ci
$(DCF_{CEDE})_i$	= CEDE DCF for isotope i, rem/Ci (Table 15A-1)

APPENDIX 15B

SENSITIVITY ANALYSIS OF LOCA DOSE CALCULATIONS

(HISTORICAL INFORMATION)

15B.1 Introduction

The critical parameters which affect offsite doses from the postulated LOCA were investigated to determine the sensitivity of the doses to these parameters. The effect of the ice condenser iodine removal is given as well as an analysis of the key conservatisms in the dose model.

15B.2 Parametric Study

Table 15B-1 gives the results of 9 cases and the assumptions used. Assumptions not listed in Table 15B-1 are identical to those used in Subsection 15.5.3 for the core release source. Case 1 is the base case which is discussed in Subsection 15.5.3 and is used as the reference case when relative doses are presented. The cases given in Table 15B-1 along with other calculations are the basis for the discussion of sensitivity.

15B.3 The Effect of Ice Condenser Iodine Removal

The removal of elemental iodines by the ice bed following blowdown is discussed in Subparagraph 6.2.3.3.4. The effect of the ice condenser, (along with the charcoal filters) using the efficiencies given in Table 15.5.3-2 is to reduce the offsite doses due to elemental iodines to the same magnitude as that due to organic iodines, at times in excess of about 0.2 hours. Therefore, increased ice condenser removal of elemental iodines (or any other removal system for elemental iodines) will not significantly reduce thyroid doses.

Table 15B-2 shows the two hour thyroid exclusion area boundary doses calculated for several cases with and without ice condenser iodine removal credit using the TID-14844 source term. Dose reduction factors (DRFs) are given for total thyroid doses as well as for the release components (via the annulus and via the Auxiliary Building). All DRFs are in the neighborhood of 3.75. The DRFs for the releases via the annulus are lowest and reflect the importance of the high initial EGTS exhaust rate on these releases. Over the period when the exhaust flow is high the ice condenser has not yet had time to fully reduce the elemental iodine inventory.

Table 15B-3 gives similar information for the 30-day doses at the LPZ distance. The DRFs are in the neighborhood of 4.25 for the 30-day doses. The DRFs for the annulus releases would be expected to be lower than those for the Auxiliary Building releases due to the importance of the first half hour on annulus releases and because multiple passes through the EGTS charcoal filters reduce the relative importance of elemental iodines slightly.

15B.4 Sensitivity of Releases to Holdup in the Auxiliary Building

The model used to describe transport of radioactivity through the Auxiliary Building to the Auxiliary Building Gas Treatment System (ABGTS) is based on a constant delay time between leakage and exhaust. This delay time is used to calculate the reduction in activity release due to decay, but is neglected when considering the time of exposure to the release, i.e., the 2-hour dose is calculated on the basis of the release from the EGTS for the first two hours plus the release from the primary containment to the Auxiliary Building for the first two hours reduced by decay.

APPENDIX 15B

SENSITIVITY ANALYSIS OF LOCA DOSE CALCULATIONS

(HISTORICAL INFORMATION)

The decay time was determined by investigating probable leakage and transport paths to and through the Auxiliary Building. The Auxiliary Building free volume is approximately 3.5 million cubic feet. The ABGTS design flow rate is 9,000 cfm per train. Each train is capable of maintaining the Auxiliary Building at negative pressure, since inleakage is expected to be less than 8,000 cfm. However, even with both systems operating at capacity, the exhaust rate is about 0.3 volumes per hour, providing a mean holdup time of more than 3 hours. For conservatism no delay time was used for the base case.

The ABGTS will reduce the pressure in the Auxiliary Building in less than 10 minutes to the point where no outleakage is assured. Case 9 of Table 15B-1 shows the doses to be expected at the exclusion area boundary and the LPZ distance under the assumptions of ice condenser removal credit, 90 percent containment leakage directly to the EGTS suction, with the remaining 10 percent going directly to the environment for the first 10 minutes following the LOCA and to the Auxiliary Building thereafter where the activity will experience a 0.3 hour average delay.

Figure 15B-1 shows the relative dose for the first two hours at the exclusion area boundary as a function of decay time in the Auxiliary Building. Figure 15B-2 gives similar information for the 30-day doses at the LPZ distance. Note that delay has little effect on the thyroid dose. This is to be expected since about 90 percent of the thyroid dose is due to the long lived isotopes I-131 and I-133. The ß and γ doses are principally due to relatively short-lived noble gases and therefore, show a significant reduction with delay in the Auxiliary Building.

15B.5 Sensitivity of Releases to the Assumed Fraction Entering the EGTS Suction Directly

No significant amount of primary containment leakage is expected to enter the EGTS suction at the top of the dome directly. However, the conservative assumption was made for the base case that 10 percent of the leakage to the annulus would enter the suction directly. Dose calculations for the exclusion area boundary were performed for EGTS direct leakage fraction from 0.0 up to 100 percent and the results are shown in Figure 15B-3. Even if the very conservative assumption is made that all primary containment leakage into the annulus enters the EGTS suction directly, the resulting two-hour thyroid dose is only 10 percent of the 10 CFR 100 guideline value, the beta dose is less than 12 percent of the 10 CFR 100 guideline value, and the gamma dose is less than 27 percent of the 10 CFR 100 guideline value.

Figure 15B-4 gives similar information for the 30-day doses at the LPZ distance.

The case analyzed in which none of the primary containment leakage enters the EGTS suction directly is the complete mixing model. In this model, the secondary containment acts similar to a large hold-up tank which collects the primary containment leakage. All fission products escaping from the primary containment to the secondary containment are assumed to mix with the air in the secondary containment. Ninety percent of the primary containment leakage is assumed to go into the secondary containment while the remaining 10 percent goes to the Auxiliary Building. The Auxiliary Building release path is discussed in Subsection 15.5.3.

APPENDIX 15B

SENSITIVITY ANALYSIS OF LOCA DOSE CALCULATIONS

(HISTORICAL INFORMATION)

The initial pressure in the annulus is less than atmospheric. After blowdown, the annulus pressure will increase rapidly due to expansion of the containment vessel as a result of primary containment atmosphere temperature and pressure increases. The annulus pressure will continue to rise due to heating of the annulus atmosphere by conduction through the containment vessel. After a delay of 38 seconds, the Emergency Gas Treatment System (EGTS) will be operating at full flow to maintain the annulus pressure to below atmospheric pressure.

During the initial 30 second period following the LOCA, primary containment leakage is assumed to mix uniformly with the secondary containment air. No activity is released to the environment during this period.

After the initial 30 second period following the LOCA, the EGTS draws air and fission products at uniform concentration from the secondary containment volume, passes it through HEPA-charcoal filters and exhausts a portion to the atmosphere. The remainder is exhausted back into the secondary containment where it is assumed to mix uniformly with the secondary containment air; it is then available for reentry into the EGTS in a similar manner to the primary containment leakage. The EGTS exhaust and recirculation flow rates as a function of time are given in Table 15.5.3-3.

The case analyzed in which all of the primary containment leakage enters the EGTS directly is the no mixing model. During the initial 30 second period following the LOCA, the no mixing model is similar to that used for the complete mixing case, discussed above in that no activity is released to the environment during this period.

After the initial 30 second period following the LOCA, all of the primary containment leakage to the secondary containment is drawn immediately into the EGTS where it is filtered. A portion is then exhausted to the atmosphere (see Table 15.5.3-3) while the remainder is returned to the secondary containment where it is assumed to mix uniformly in that volume.

15B.6 Sensitivity of Releases to Annulus Holdup Effectiveness

The holdup time in the annulus is a function of both the exhaust rate and the active annulus volume. The geometry of the annulus volume, as well as the locations of the EGTS suctions and recirculation exhausts, should provide uniform and complete circulation over essentially all the annulus volume. To demonstrate the capabilities of the containment design, doses were calculated assuming that large regions of the annulus (50 percent or more of the annulus free volume) do not contribute to fission product holdup. The results of this analysis are shown in Figure 15B-5, and demonstrate that offsite doses are still within 10 CFR 100 guidelines even for the unrealistic assumption of large reductions in the active annulus volume.

15B.7 Dose Models

The dose model discussed in Appendix 15A and used in the analyses in this appendix is conservative in three principle areas as conventionally applied. First, the decay of fission products downwind is neglected; second, the actual transport time (time to reach the receptor)

APPENDIX 15B

SENSITIVITY ANALYSIS OF LOCA DOSE CALCULATIONS

(HISTORICAL INFORMATION)

is neglected; and third, the dose is based on a uniform cloud which may, in fact, be quite nonuniform. All three factors have only a small effect when wind speeds are greater than 1 meter per second, however, for wind speeds less than 1 meter per second the first considerations tend to result in the "two-hour" doses being over estimated, while the third consideration overestimates the long term doses.

Figure 15B-6 shows the relative effect of decay of the activity releases during downwind transport on the two hour LOCA doses given in case 1. Due to the importance of long lived isotopes, the thyroid doses are not significantly affected. However, the beta and gamma doses show a stronger decrease with increasing transport time since the short lived kryptons contribute significantly to the doses.

Figures 15B-7 and 15B-8 show the total effect of the wind speed on the doses given in case 1 for Pasquill G and Pasquill F meteorological conditions. The curves take into account the effect of changing wind speed on the atmospheric dilution factor and the activity reduction due to decay during transport to the receptor. Four curves are presented in each figure. One curve shows the relative dose as a function of wind speed taking into account only the variance in the x/Q. The other three curves show the combined effect of the wind speed on the relative doses taking into account decay during transport and a variance in the x/Q.

Figure 15B-9 shows the effect of the receptor exposure time on the relative dose. The intent of the figure is to show the relative dose a receptor at the exclusion area boundary would receive under very low wind speed conditions during the first two hours following the initiation of a postulated LOCA. If the wind speed were such that it would take 1-1/2 hours for the radioactive cloud to reach the exclusion area boundary, the receptor would only be exposed to the cloud for 1/2 hours during the initial two hours following a postulated LOCA. Therefore, in the initial 2 hours he would only be exposed to that portion of the radioactivity that was released from the plant during the first 1/2 hour.

The information in Figures 15B-6 through 15B-9 is used to construct Figures 15B-10 and 15B-11. Figures 15B-10 and 15B-11 show the relative dose at the minimum exclusion distance during the first two hours of the accident for various wind speeds. The curves include (1) the effect of decay during transport, (2) the dependence of the dispersion factor on wind speed, and (3) the transport time required to reach the exclusion area boundary. This analysis demonstrates that the dose models used in Appendix 15A for the two-hour thyroid dose are conservative by a factor of 1.11 for Class G stability conditions and 1.33 for Class F stability conditions.

The conclusion to be drawn on beta and gamma doses is complicated by the assumption of a semi-infinite cloud, which ignores doses before the arrival of the plume at the receptor location. A detailed calculation of doses due to travel of the nonhomogenous plume would be required to determine the level of conservatism of the semi-infinite cloud model and to determine the effect of wind speed on doses.

The dispersion factor used for the initial two-hour period following the LOCA corresponds to Pasquill Class F and a wind speed of 0.25 meters/ second. At this low wind speed considerable

APPENDIX 15B

SENSITIVITY ANALYSIS OF LOCA DOSE CALCULATIONS

(HISTORICAL INFORMATION)

meandering of the wind can be expected; thus increasing the dispersion at the receptor location, thereby reducing doses. Actual measurements of dispersion factors at other sites have shown that the equation used in this analysis for the dispersion factor is quite conservative for low wind speeds.*

15B.8 Conclusions

Three conclusions can be drawn from the analyses in this appendix.

1. The effectiveness of the double containment concept utilizing the Shield Building augmented by treatment of the Auxiliary Building exhaust is relatively independent of a wide range of conservative assumptions which might be postulated. The major factor in the effectiveness of the secondary containment is its inherent capability to collect the containment leakage for filtration of the radioactive iodine prior to release to the environment. This effect is greatly enhanced by the recirculation feature of the air handling systems, which forces repeated filtration passes for the major fraction of the primary containment leakage before release to the environment.

2. The offsite doses for the hypothetical LOCA with the TID-14844 activity release will be less than those presented for the Regulatory Guide 1.4 (1973) (TID-14844 activity release) evaluation presented in Subsection 15.5.3 and considerably below the guideline values of 10 CFR 100.

3. The containment concept used in the Sequoyah design is highly effective in minimizing the release of radioactivity to the environment as a result of a loss-of-coolant.

APPENDIX 15C

FUEL ROD MODEL DISCUSSION

(HISTORICAL INFORMATION)

LIST OF FIGURES

APPENDIX 15C

FUEL ROD MODEL DISCUSSION

(HISTORICAL INFORMATION)

The U.S. Nuclear Regulatory Commission (NRC) issued a letter dated November 9, 1979 [1] to operators of light water reactors regarding fuel rod models used in Loss of Coolant Accident (LOCA) ECCS evaluation models. This letter describes a meeting called by the NRC on November 1, 1979 to present draft report NUREG-0630, "Cladding Swelling and Rupture Models for LOCA Analysis" [2]. At the meeting, representatives of NSSS vendors and fuel suppliers were asked to show how plants licensed using their LOCA/ECCS evaluation model continued to conform to 10 CFR Part 50.46 in view of the new fuel rod models presented in reference 2. Westinghouse representatives presented information on the fuel rod models used in analyses for plants licensed with the Westinghouse ECCS evaluation model and discussed the potential impact of fuel rod model changes on results of those analyses. That information was formally documented in letter NS-TMA-2147, dated November 2, 1979 [3], and formed the basis for the Westinghouse conclusion that the information presented in Reference 2 did not constitute a safety problem for Westinghouse plants and that all plants conformed with NRC regulations. The NRC requested [1] that operators of light water reactors provide, within sixty (60) days, information which would enable the staff to determine, in light of the fuel rod model concerns, whether or not further action was necessary.

This Appendix provides information on the LOCA analysis of Sequoyah Nuclear Plant unit 1 required to respond to such a request. Note, however, that a significant amount of discussion and information exchange between Westinghouse and the NRC has transpired since Reference 3 was prepared and the basis for demonstrating compliance with 10 CRF Part 50 has been modified. The following is an outline of the significant events that have occurred since November 2, 1979 and provides an update on this situation.

As a result of compiling information for Reference 3, Westinghouse recognized a potential discrepancy in the calculation of fuel rod burst for cases having clad heatup rates (prior to rupture) significantly lower than 25°F per second. This issue was reported to the NRC staff, by telephone, on November 9, 1979, and although independent of the NRC fuel rod model concern, the combined effect of this issue and the effect of the NRC fuel rod models had to be studied. Details of the work done on this issue were presented to the NRC on November 13, 1979 and documented in letter NS-TMA-2163 dated November 16, 1979 [4]. That work included development of a procedure to determine the clad heatup rate prior to burst and re-evaluation of operating Westinghouse plants with consideration of a modified Westinghouse fuel rod burst model. As part of this re-evaluation, the Westinghouse position on NUREG-0630 was reviewed and it was still concluded that the information presented in Reference 1 did not constitute a safety problem for plants licensed with the Westinghouse ECCS evaluation model.

On December 6, 1979, NRC and Westinghouse personnel discussed the information thus far presented. At the conclusion of that discussion, the NRC staff requested Westinghouse to provide further detail on the potential impact of modifications to each of the fuel rod models used in the LOCA analysis and to outline analytical model improvements in other parts of the

analysis and the potential benefit associated with those improvements. This additional information was compiled from various LOCA analysis results and documented in letter NS-TMA-2174 dated December 7, 1979 [5].

Another meeting was held in Bethesda on December 20, 1979 where NRC and Westinghouse personnel established:

1. The currently accepted procedure for assessing the potential impact on LOCA analysis results of using the fuel rod models presented in Reference 1 and

2. Acceptable benefits resulting from analytical model improvements that would justify continued plant operation for the interim until differences between the fuel rod models of concern are resolved.

The information following on pages 15C-3 through 15C-6 is expected to satisfy the NRC request for information on SQN which will enable the NRC to determine whether or not further action is necessary.

Part of the Westinghouse effort provided to assist in the resolution of these LOCA fuel rod model differences is documented in letter NS-TMA-2175, dated December 10, 1979 [6], which contains Westinghouse comments on draft NUREG-0630. As stated in that letter, Westinghouse believes the current Westinghouse models to be conservative and to be in compliance with Appendix K.

A. Evaluation of the potential impact of using fuel rod models presented in draft NUREG-0630 on the Loss of Coolant Accident (LOCA) analysis for Sequoyah.

This evaluation is based on the limiting break LOCA analysis identified as follows:

BREAK TYPE - DOUBLE ENDED COLD LEG GUILLOTINE

BREAK DISCHARGE COEFFICIENT - 0.6 IMP MIXING

WESTINGHOUSE ECCS EVALUATION MODEL VERSION - FEB '78

CORE PEAKING FACTOR - 2.25

HOT ROD MAXIMUM TEMPERATURE CALCULATED FOR THE BURST REGION OF THE CLAD - 1705°F = PCT_B

ELEVATION - 6.5 Feet

HOT ROD MAXIMUM TEMPERATURE CALCULATED FOR A NON-RUPTURED REGION OF THE CLAD - 2143°F = PCT_N

ELEVATION - 7.5 Feet

CLAD STRAIN DURING BLOWDOWN AT THIS ELEVATION	10	Percent
MAXIMUM CLAD STRAIN AT THIS ELEVATION	10	Percent

Maximum temperature for this non-burst node occurs when the core reflood rate is less than 1.0 inch per second and reflood heat transfer is based on the (STEAM COOLING) calculation.

AVERAGE HOT ASSEMBLY ROD BURST ELEVATION - 7.25 Feet

HOT ASSEMBLY BLOCKAGE CALCULATED - 34.9 Percent

1. BURST NODE

The maximum potential impact on the ruptured clad node is expressed in letter NS-TMA-2174 in terms of the change in the peaking factor limit (FQ) required to maintain a peak clad temperature (PCT) of 2200°F and in terms of a change in PCT at a constant FQ. Since the clad-water reaction rate increases significantly at temperatures above 2200°F, individual effects (such as WPCT due to changes in several fuel rod models) indicated here may not accurately apply over large ranges, but a simultaneous change in FQ which causes the PCT to remain in the neighborhood of 2200°F justifies use of this evaluation procedure.

From NS-TMA-2174:

For the Burst Node of the clad:

- 0.01 ΔFQ 150°F BURST NODE ΔPCT
- Use of the NRC burst model and the revised Westinghouse burst model could require an FQ reduction of 0.027
- The maximum estimated impact of using the NRC strain model is a required FQ reduction of 0.03.

Therefore, the maximum penalty for the Hot Rod burst node is:

$$\Delta PCT_1 = (0.027 + .03)\,(150°F/.01) = 855°F$$

Margin to the 2200°F limit is:

$$\Delta PCT_2 = 2200°F - 1705\ PCT_B = 495\ °F$$

The FQ reduction required to maintain the 2200°F clad temperature limit is:

$$\Delta FQ_B = (\Delta PCT_1 - \Delta PCT_2)\left(\frac{.01\ \Delta FQ}{150°F}\right)$$

$$= \left(\underline{855 - 495}\right)\left(\frac{.01}{150}\right)$$

$$= .\underline{024}\ \text{(but not less than zero)}$$

2. NON-BURST NODE

The maximum temperature calculated for a non-burst section of clad typically occurs at an elevation above the core mid-plane during the core reflood phase of the LOCA transient. The potential impact on that maximum clad temperature of using the NRC fuel rod models can be estimated by examining two aspect of the analyses. The first aspect is the change in pellet-clad gap conductance resulting from a difference in clad strain at the non-burst maximum clad temperature node elevation. Note that clad strain all along the fuel rod stops after clad burst occurs and use of a different clad burst model can change the time at which burst is calculated.

The effect of the change in pellet-clad gap conductance in the non-burst node was determined by performing a sensitivity study using various rate dependent burst curves. The results of these studies are presented in Table I. It is seen that the most representative case, as defined by the relationship between the actual clad heatup rate and the heatup rate used in the burst mode, is the 8.4°F/sec ramp rate. The increase in calculated peak clad temperature, ∆PCTs, for this case was 19°F. It is also noted that hot rod burst occurs 6.9 seconds earlier and the blockage increases by 9.7% over the base case results.

The sensitivity study included the effect of blockage as well as the effect of the change in gap conductance on the peak clad temperature. The value of ΔPCT_3 includes an increased blockage penalty. Thus in the evaluation of the increase in PCT, ΔPCT_4, due to blockage, the 45% blockage value from the sensitivity rather than the 34.9% value from the limiting break LOCA analysis identified at the beginning of section A will be used in order to prevent a double accounting of the 9.7% blockage increase noted in the sensitivity study.

A comparison of the ramp dependent burst curves used in this study with the NUREG-0630 is shown in Figure 15C-1. It can be seen that the burst temperatures predicted by the Westinghouse rate dependent models predict higher burst temperatures than the ORNL correlations.

Detailed discussion of these differences are provided in the December 10 letter (NS-TMA-2175), including an explanation of the conservatism of the model and demonstration of compliance with Appendix K.

The second aspect of the analysis that can increase PCT is the flow blockage calculated. Since the greatest value of blockage indicated by the NRC blockage model is 75 percent, the maximum PCT increase can be estimated by assuming that the current level of blockage in the analysis (see above discussion) is raised to 75 percent and then applying an appropriate sensitivity formula shown in NS-TMA-2174.

Therefore,

$$\Delta PCT_4 = 1.25°F\ (50 - \text{PERCENT CURRENT BLOCKAGE})$$

$$+\ 2.36°F\ (75-50)$$

$$= 1.25\ (50 - 45) + 2.36\ (75-50)$$

$$= 65.25°F$$

If PCT_N occurs when the core reflood rate is greater than 1.0 inch per second $\Delta PCT_4 = 0$. The total potential PCT increase for the non-burst node is then

$$\Delta PCT_5 = \Delta PCT_3 + \Delta PCT_4 = 19.0 + 65.25 = 84.25°F$$

Margin to the 2200°F limit is

$$\Delta PCT_6 = 2200°F - PCT_N = 2200 - 2143 = 57°F$$

The FQ reduction required to maintain this 2200°F clad temperature limit is (from NS-TMA-2174)

$$\Delta FQ_N = (\Delta PCT_5 - \Delta PCT_6)\left(\frac{.01\Delta FQ}{10°F\Delta PCT}\right) = (84.25 - 57)\left(\frac{.01}{10}\right) = .027$$

$\Delta FQ_N = .027$ but not less than zero.

The peaking factor reduction required to maintain the 2000°F clad temperature limit is therefore the greater of ΔFQ_B and ΔFQ_N.

B. The NRC has recently approved the removal of the 65°F uncertainty on hot rod fuel pellet temperature for ECCS analysis. The effect of removing this uncertainty on the calculated PCT has been determined based on previously established sensitivities performed to quantify this effect (WCAP-9180). From these, it is estimated that this reduction in applied model uncertainty would result in a decrease in calculated PCT of 15°F for UHI plants. Applying the same sensitivity used in calculating ΔFQ_N.

$$\Delta FQ_{CREDIT} = 15°F\left(\frac{.01\Delta FQ}{10°F\ \Delta PCT}\right) = .015$$

C. The peaking factor limit adjustment required to justify plant operation for this interim period is determined as the appropriate WFQ credit identified in Section B above, minus the WFQ[PENALTY] calculated in Section A above (but not greater than zero).

FQ ADJUSTMENT = .015 - .027 = .012

D. The revised peaking factor is then FQ FSAR minus the FQ adjustment, or:

FQ = 2.25 - .012 = 2.237

APPENDIX 15D
PRIMARY COOLANT ACTIVITY MODEL USED TO EVALUATE THE RADIOLOGICAL CONSEQUENCES OF ACCIDENTS

TABLE OF CONTENTS

LIST OF TABLES

APPENDIX 15D

PRIMARY COOLANT ACTIVITY MODEL USED TO EVALUATE THE RADIOLOGICAL CONSEQUENCES OF ACCIDENTS

15D.1 Introduction

This appendix describes the model used to define the primary and secondary coolant fission product concentrations that are used in the design basis accident radiological consequences analyses. The accidents incorporating this modeling are:

1. Loss of A.C. Power
2. Steam Line Break
3. Steam Generator Tube Rupture

15D.2 Primary Coolant Equilibrium Activity

The Technical Specification limit for noble gas specific activity is assumed to be1612.6 µCi/gm DOSE EQUIVALENT XE-133. The Technical Specification definition for DOSE EQUIVALENT XE-133 states: DOSE EQUIVALENT XE-133 shall be that concentration of Xe-133 (microcuries per gram) that alone would produce the same acute dose to the whole body as the combined activities of noble gas nuclides Kr-85m, Kr-85, Kr-87, Kr-88, Xe-131m, Xe-133m, Xe-133, Xe-135m, Xe-135, and Xe-138 actually present. Table 15.D-1 lists the primary coolant noble gas concentrations when operating at the Technical Specification limit.

For the primary coolant iodines, the Technical Specification limit is 0.35 µCi/gm of Dose Equivalent I-131 for equilibrium operation. Table 15D-1 lists the iodine concentrations associated with operation at the Technical Specification limit. The individual isotope concentrations were determined based on the isotopic distribution that is expected during normal operation and using the thyroid dose conversion factors listed in Appendix 15A.

15D.3 Iodine Spike Modeling

Iodine spikes (periods of time during which the iodine appearance rate in the primary coolant is elevated) are part of the accident analysis modeling for the steam line break, the steam generator tube rupture, and the loss of A.C. power events. These accidents are analyzed considering both the situation of a pre-existing iodine spike and the situation in which the event initiates an iodine spike (accident-initiated spike).

For these accident analyses the pre-existing iodine spike is assumed to be the maximum iodine concentration allowed by Technical Specifications (21 μCi/gm Dose Equivalent I-131). This is the limit applied for a transient duration of <48 hours. The pre-existing spike coolant concentrations are a factor of 60 greater than the concentrations reported in Table 15D-1 for equilibrium operation at 0.35 μCi/gm Dose Equivalent I-131.

For analysis modeling the accident-initiated spike it is assumed that the initial iodine concentration in the primary coolant is at the Technical Specification value of 0.35 μCi/gm Dose Equivalent I-131 and that the equilibrium iodine appearance rates are those which support this coolant concentration. As a result of the accident, an iodine spike is initiated which increases the iodine appearance rate by a factor of 500 resulting in an increasing primary coolant iodine concentration. The iodine appearance rates associated with maintaining the primary coolant concentration of 0.35 μCi/gm are provided in Table 15D-2.

15D.4 Secondary Coolant Activity

There is no noble gas activity retained in the secondary coolant.

The iodine activity concentration of the secondary coolant at the time an accident occurs is assumed to be at the Technical Specification limit of 0.1 μCi/gm Dose Equivalent I-131 (see Table 15D-3). Iodine spiking phenomena are assumed.

TABLE 15D-1

PRIMARY COOLANT ACTIVITY (μCi/gm)

Noble gas (D.E. Xe-133)	
Kr-85m	6.74E0
Kr-85	1.05E1
Kr-87	6.35E0
Kr-88	1.18E1
Xe-131m	2.58E1
Xe-133m	2.83E0
Xe-133	9.98E1
Xe-135m	5.48E0
Xe-135	3.56E1
Xe-138	5.09E0
Iodines (Equilibrium concentration of 0.35 μCi/gm D.E. I-131, no spike)	
I-131	2.03E-1
I-132	9.57E-1
I-133	6.34E-1
I-134	1.55E0
I-135	1.18E0

TABLE OF CONTENTS

17.0 QUALITY ASSURANCE

17.1A QUALITY ASSURANCE DURING DESIGN AND CONSTRUCTION

The original QA program for design and construction was described in Appendix B of the Preliminary Safety Analysis Report. The program has been revised and upgraded several times to reflect both organizational changes and changes in requirements. The program was included as Chapter 17.1A of the Final Safety Analysis Report which was subsequently revised and is now included in the latest revision to the TVA Nuclear Quality Assurance Plan, TVA-NQA-PLN89-A. Design and construction activities after licensing shall be in accordance with the latest approved revision of TVA-NQA-PLN89-A.

17.1B WESTINGHOUSE QUALITY ASSURANCE PROGRAM

The original Quality Assurance Program implemented by Westinghouse for the Sequoyah Nuclear Plant was described in Appendix A of the Preliminary Safety Analysis Report. Over the course of performing the design and initial procurement activities for the Sequoyah Nuclear Plant, the Westinghouse Quality Assurance Program was upgraded several times to reflect changes in requirements and industry standards. These changes were described and included in the various revisions to Chapter 17.1B of the Final Safety Analysis Report. The present quality assurance program is included in the Westinghouse Electric Company, Quality Management System (QMS) document.

17.1B.1 References

17.2 QUALITY ASSURANCE PROGRAM FOR STATION OPERATION

17.2.1 Compliance

The information presented in the Tennessee Valley Authority Nuclear Quality Assurance Plan, TVA-NQA-PLN89-A, Reference [1], presents an accurate and complete description of the quality assurance program for operation of Sequoyah Nuclear Plant.

17.2.2 Quality (Q) - List

TVA has prepared a Q-List for the Sequoyah Nuclear Plant (SQN). Items designated on this list are handled in accordance with the requirements of the nuclear quality assurance program as set forth in Reference [1]. At SQN, the Site Engineering organization is responsible for the establishment and maintenance of the Q-List. The Q-List will be issued and controlled similar to design output. Site procedures control the issue, revision process, and maintenance of the Q-List.

The requirements of inclusion of items on the Q-List is that they be safety related or a TVA identified Quality Related feature.

1. For the purposes of the Q-List, "safety-related items" have been defined as those that meet the following criteria:

   a. Those items that are necessary to ensure:

      (1) The integrity of the reactor coolant pressure boundary.

      (2) The capability to shutdown the reactor and maintain it in a safe condition.

      (3) The capability to prevent or mitigate the consequences of an incident which could result in potential offsite exposure comparable to those specified in 10 CFR 100.

2. TVA identified quality-related features are defined by Reference [1].

To ensure uniform application of these criteria, TVA has developed a set of general notes for the Q-List which is part of the site administrative procedure for Q-List use and control.
